## Acknowledgments

The authors are grateful to the Wyoming Department of Transportation (WYDOT) and the Mountain Plains Consortium (MPC) for funding this study. We will like to acknowledge Dr. Shaun Wulff for his help in finalizing the statistical model.

We will also like to thank the planning and traffic departments at WYDOT and Nebraska Department of Roads (NEDOR) respectively for providing the necessary data for this study.

#### Abstract

The trucking industry continues to contribute significantly to the economy of the United States. The surface transportation system has been a critical component for the movement of goods and services by the trucking industry across the country. Recent decades have seen substantial growth in freight miles traveled, due to globalization, trade growth, and improvements in logistics and supply chain management. Although these developments have led to economic growth, there has been a sharp increase in the proportion of freight/truck traffic traveling along key routes that has caused significant interactions between trucks and other vehicles. These interactions have raised safety and capacity concerns on the freeways.

Interstate 80 was identified for this research because of the high percentage of truck traffic ( $40 \%$ $-70 \%$ ) that it carries. This Interstate is a popular route for most freight transporting goods from the east (Chicago) to the west (California) and vice versa. Interstate 80 in the states of Wyoming and Nebraska was selected as a test case for this research, which seeks to develop a statistical modeling of the relationship between the high percent trucks and crash rates. Findings from this research are intended to aid transportation managers when deciding on actions to take on highway facilities carrying a large percentage of trucks.

## 1. INTRODUCTION

### 1.1 Background and Problem Statement

The trucking industry continues to contribute significantly to the economy of the United States. The surface transportation system has been a critical component for the movement of goods and services by the trucking industry across the country. The tonnage transported by domestic freight is estimated to increase by $65 \%$ to $70 \%$ by the year 2020, of which trucks are expected to haul about three quarters of the total tonnage. (Mallet, Schmitt, \& Sedor 2004). An increase in the number of trucks on the transportation system means more interaction between trucks and other vehicles.

Recent decades have seen substantial growth in freight miles traveled, due to globalization, trade growth, and improvements in logistics and supply chain management. Although leading to economic growth, these developments have led to a sharp increase in the proportion of freight traffic along key routes, many of which pass through rural areas. As one example, Interstate 80 forms a major corridor for transporting goods between the west coast and major cities to the east (including Chicago and the Northeast). In 2009, the Wyoming Department of Transportation reported a heavy vehicle proportion ranging from $40 \%$ (in urban areas) to $60 \%$ (in rural areas) on this facility. These increases in heavy truck traffic on the nation's highways have raised concerns about safety and capacity, particularly on the Interstate system.

Despite this growth, traditional measures of freeway performance (such as density or travel speed) report that these facilities continue to function well and fail to capture the impacts of such a large heavy vehicle proportion on traffic operations, safety, and public perceptions of comfort. Past research into the impact of heavy vehicles, mostly performed in the 1970s and 1980s, has typically been derived from data sets with little to no coverage of traffic streams with more than $20 \%-25 \%$ heavy vehicles (Huber 1982; Roess \& Messer 1984).

This past research forms the basis of the Highway Capacity Manual procedures commonly used in engineering practice. For instance, the most recent version of the manual does not provide passenger-car equivalents for heavy vehicle proportions exceeding $25 \%$, and recommends a default heavy vehicle proportion of $10 \%$ on rural freeways (HCM 2000). It is not at all clear whether these procedures are appropriate in locations with heavy vehicle volumes nearly double this upper limit, particularly on rural freeways where high heavy vehicle volume is juxtaposed with low total volumes and infrequent congestion.

From the standpoint of driver comfort and perceived quality of service, Washburn et al. (2004) report that four important factors are the ability to maintain a desired travel speed, the ability to change lanes freely, the ability to travel at least the speed limit, and smooth road conditions. They stated that the presence of heavy vehicles affects the first three of these factors directly. For instance, even if average travel speeds can remain high, frequent passing maneuvers (or situations where one heavy vehicle overtakes another) will affect these measures of comfort and perceived quality (Washburn, Ramlackhan, \& McLeod 2004). Public perceptions of safety are also affected by the severity of incidents involving heavy
vehicles, as discovered by Moore et al. (2005) through a combination of surveys and focus groups, even though it remains unclear whether such perceptions are accurate (Moore, et al. 2005).

The combination of high heavy vehicle volume, low total volume, and extensive ITS instrumentation on Interstate 80 makes this corridor an ideal test bed for evaluating existing methodologies and developing novel ones, although other rural corridors in diverse locations will also be considered in future studies. In particular, the overall research study will measure the impacts of very high heavy vehicle proportion, adopting a three-tiered approach to quantify the effects on operations, safety, and public perception. This study will focus on the relationship study between percent trucks and crash rates.

### 1.2 Research Objective

The overall objective of this research is to develop a methodology for quantifying the impacts of very high heavy vehicle proportion on rural freeways in three different areas:

- Traffic operations (developing new metrics to reflect the localized impact of heavy vehicles on such freeways, augmenting existing ones such as average density or speed)
- Traffic safety (including frequency of incidents and unsafe maneuvers occurring in the presence of heavy vehicles)
- Public perception of comfort and safety.

This report is part of the overall research objectives stated above, but will focus on the following objectives:

- Develop a statistical modeling of the relationship between percent trucks and crash rates.
- Analyze the impact of high percent trucks.

### 1.3 Research Approach

The research objectives will be accomplished through the following six tasks, focusing on rural locations with very high heavy vehicle proportion:

1. Conduct a comprehensive survey of past research on the impact of heavy vehicles, focusing on modeling assumptions, data sources, and relevance to rural freeways with high volume.
2. Identify test bed locations, and obtain operations and safety data needed for analysis.
3. Operations: Identify and develop a suite of metrics quantifying the operational effects of high heavy vehicle volume and low total volume.
4. Safety: Create a methodology to describe effects of heavy vehicles on incident frequency and unsafe driving behavior.
5. Comfort: Identify the impact of heavy vehicles on drivers' perceptions by analyzing measures of comfort such as following distance, visibility, and lateral clearance.
6. Synthesis: Develop one or more practical methodologies for engineers, delivering an aggregate assessment based on the models developed for operations, safety, and comfort.

This research will address partially or fully some of the tasks stated above. The tasks that will be focused on by this research are:

- Review of traffic data to determine percent trucks and vehicle miles traveled for both all vehicles and trucks.
- Analyze crash information to obtain the crash frequency and crash rates.
- Determine the safety and economic impact of crashes.
- Examine the relation between high percent trucks and crash rates.

### 1.4 Report Outline

The first section provides a brief description of the problem statement and research objectives. Section 2 describes the findings of the literature review, including the assessment of prior published studies regarding the safety impacts of high percent trucks and driver perceptions in relation to car-truck interactions. Section 3 includes the description of the project location and the crash dataset used. Section 4 focuses on an in-depth analysis of the crash dataset in terms of truck volumes and crash rates. Section 5 analyzes the environmental factors that contributed to the crashes. Section 6 describes the statistical model used to examine the relationship between percent trucks and crash rates. Section 7 provides conclusions and recommendations for further study.

## 2. LITERATURE REVIEW

This literature review gives an overview of the previous research studies into the safety impact of high percentage of freight vehicles on rural freeways. The literature review focuses on the areas of safety and driver perception in relation to car-truck interactions. A summary of the literature review will be presented at the end of the section.

### 2.1 SAFETY

Because truck safety has significant implications for both truck drivers and other motorists with whom they share the road, safety is a major consideration for the trucking industry. Transportation safety is vital to the socio-economic development of nations. About 37,000 died as a result of highway crashes in 2008 on U.S. roadways. (NHTSA 2008). In a report by the National Highway Transportation Safety Administration, Traffic Safety Facts 2008, they reported that $74 \%$ of fatalities resulted from crashes involving large trucks were occupants of passenger cars, $10 \%$ were non-occupants, and only $16 \%$ were occupants of a large truck. One out of nine traffic fatalities in 2008 resulted from a collision involving a large truck. Large trucks accounted for $8 \%$ of all vehicles involved in fatal crashes, and $4 \%$ of all vehicles involved in injury and property damage only (PDO) crashes (NHTSA 2008). Thus, truck traffic had an influence on crashes. The causes of crashes are complex and have many variables and determining factors that come into play. There are a number of options looked at by numerous agencies and institutions for reducing crash rates, limiting their severity, and investigating behaviors that lead to those crashes. Truck travel has increased tremendously by $216 \%$ since 1970, as measured in vehicle-miles traveled (NTS 2000). Overall, vehicle-miles traveled (total VMT) also increased by $137 \%$ over the same period (NTS 2000).

Most of the fatal crashes involving large trucks occurred in rural areas (64\%), during the daytime (67\%), and on weekdays (80\%) (NHTSA 2008). It is anticipated that the growth in the number of trucks will bring a commensurate increase in the number and severity of vehicle crashes, if all other factors are equal. Statistics indicate that total crash rates for large trucks are lower than for passenger vehicles, but fatal rates are higher. In 2006, large trucks were involved in 223,037 total crashes per million vehicle-miles traveled (MVMT) and 1.94 fatal crashes per 100 million vehicle-miles traveled, whereas passenger vehicles were involved in 2,771,684 total crashes per million vehicle miles traveled and 1.23 fatal crashes per 100 million vehicle-miles traveled (FMCSA 2006).

Roadway safety is dependent on many factors such as density, volume to capacity ratio, facility type (interstate, major/minor arterial), facility location (rural or urban) and vehicle mix. The primary issue of safety is of great concern to transportation professionals, but indepth research into the possibility of an interaction between the percentages of large trucks vis-à-vis crash rates on the transportation facilities has not been extensively studied. This topic should be of particular concern to state department of transportation (DOT) engineers, especially in Wyoming and Nebraska, who operate facilities with large percentages of trucks on roads such as Interstate 80 (I-80).

Large truck crashes present both a public and an occupational safety problem. From the public safety perspective, given the substantial differences in vehicle mass, it is not surprising that the majority of persons who die in large-truck crashes are occupants of other vehicles or nonmotorists ( $82 \%$ in 2005). However, it is important to note that more truck drivers die on the job than do workers in any other single occupation (Burks, Belzer, Kwan, Pratt, \& Shackelford 2010).

Due to the safety concerns that trucks pose to smaller/passenger vehicles, most highway agencies have implemented various truck restriction strategies to improve safety and efficiency of highway travel. These types of restrictions include differential speed limits, truck-only lanes, and no-truck routes.

### 2.1.1 Speed Restrictions

The relationship between increased speed and crashes has been well documented by Stuster et al. in 1998, with the key correlation being speed and crash severity. Excessive speeding decreases a driver's response time in an event and may increase risk as a result of speedrelated increases in crash exposure (Stuster, Coffman, \& Warren 1998).

Similarly, a rigorous meta-analysis conducted by Elvik et al. (2004) included 97 different studies with a total of 460 estimates of the relationship between changes in speed and changes in the frequency of crashes or associated injuries and fatalities. Using the Power Model, this study assessed the relationship between speed and road safety. The study concluded there was a relationship between speed and the number of crashes and the severity of crashes. The data suggest that speed is likely to be the single most important determinant in the frequency of traffic fatalities; a $10 \%$ reduction in the mean speed of traffic is likely to reduce fatal traffic crashes by $34 \%$ and have a greater impact on traffic fatalities than a $10 \%$ increase in traffic volume. These data include all vehicles and are not specific to large trucks (Elvik 2004).

While traveling above the posted speed limit or driving too fast for conditions has been shown to increase crash exposure (i.e., risk), speed variance among vehicles sharing the same road has also been shown to be correlated with vehicular crash risk. Lower speed variance is associated with fewer crashes (Finch, Kompfner, Lockwook, \& Maycock 1994); (Kallberg \& Toivanen 1998).

The Insurance Institute for Highway Safety (IIHS) ("Institute Supports Speed Limiters . . ." 2007) concluded that truck speeds are increasing on rural Interstates (pp. 5, 7): "In New Mexico, where the speed limit for trucks is 75 mph , the proportion of large trucks exceeding 70 mph increased from $27 \%$ in 1996 to about $43 \%$ in 2006. The percentage exceeding 75 mph more than doubled, rising from $4 \%$ to $10 \%$. Truck speeds also increased substantially in Nevada, which has 75 mph speed limits on rural interstates. The proportion of trucks traveling faster than 70 mph increased from $29 \%$ in 1996 to $41 \%$ in 2006. During the same decade, the proportion of trucks topping 75 mph jumped from 8 to $14 \%$ " (IIHS 2007).

The IIHS nationwide survey ("Institute Supports Speed Limiters . . ." 2007) indicated that $64 \%$ of drivers favor speed limit requirements for large trucks. More than three-quarters of respondents who favored speed limit requirements supported a maximum speed limit below 70 mph . More than $80 \%$ of drivers reported that speeding on Interstate highways and freeways was a safety problem, whereas $40 \%$ of drivers reported that speeding was a "big" safety problem (IIHS 2007).

The safety impact of lowering speed limits and creating differential speed limits for cars and trucks has been the subject of debate among researchers and policymakers. Research clearly finds that lower vehicle speeds reduce the severity of crashes and the incidence of fatalities (Bishop, Murray, McDonald, Hickman, \& Bergoffen 2008). Lower speeds also improve truck-braking distances. On the other hand, differential speeds caused by lower speed limits can increase crash risk. Many researchers have argued that it is the speed differential between vehicles, not the absolute speed, that is most important for creating crash risk. Trucks traveling at speeds lower than the rest of the traffic interact with more vehicles, increasing risk. In addition to the car-truck differential, speed limits over 65 mph tend to increase speed differentials between trucks by dividing trucks into company drivers (who tend to have speed limited to lower levels) and owner-operators (who typically can travel at higher speeds). Overall, researchers and policymakers have not reached consensus on the impact of differential speeds. A study conducted by Mannering et al. showed that 12 states had implemented speed restrictions for trucks using certain routes. The speed limit for trucks of a specific size, weight, or axle configuration was set to either 5 mph or 10 mph below the speed limit for passenger cars (Mannering 1993).

According to Johnson and Pawar (2005), 11 states have adopted the Differential Speed Limits (DSL) for both automobiles and heavy trucks with speed differentials ranging between 2 mph to 15 mph . About eight of the states have differential speed limits of 5 mph , with one or two states having speed differentials of 10 mph and 15 mph , respectively (Johnson \& Pawar 2005). They stated that although there have been a number of studies that have investigated the safety implications of speed differentials between automobiles and trucks, the results have been inconclusive (Johnson \& Pawar 2005).

Naziru and Mussa (2002) argued in favor of restrictions for truck speeds because truck crashes, like truck traffic, tend to increase during off-peak time periods and reducing truck speed during off-peak time periods would mitigate trucks' involvement in crashes (Naziru \& Mussa 2002). However, Stokes and McCasland also argued that speed reduction aimed at trucks only creates speed differential that might increase crash potential between trucks and passenger cars (Stokes \& McCasland 1984).

Other research has revealed that the results from the DSL study are varied and conflicting or inconclusive. Johnson and Pawar cited some of the results as having negative as well as positive effects on safety. They pointed out that these are based on little empirical evidence and were mainly supported merely by different theories. Proponents of the DSL cited the fact that trucks require longer braking distances for any given speed and therefore traveling at lower speeds help equalize the stopping distance. This is offset by the fact that truck drivers
have a higher seat position above the road, which allows a longer sight distance, reducing the effect of the differences in braking distance. The opponents suggested that the differential speeds increase the speed variance, thus having a negative impact on safety (Johnson \& Pawar 2005). They stated it is possible that the two arguments are correct, and that the DSL has two effects:

- The positive effect that results from improved vehicle dynamics (braking and maneuvering) for trucks at lower speeds
- The negative effect of increasing speed variation and the number of interactions among vehicles

DSLs increase interactions among vehicles and increase the probability of rear-end, sideswipe, and on-ramp accidents (Johnson \& Pawar 2005).

### 2.1.2 Truck-Lane Restriction

Truck Lane Restrictions (TLRS) are a means of managing truck traffic on highways by prohibiting trucks from using certain lanes to minimize interaction between trucks and other vehicles. TLRS are widely practiced in the United States, with some restrictions being site specific or statewide, and compliance is either mandatory or voluntary. Usually one or more lanes are restricted from use by heavy trucks. These restrictions have been implemented by most states, notably Virginia and Florida. From a national survey conducted in 1986 by the FHWA to evaluate the benefits of truck lane restrictions, it was found that 26 states had implemented TLRS at one or more locations in their area but most implemented them for different reasons (FHWA 1986). Fourteen states believed lane restrictions helped improve highway operations; eight states implemented them to reduce crashes; seven states used TLRS to address pavement wear and tear; and five states used TLRS for better safety in work zones (FHWA 1986). A potential means of reducing interaction between trucks and cars is restricting trucks from using certain lanes on multilane highways (FHWA 1986).

Prohibiting trucks from using certain lanes on multilane highways gives other vehicles the opportunity to occupy and attain higher travel speeds on these restricted lanes without any interference from heavy vehicles. This can possibly lead to improved traffic flow, thereby increasing the throughput (i.e., traffic flow) (Radhakrishnan \& Wilmot 2009).

Gan and Jo (2003) developed operational performance models to study truck lane restriction policies for freeways. They developed a simulation model to represent maximum service flow rate and minimum speed values as close to Highway Capacity Manual values as possible using VISSIM for the Florida Department of Transportation. The model was then used to assess the impact of prohibiting trucks from using the left most lanes on freeway sections with three, four, or five lanes in one direction. The input to the model was different combinations of number of lanes, lane restrictions, free flow speed, traffic volume, truck percentage, interchange density, and ramp volume. Throughput on three-, four-, and five-lane roadways was found to increase under low truck percentages and increased truck lane restrictions, while the opposite was true under high truck percentages. It was found that when ramp volumes increased to 1,000 vehicles per hour ( vph ) or more, truck percentages were greater than $15 \%$
and interchange density was greater than two per mile; truck lane restrictions reduced throughput. The study found that TLRS increased throughput only when the number of lanes restricted were limited and truck percentages were less than $25 \%$. Restricting trucks from using the two left-most lanes was recommended for four-lane or five-lane highways. For three-lane highways, it was recommended that trucks be restricted from using one left-most lane only (Gan \& Jo 2003).

Yang and Regan (2007) also studied the impact of left-lane truck prohibition on the I-710 corridor in Los Angeles County, California, which has the highest truck volumes using simulation models. In this study, a pair-wise comparison of average speed, frequency of lane changes, and total volume for different values of maximum service flow rate and truck percentages were estimated. The simulation was conducted on a hypothetical five-mile section having one on ramp and one off ramp and four through lanes in one direction. Between 5\% and 20\% truck percentages were considered for the study. Pair-wise comparison results indicated an increase in throughput due to truck lane prohibition, provided the flow rate is greater than 1,300 vehicles per hour per lane (vphpl) and where trucks make up to at least $10 \%$ of the total traffic stream. This simulation study used variable flow rates but a fixed ramp volume of 500 vehicles per hour (Yang \& Regan 2007).

A study by S. Peeta et al. found that when truck percentages are relatively low (10\% and $30 \%$ ) and demand loads are not very high, the strategy restricting trucks to the right-most lane is a good strategy that lessens car-truck interactions without deteriorating the traffic performance. However, for high truck percentages ( $50 \%$ and $70 \%$ ) with high to very high demand, the strategy makes the lane highly congested leading to significant deterioration (Peeta \& Zhou 2004).

### 2.1.3 Truck-Only Lanes

Truck-only lanes are defined as lanes that are separated from the remaining roadway lanes by a physical barrier and equipped with their own access and exit ramps. These truck lanes are custom designed for longer and heavier trucks because trucks have very different accelerating, turning, and braking characteristics in comparison with cars. There are a number of important factors to be considered when the construction of the facility is contemplated, such as cost, demand, financing options, location, improved level of service for trucks and other vehicles, improved productivity and increased safety.

The only separated truck lane facility that currently exists is a 35 -mile segment of the New Jersey Turnpike, where trucks are physically separated from non-commercial traffic with a barrier; with the inner roadway reserved for light vehicles or non-commercial vehicles only, while the outer roadway is open to all vehicles (Middleton 1992). Another study conducted by Janson et al. described a set of specific feasibility thresholds for the consideration of constructing dedicated truck lanes. The study found that the truck facilities were most costeffective when they were constructed with barrier separation in the existing median. They concluded that barrier separated dedicated trucks lanes achieve optimum feasibility when truck volumes exceed $30 \%$ of the total vehicle mix, peak hour volumes exceed 1,800 vehicles
per lane hour, and off-peak volumes exceed 1,200 vehicles per lane hour (Janson \& Rathi 1990).

Researchers from the truck-only lanes study have argued that the benefits of truck-only lanes go beyond operational gains for trucking firms, which include traffic safety improvements, reduced conflicts, and lower maintenance costs on general-traffic lanes (Mannering 1993). Forkenbrock (2005) also observed that having truck-only lanes could improve the comfort and convenience of those traveling in passenger vehicles, which would have positive implications for the quality of life of these travelers (Forkenbrock; Hanley 2005).

The Federal Highway Administration (FHWA) and Forkenbrock and March estimated that truck vehicle miles traveled (TVMT) will increase by more than $70 \%$ by the year 2020 (Forkenbrock \& March 2005).

A study conducted by the Southern California Association of Governments provided specific conditions to warrant the need for truck-only lanes as total truck volumes not exceeding $30 \%$ of the traffic mix and about 1,800 vehicles per lane-hour (vplh) and 1,200 vplh in each direction for peak and off-peak hours, respectively (Caltrans 2004). Poole and Samuel (2004) also proposed similar parameters in terms of 40,000 average daily traffic in each direction with $20 \%$ being truck volume as a warrant for a truck-only lane (Poole \& Samuel 2004). These conditions, according to Forkenbrock and Hanley (2005), are not likely to be met on most rural Interstate highways, that truck-only lanes are likely to be cost-effective solutions for rural Interstate highways when traffic volumes are comparatively high, with a high percentage of heavy trucks (Forkenbrock; Hanley 2005).

Killough (2008), in his paper "Value Analysis of Truck Toll Lanes in Southern California," concluded that the economic benefits of providing truck-only lanes on freeways outweigh the investments. He cited the improvement in both travel time and reliability due to the reduction of congestion of vehicles using the facility (Killough 2008).

Forkenbrock \& March (2005) advanced three different proposals for the construction of truckonly lanes in their research paper "Issues in the Financing of Truck-Only Lanes." For the first type, they proposed two additional lanes in each direction for heavy trucks only separated by barriers from passenger vehicles and light trucks under 25,000 pounds gross weight. The second type should have one additional lane in each direction limited to heavy trucks separated by a barrier from the main traffic stream, including a breakdown lane and additional passing lane every few miles for trucks. The third type should have one additional lane for a total of three lanes in each direction, with the right lane reserved exclusively for trucks, the left lane for non-truck vehicles and the middle lane used by all vehicles. Although it is expensive to construct truck-only lanes, the concept has a broader appeal in principle (Forkenbrock \& March 2005).

Poole et al. estimated that it would cost approximately $\$ 2.5$ million per single lane-mile and about $\$ 10$ million per route-mile for two lanes in each direction to construct a truck-only facility alongside an existing rural Interstate (Poole \& Samuel 2004). There are many benefits
associated with truck-only lanes to both trucking firms and the traveling public. Some of the potential benefits for trucking firms are reduced crashes as the interaction between passenger cars and trucks are reduced, thereby improving safety. Increased throughput and efficiency for trucks as low traffic would occupy the lanes and reduce congestion, which will eventually increase travel time reliability. Finally, there would be stronger argument for greater use of the longer twin-trailer or three-trailer combination (LCVs) trucks as these LCVs improve the productivity of the trucking industry. The benefits for passenger vehicles are improved safety, increased quality traveling experience as passengers' cars do not feel intimated due to the separation of trucks and passenger vehicles, and improved traveling speeds of the passenger vehicles as trucks operate in the truck-only lanes (Forkenbrock \& March 2005).

### 2.2 DRIVER FACTORS

A paper by Peeta, Zhang and Zhou, "Behavior-Based Analysis of Freeway Car-Truck Interactions and Related Mitigation Strategies," focused on modeling the behavior of nontruck drivers in the vicinity of trucks by quantifying a time-dependent "discomfort level" for every non-truck driver interacting with trucks in the ambient traffic stream. According to the researchers, trucks contribute to traffic congestion, infrastructure deterioration, and crashes due to their physical and operational characteristics such as size, weight, braking distance, blind spots, turning radii, and driver fatigue. They indicated that the influence of trucks on traffic safety and the deterioration of the pavement can be inferred from quantifiable measures, including truck operational characteristics such as acceleration, deceleration, and speed. They noted that traffic performance can be affected by the behavior of truck drivers and non-truck drivers; truck driver behavior is influenced by the presence of large blind spots and geometry constraints, and non-truck driver behavior is affected by the truck's physical and operational characteristics (Peeta, Zhang, \& Zhou 2004). The study suggested that the non-truck drivers' discomfort level is a quantifiable measure that varies based on socioeconomic characteristics, past experience, and inherent behavioral tendencies of the drivers. They emphasized that the discomfort level is time-dependent and influenced by situational factors such as weather, time of day, and ambient traffic conditions. The study proposed a fuzzy logic-based modeling framework by introducing the notion of "discomfort" for non-truck drivers in the vicinity of trucks and using that to extend existing microscopic traffic flow modeling logic. The results from the study "indicate that the number of interactions involving trucks and non-trucks vehicles increases with truck percentage up to a certain point and reduces beyond that point, especially for low demand loadings (2,000 and 3,500 vehicle per hour) as well as higher demand loading scenarios" (Peeta, Zhang, \& Zhou 2004). They explained that for lower congestion levels, there is a lower potential for car-truck interactions even with high truck percentages and fewer non-truck vehicles on the freeway. However, at higher congestion levels (5,000, 6,000 vehicles per hour) with higher density, the interactions will be reduced. Thus, medium level congestion and a high percentage of trucks could cause passenger car drivers the highest level of distress (Peeta, Zhang, \& Zhou 2004).

A study by Johnson and Pawar stated that another driver factor associated with accidents is fatigue. They indicated that driver fatigue can be caused by both physical and mental stress, and inattention caused by boredom. This driver factor is prominent on most rural Interstates,
as these drivers drive for very long periods, concentrating without any interruptions compared with driving in areas with traffic congestion such as urban freeways (Johnson \& Pawar 2005). They concluded that driver fatigue causes several problems ranging from slower driver reaction and decision making to decreased tolerance for other road users, which will eventually cause accidents.

A study by the National Transportation Safety Board (1995) on fatal accidents in professional trucks drivers showed that the mean duration of sleep among drivers was less than six hours in the last 24 hours before the accident (NTSB 1995).

A study to investigate fatigue in local or short haul trucking by Hanowski et al. concluded that driver fatigue was found to influence a crash. They suggested that the off-duty behavior of drivers was likely a primary contributing factor in the level of fatigue during the workday. This was confirmed by the results of the analyses conducted, which indicated that the fatigue experienced by drivers was brought with them to the job rather than being caused by the job (Hanowski, Wierwille, \& Dingus 2003).

A study by Dingus et al. to investigate safety and fatigue issues in long-haul trucking concluded that the frequency of critical incidents and fatigue-related critical incidents vary significantly by the hour of the day. They indicated that severe critical incidents were caused by extreme fatigue levels in single long-haul drivers (Dingus, Neale, Klauer, Petersen, \& Carroll 2006).

Haworth (1998) examined the factors that contribute to the development of driver (both automobile and truck) fatigue in Australia. The five main factors that induced fatigue according to this report were (in no particular order): (a) intensity and length of manual and mental work; (b) psychic factors such as responsibilities, worries and conflicts; (c) features of the surroundings such as illumination, climate, and noise; (d) monotony; and (e) illness, pain, and eating habits (Haworth 1998).

A study by the University of Michigan Transportation Research Institute (UMTRI) into tractor-trailer drivers' behavior revealed that truck drivers frequently drive longer than the 10hour maximum permitted under current law (Campbell \& Belzer 2000).

Kostyniuk et al. concluded in their study that four driver factors contributing to car-truck crashes were fatigue or drowsiness, following improperly, improper lane changing, and driving with vision obscured by rain, snow, fog, smoke, sand, or dust. They indicated that the consequences of these driver actions were more severe for car drivers in the vicinity of trucks. Kostyniuk et al. pointed out that the majority of deaths were the occupants of the car instead of the trucks (Kostyniuk, Streff, \& Zakrajsek 2002).

A report by Stuster to determine the risky behavior of motorists near trucks noted about 27 reasons for motorists' behavior that resulted in truck-car crashes. They indicate that the reasons for motorists' behavior include aggression, inattentiveness, incompetence, and ignorance (Stuster 1999).

A study conducted by Moore et al. investigated motorists' perceptions of trucks on the highway and the relationship between the established predictors of highway behavior and perceptions of trucks (Moore et al. 2005). To achieve the objective of the study, they conducted a telephone survey of 1,392 people. Based on the survey results, they concluded that the overall perception of truck behavior on highways is negative and that it is a safety hazard. The frequency of the perceptions as recorded from the survey indicated that about $53.3 \%$ of large trucks create dangerous conditions by trying to pass each other when they drive fast ( $56.2 \%$ ). About $63.5 \%$ of passenger vehicle drivers become nervous when driving beside or near large trucks (Moore et al. 2005).

A study conducted by researchers in Finland investigated the contributing factors to truck fatal accidents and the driver factors for those accidents. They conducted a questionnaire survey of which 251 responded, all of whom were long-haul drivers. Results from the survey indicated that driver fatigue contributed slightly to truck accidents. To reduce the risk of accidents associated with fatigue, the researchers proposed a technological, in-car countermeasure to detect driver fatigue (Hakkanen \& Summala 2001).

### 2.3 SUMMARY

This literature review was conducted to obtain an overview of previous/related research studies done by other researchers regarding the safety impacts of high percent trucks and driver perceptions in relation to car-truck interactions. Although several key findings were identified, the literature search revealed a scarcity of relevant published research on this topic.

## 3. PROJECT LOCATION

### 3.1 PROJECT LOCATION

Interstate 80 (I-80) was chosen for this research because of the high percentage of freight traffic that it carries. It stretches from east to west for approximately 3,000 miles through states such as Wyoming, Nebraska, Nevada, California, Utah, etc. It is a popular route for freight transportation from the east coast to the west coast and vice versa.

Originally, I-80 sections in three states, Wyoming, Nebraska and Utah, were identified for a preliminary study. Upon further checks in the three states, it became evident that the I-80 corridor in Utah intersects with two major interstates (I-15 and I-84) near Salt Lake City. Due to the huge amount of traffic that might divert to/from I-80 at that location, which might affect the total volume, the Utah section of I-80 was recommended for further studies.

The Wyoming and Nebraska sections of I-80 were selected for the analyses presented in this report. The length of I-80 in Wyoming is about 400 miles starting from Evanston near the Utah-Wyoming border to Pine Bluffs near the Wyoming-Nebraska border. The Nebraska section of I-80 runs west to east from Bushnell near the Wyoming-Nebraska border to Omaha near the Nebraska-Iowa borders, spanning a distance of about 455 miles. Figure 3.1 shows a map of the I-80 corridor from Wyoming to Nebraska.

### 1.80 CORRIDOR FROM WYOMING TO NEBRASKA

Figure 3.1 Corridor Map

The corridor passes through series of mountainous and low lying areas with extreme weather conditions. I-80 reaches its maximum elevation of 8,640 feet in Wyoming between Laramie and Cheyenne. The Interstate passes over the Continental Divide as well. With the exception of urban areas, such as Lincoln and Omaha in Nebraska and Cheyenne in Wyoming, the corridor traverses mainly through small rural towns in both states. The longest straight stretch of the I-80 system is about 72 miles in Nebraska from milepost 318 in Grand Island Area to milepost 390 near Lincoln, Nebraska. Figures 3.2 and 3.3 show the traffic stream on I-80 near Happy Jack, milepost 322 near Laramie, Wyoming.

Figure 3.2 Traffic Stream on I-80 near Happy Jack in Wyoming at Milepost 332. (Source: Google Map 2009)

Figure 3.3 Trucks on I-80 in Wyoming. (Source: Google Map 2009)

### 3.2 DATA DESCRIPTION

The data for this research were obtained from the Wyoming Department of Transportation (WDOT) and the Nebraska Department of Roads (NDOR). The data include the average daily traffic volumes for all vehicles and trucks on I-80 in both states. Accident data for a 10-year period from 2000-2009 were also obtained.

### 3.2.1 Automatic Traffic Recorders

The WYDOT and the NDOR maintain multiple fixed and mobile automatic traffic counter stations on road facilities across each state. The automatic traffic counters record traffic data, which are reported annually in the Automatic Traffic Recorder Report issued by the WYDOT's Planning Office and the Planning and Project Development Division of NDOR. The data usually include the counter's location, the Average Daily Traffic (ADT) listed for all days of the month, and the percent of the average day and month for each of the 12 months and vehicle classification.

ADT is the average 24-hour volume at a given location over a defined time period less than one year. The common application is to measure an ADT for each month of the year. The Average Annual Daily Traffic (AADT) is the average 24 -hour volume over a full 365 -day year at a given location; that is, the number of vehicles passing a site in a year divided by 365 days.

### 3.2.2 Vehicle Miles Traveled (VMT) Data

The traffic count data or the AADT count is used to quantify the number of vehicles miles traveled along a section and is useful for various calculations, such as truck volumes, Level of Service (LOS), or crash rates.

The Vehicle Miles Traveled (VMT) data per section are estimated by multiplying the AADT by the length traveled within the network throughout the year. The VMT data are an important component in computing the percent trucks and crash rates for this research. I-80 was divided into 108 sections and 80 sections in Wyoming and Nebraska, respectively.

### 3.2.3 Crash Data

Crash data and crash information were obtained for the 10-year study period from 2000 to 2009 for all reported crashes on I-80 in both states. The crash information contains the following: crash date, crash identification number, time of crash, accident location or milepost, and pertinent crash-related information, such as first harmful event, manner of collision, road geometry, passenger data, vehicle type, road, light and weather conditions, posted and estimated speeds, etc. The information of interest for this study included the crash date, the milepost where the crash occurred, road, light, and weather conditions, and whether or not a truck was involved. The crash records supplied were used to determine the crash frequencies along the I-80 corridor for the study period. This information, together with the VMT data, is used to calculate the crash rates.

## 4. DATA ANALYSIS

### 4.1 ANALYSIS OF DATA

Roadway crashes cause economic loss to every country. It is, however, very important for transportation policy makers to find out the causes of these accidents and find ways of addressing them. This requires that the crash information needs to be investigated to identify sections on interstates that have high crash rates so that the necessary remediation measures can be undertaken. Interstate 80 carries a lot of freight traffic, mostly from the port city of Los Angeles in Southern California, which handles two-thirds of all container traffic entering the United States from the Pacific Rim countries to the eastern states of Nevada, Utah, Illinois, Iowa, etc. and freight traffic from the east to the west (Killough 2008).

Interstate 80 in Wyoming goes from Milepost (MP) 0 at the Wyoming-Utah border near Evanston to MP 402 at the Wyoming-Nebraska border near Pine Bluffs. The total number of crashes per milepost for the study period 2000-2009 for all vehicles and trucks in Wyoming is shown in Figure 4.1. MP 238 to 255 recorded the highest number of crashes for both All Vehicles and Trucks during the study period under investigation. It is important to note that this section of I-80 in Wyoming is the Elk Mountain corridor, which experiences severe weather conditions especially during the winter. It is most likely that the truck crashes within this section are due to the severe weather conditions.

Figure 4.2 shows the crash frequency for all vehicle and truck crashes on I-80 in Nebraska from 2000-2009. The I-80 corridor in Nebraska runs from west to east beginning with MP 0 from the Wyoming-Nebraska border near Bushnell to MP 455 on the Nebraska-Iowa border near Omaha. With regard to the crash frequency in Nebraska, truck crashes seems to be evenly distributed along most of the corridor with the highest crashes occurring between MP 409.77 at Waverly near Lincoln and MP 420.94 at Greenwood near Omaha. A higher allvehicle crash rate occurs between MP 382.11 and MP 451.8 at Seward near Lincoln and Omaha. Frequency of crashes occurs mostly in the towns (densely populated areas) along the corridor compared with other areas. The crash frequency tables for both states can be found in Appendix A.

Crash Frequency on 1-80 in Wyoming from 2000-2009

Figure 4.1 Crash Frequency on I-80 for Both All Vehicle and Truck Crashes in Wyoming from 2000-2009.

Crash Frequency on I-80 in Nebraska from 2000-2009

1.80 Milepost

Figure 4.2 Crash Frequency on I-80 for Both All Vehicle and Truck Crashes in Nebraska from 2000-2009.

Figures 4.3 and 4.4 show the truck fatalities in Wyoming and Nebraska on I-80 from 20002009 , respectively. These are fatality crashes involving at least one truck. The truck fatalities in both Wyoming and Nebraska were analyzed by year. It became evident that truck fatalities on I-80 in Wyoming were significantly higher fromr 2002 to 2004 than the rest of the study period. The highest number of truck fatalities in Nebraska was recorded in 2002. Compared to Wyoming truck fatalities, Nebraska has fairly distributed fatal crashes per year for the 10-year study period, with the exception of the low truck fatalities in 2006. Observations from both states indicate that Nebraska had more fatal truck crashes than Wyoming for most of the years.

Figure 4.3 Truck Fatalities by Year on I-80 in Wyoming

Figure 4.4 Truck Fatalities by Year on I-80 in Nebraska
Figures 4.5 and 4.6 show the average truck crashes by month on I-80 in Wyoming and Nebraska, respectively. These graphs show that higher truck crashes occur during the months of October through March. The reason for the high number of truck crashes might be due to the severe winter conditions, especially in Wyoming, coupled with the high wind conditions across the state.

Figure 4.5 Average Truck Crashes by Month on I-80 in Wyoming

Figure 4.6 Average Truck Crashes by Month on I-80 in Nebraska

### 4.1.1 Truck Volume Analysis

Freight transportation is crucial to the economic success of any nation. Knowledge about truck volumes and movement on our freeways is important to transportation engineers, to ensure that the facility is operated effectively and to allow necessary maintenance decisions to be made. Traffic volume and vehicle mix is utilized for estimating the effects of current truck traffic on Level of Service (LOS) and safety.

The traffic volumes were obtained from the WYDOT and NDOR. The data were manually validated to check for inconsistencies and errors. The Vehicle VMT on I-80 in Wyoming and Nebraska for both All Vehicle and Trucks was calculated from the traffic volumes and can be found in Appendix A. After the validation, the percentage of trucks in the traffic stream was calculated using data from both the total all vehicle miles traveled (AVMT) and the total truck vehicle miles traveled (TVMT). The percent trucks on I-80 in Wyoming and Nebraska can be found in Appendix A. Figure 4.7 shows the percent trucks for both Wyoming and Nebraska. The graph shows a higher truck percentage in Wyoming than Nebraska throughout the 10 -year study period.

Figure 4.7 Truck Percentage by Year on I-80 in Both Wyoming and Nebraska
The truck volumes for the 10-year study period on I-80 in both Wyoming and Nebraska can be found in Figure 4.8. From the figure, it is clear that Nebraska had almost double the volume of truck traffic traveling on I-80 during the 10-year study period than in Wyoming. The year 2007 saw a higher truck volume on I-80 in both Nebraska and Wyoming than any other year. The high truck volumes in Nebraska could be attributed to more freight traffic using other routes such as Interstates 70 and 76 to link Interstate 80 in Nebraska instead of traveling through Wyoming. Although the truck volume in Nebraska is higher than Wyoming, the percent trucks are higher in Wyoming.

Figure 4.8 Truck Volume by Year on I-80 in Both Wyoming and Nebraska

### 4.1.2 Crash Rate Analysis

This section quantifies the crash rates on I-80 in both Wyoming and Nebraska. The crash rates for this research are expressed as the number of crashes per million vehicles miles traveled (MVMT). The crash rate measures the level of safety of a particular roadway section allowing for a comparison between sections of the roadway with varying traffic volumes. AADT is from permanent counts and represents a true average of volume counts over a year period. ADT is from temporary counters on a day considered to be average. AADTs are considered more accurate than ADTs.

VMT is calculated by multiplying the ADT by the length of road section by 365 days, thus the formula is:

VMT $=$ ADT*Length*365
The crash rates are calculated by dividing the number of crashes (for all vehicles and trucks) by the VMT and then multiplied by one million. The formula for crash rate is:

$$
\text { Crash Rate }=\frac{\text { Number of Crashes } * 1,000,000}{V M T}
$$

Equation 4.1 Crash Rate Formula

The crash rate for all vehicles and trucks only were calculated for crashes in both Wyoming and Nebraska. VMT and crashes involving all vehicles were used in computing for the all vehicle crash rates. On the other hand, truck crash rates were computed using the truck only crashes and TVMT.

### 4.1.3 Crash Rate Comparison

WDOT divided I-80 into 108 sections for reporting the AADT and the NDOR also divided I80 into 80 sections for reporting the AADT. The crash data for each individual section along I-80 were used to calculate the crash rate for each section per year. The crash rates were then averaged over the entire corridor for the year to obtain the average crash rate for each year. The crash rates were computed for Wyoming and Nebraska on the I-80 corridor from 2000 2009. Table 4.1 shows the single year crash rates in Wyoming on the I-80 corridor.

The average crash rates for the study period 2000-2009 along the I-80 corridor in Wyoming were 2.554 crashes per million VMT for all vehicles and 1.467 truck crashes per million TVMT.

The crash rates per sections of I-80 varied over the 10-year study period, where each year had different maximum and minimum rates. From Table 4.1, year 2002 has the highest maximum crash rates for both all vehicles and trucks. The average maximum crash rates for all vehicles and trucks only during the study period was 11.548 crashes per million VMT and 10.138 crashes per million TVMT, respectively. The average minimum crashes for both all vehicle and trucks only were zero crashes per million VMT and zero crashes per million TVMT, respectively. The zero crash rates indicate there were some sections that had no crashes for that year.

Table 4.1 Single Year Crash Rates in Wyoming on I-80 (Crashes per million VMT or TVMT)

| All Vehicles | $\mathbf{2 0 0 0}$ | $\mathbf{2 0 0 1}$ | $\mathbf{2 0 0 2}$ | $\mathbf{2 0 0 3}$ | $\mathbf{2 0 0 4}$ | $\mathbf{2 0 0 5}$ | $\mathbf{2 0 0 6}$ | $\mathbf{2 0 0 7}$ | $\mathbf{2 0 0 8}$ | $\mathbf{2 0 0 9}$ |

Table 4.2 shows the average, maximum, and minimum crash rates for Nebraska on I-80 for all vehicles and truck crash rates for the 10-year study period from 2000-2009. The 10-year average crash rates for all vehicles and trucks are 0.547 crashes per million VMT and 0.383 truck crashes per million TVMT. Maximum crash rates of 3.673 crashes per million VMT and 7.641 crashes per million TVMT occurred in 2002 and 2007 for all vehicles and trucks, respectively. The average minimum crash rates for all vehicles and trucks are 0.067 crashes per million VMT and 0.0 truck crashes per million VMT.

Table 4.2 Single Year Crash Rates in Nebraska on I-80 (Crashes per million VMT or TVMT)

| All Vehicles | $\mathbf{2 0 0 0}$ | $\mathbf{2 0 0 1}$ | $\mathbf{2 0 0 2}$ | $\mathbf{2 0 0 3}$ | $\mathbf{2 0 0 4}$ | $\mathbf{2 0 0 5}$ | $\mathbf{2 0 0 6}$ | $\mathbf{2 0 0 7}$ | $\mathbf{2 0 0 8}$ | $\mathbf{2 0 0 9}$ |

From the analysis, it became evident that Wyoming has higher average crash rates than Nebraska. This could be due to certain factors such as the weather and road conditions, road geometry, etc. Apart from the yearly crash rate averages, the crash rates for multi-year periods were also analyzed. The three-year averages were used to smooth out any variations and remove the single year bias from the model. Table 4.3 shows the average, maximum, and minimum crash rates for Wyoming on I-80 for the three-year average for both all vehicles and trucks only. From the table, years 2001-2003 has the highest crash rates of 2.702 crashes per million VMT for All Vehicles and years 2007-2009 has the highest truck crash rates of 1.614 truck crashes per million TVMT.

Table 4.3 Multiple Year Average Crash Rates in Wyoming on I-80 (Crashes per million VMT or TVMT)

| All Vehicles | $\mathbf{2 0 0 0} \mathbf{- 2 0 0 9}$ | $\mathbf{2 0 0 1 - 2 0 0 3}$ | $\mathbf{2 0 0 4 - \mathbf { 2 0 0 6 }}$ | $\mathbf{2 0 0 7} \mathbf{- 2 0 0 9}$ |

| Minimum | 0.000 | 0.000 | 0.000 | 0.000 |

Table 4.4 shows the average, maximum, and minimum crash rates for Nebraska on I-80 for the three-year average for both all vehicles and trucks only. The years 2001-2003 had the highest crash rate of 0.636 crashes per million VMT for all vehicles. The truck crash rate for the years 2001-2003 is the highest with a value of 0.411 truck crashes per TVMT.

| Maximum | 1.982 | 3.673 | 1.579 | 1.786 |
| Minimum | 0.067 | 0.000 | 0.000 | 0.000 |
| Trucks | $\mathbf{2 0 0 0} \mathbf{- 2 0 0 9}$ | $\mathbf{2 0 0 1 - 2 0 0 3}$ | $\mathbf{2 0 0 4} \mathbf{- 2 0 0 6}$ | $\mathbf{2 0 0 7 - 2 0 0 9}$ |
| Average | 0.383 | 0.411 | 0.348 | 0.392 |
| Maximum | 4.674 | 4.090 | 6.082 | 7.641 |
| Minimum | 0.000 | 0.000 | 0.000 | 0.000 |

Figure 4.9 shows the spatial map of the 10-year average crash rates for both all vehicles and trucks only in Wyoming. Most of the locations have all vehicle crash rates ranging from 1.513.00 crashes per million VMT. High truck crash rate frequencies occur between 0.00-1.51 crashes per million TVMT. The all vehicle crash rates show a relatively high crash rate between Laramie and Cheyenne. Between Evanston and Rock Springs, there were about 3.014.50 crashes per million VMT. Higher truck crash rates occur within the ranges of 3.01-4.50 crashes per million TVMT near Laramie.

The crash rate for all vehicles and trucks only were calculated for crashes in both Wyoming and Nebraska. VMT and crashes involving all vehicles were used in computing the all vehicle crash rates. On the other hand, truck crash rates were computed using the truck-only crashes and TVMT.

Figure 4.9 10-Year Average Crash Rates for All Vehicles and Trucks Only in Wyoming
Figure 4.10 shows the 10-year average crash rates for all vehicles and trucks only in Nebraska. The map shows that crash rates ranging from 0.0-0.5 crashes per million VMT have a higher frequency on most sections of I-80 for both all vehicles and trucks only. It is observed that higher crash rates for both all vehicles and trucks occur in towns, with the highest truck crash rates ( $>2.01$ crashes per million TVMT) occurring near Omaha.

Figure 4.10 10-Year Average Crash Rates for All Vehicles and Trucks Only in Nebraska

### 4.1.4 Economic Impact of Vehicle Crashes

The impact of crashes on the economy of every nation cannot be over-emphasized. Crashes cause a reduction in productivity as the affected people often become hospitalized or are killed. According to the Economic Impact of Motor Vehicle Crashes by the National Highway Traffic Safety Administration, in 2000, motor vehicle crashes in the United States cost an estimated $\$ 231$ billion, about $\$ 820$ per person or $2 \%$ of the Gross Domestic Product (GDP). Figure 4.11 shows the share of the economic costs of motor vehicle crashes by type in 2000.

Figure 4.11 Economic Impact of Motor Vehicle Crashes in 2000
Source: USDOT, 2000
The largest component of the total cost ( $27 \%$ ) is market productivity, which includes the cost of paid labor due to death and disability. The next to lowest component is the workplace costs, about $2 \%$, which is the disruption due to the loss or absence of an employee such that it requires training a new employee, overtime to accomplish the work of the injured employee, and the administrative costs to process personnel changes (USDOT, 2000).

### 4.1.5 Crash Monetization

The crash cost on I-80 in both Wyoming and Nebraska were primarily obtained from the Wyoming Department of Transportation (WYDOT) and Nebraska Department of Roads (NDOR). The figures obtained from WYDOT were derived from a USDOT report, Treatment of Economic Value of a Statistical Life in Departmental Analyses. Table 4.5 shows the crash cost used by WYDOT for each crash severity on I-80.

Table 4.5 Cost per Crash on I-80 in Wyoming

| Crash Severity | Cost Per Crash |
| :--- | :---: |
| Fatal | $5,800,000$ |
| Possible Injury | 11,600 |
| Property Damage Only (PDO) | 5,800 |

There were a total of 19,526 all crashes on I-80 in Wyoming for the period 2000 to 2009. Out of which, 314 of the crashes resulted in fatalities, 9,325 in injuries and 9,887 in property damage only. These crashes resulted in huge economic losses especially in Wyoming. Economic loss due to fatal crashes amounted to $\$ 1.8$ billion, and $\$ 108$ million was the cost for injury crashes. For the property damage only (PDO) crashes, the economic loss amounted to about $\$ 57$ million. Figure 4.12 and Table 4.6 show the economic cost of crashes due to different severities on I-80 in Wyoming from 2000-2009.

Table 4.6 Economic Cost by All Vehicle Crash Severity in Wyoming

| Crash Severity | Economic Cost |
| :---: | :---: |
| Fatal | $\$ 1,821,200,000$ |
| Possible Injury | $\$ 108,170,000$ |
| Property Damage Only (PDO) | $\$ 57,344,600$ |

Figure 4.12 Economic Cost by All Vehicle Crash Severity on I-80 in Wyoming
NDOR derived its crash cost from several sources such as the Federal Highway Administration (FHWA, 1991) and U.S. Department of Commerce, Bureau of Economic Analysis (2010). These crash costs were adjusted to January 2010 costs using the Gross Domestic Product (GDP) Implicit Price Deflator. Table 4.7 is the cost per crash used by NDOR on I-80. The difference in crash costs for each state shows the different formula used in calculating the crash cost based on their respective local and economic conditions.

Table 4.7 Cost per Crash on I-80 in Nebraska

| Crash Severity | Cost Per Crash |
| :--- | :---: |
| Fatal | $\$ 4,407,800$ |
| Injury | $\$ 40,800$ |
| Property Damage Only (PDO) | $\$ 7,300$ |

The number of crashes that occurred on I-80 in Nebraska during the study period 2000-2009 was 19,059 . Fatal crashes made up 244 of the total number and 6,951 of the crashes were injury crashes. The number of property damage only crashes for the 10 -year study period was 12,224 , making it the largest severity type crash for the period. The economic loss due to the total number of fatal crashes was $\$ 1.1$ billion and the injury crash cost for the state of Nebraska for the 10 -year period amounted to $\$ 269$ million. The property damage only crashes cost an amount of $\$ 89$ million. Table 4.8 and Figure 4.13 show the economic cost due to crash severity on I-80 in Nebraska.

Table 4.8 Economic Cost by All Vehicle Crash Severity in Nebraska

| Crash Severity | Economic Cost |
| :---: | :---: |
| Fatal | $\$ 1,075,503,200$ |
| Possible Injury | $\$ 268,912,800$ |
| Property Damage Only (PDO) | $\$ 89,235,200$ |

Figure 4.13 Economic Cost by All Vehicle Crash Severity on I-80 in Nebraska

The economic impact of truck accidents during the study period was significant compared with all vehicle crashes. There was a total of 5,924 truck crashes for the period, of which 65 were fatal crashes and 2,251 resulted in injury crashes and the remaining 3,608 were in property damage only crashes. Table 4.9 and Figure 4.14 show the economic cost of truck crashes of different severities in Wyoming from 2000-2009.

Table 4.9 Economic Cost by Truck Crash Severity in Wyoming

| Crash Severity | Economic Cost |
| :---: | :---: |
| Fatal | $377,000,000$ |
| Possible Injury | $26,111,600$ |
| Property Damage Only (PDO) | $20,926,400$ |

Results show that fatal truck crashes in Wyoming led to $\$ 377$ million in economic losses for the 10 -year study period. These fatal truck crashes accounted to about $19 \%$ in overall economic loss to the state of Wyoming. This is significantly high compared with the total all vehicle crashes. The economic cost of the injury and property damage only truck crashes are $\$ 26$ million and $\$ 21$ million, respectively.

Figure 4.14 Economic Cost by Truck Crash Severity on I-80 in Wyoming
Nebraska registered a total of 2,809 truck crashes with different severities. Fatal truck crashes resulted in 93 crashes; 1,360 and 1,356 crashes resulted in injury and property damage only, respectively. These crashes resulted in economic losses to Nebraska; fatal truck crashes led to $\$ 410$ million in economic losses. The economic losses due to injury and PDO truck crashes were $\$ 55$ million and $\$ 10$ million, respectively. Figure 4.15 and Table 4.10 show the economic cost by truck crash severity in Nebraska.

Table 4.10 Economic Cost by Truck Crash Severity in Nebraska

| Crash Severity | Economic Cost |
| :---: | :---: |
| Fatal | $\$ 409,925,400$ |
| Possible Injury | $\$ 55,488,000$ |
| Property Damage Only (PDO) | $\$ 9,898,800$ |

## Economic Cost of Truck Crash Severity in Nebraska (Trucks)

Figure 4.15 Economic Cost by Truck Crash Severity on I-80 in Nebraska
These fatal truck crashes accounted for about $29 \%$ in overall economic losses to the state of Nebraska, due to truck crashes.

## 5. ENVIRONMENTAL CONDITIONS

The crash data obtained from WYDOT contains, among other information the environmental conditions; weather, road, winter and light conditions at the time of the crash at the various locations. The environmental conditions play an important role in crashes. The possible types of light conditions recorded during an accident included: darkness lighted, darkness unlighted, dawn/dusk, daylight and unknown. The types of road conditions at the time of the crash included the following: dry, icy, muddy, slippery, slush, snowy, wet or unknown. Nine different types of weather factors contributed to crashes. These are clear, dust, fog, ground blizzard, rain, sleet/hail, snowing, strong wind and unknown.

Figure 5.1 Crashes During Specific Light Condition on I-80 in Wyoming
Figure 5.1 shows the different types of light conditions during crashes on I-80 in Wyoming. Sixty-three percent of crashes occurred during daylight, whereas most of the remaining occurred when it was dark. Of the remaining, $28 \%$ occurred during unlighted darkness condition. This is because most sections of the Interstate are not lighted.

Figure 5.2 Crashes during Specific Road Conditions on I-80 in Wyoming
Figure 5.2 indicates that $53 \%$ of the crashes occurred during icy road conditions and $36 \%$ of crashes occurred during dry road conditions during the 10-year period. Snowy and wet road conditions both contributed to $4 \%$ of the crashes. The rest of the road conditions: muddy, slippery, slushy, and unknown, contributed to less than $1 \%$ of all crashes.

Figure 5.3 Crashes During Specific Weather Conditions on I-80 in Wyoming
Figure 5.3 shows number of crashes occurred during specific weather conditions. Most of the crashes occurred during clear weather conditions, about 54\%. Snowy weather conditions contributed approximately $26 \%$ of crashes. About $9 \%$ and $7 \%$ of crashes occurred during ground blizzard and strong winds respectively. Fog, dust, sleet/hail and unknown road conditions accounted for the rest of crashes.

The light conditions in Nebraska during crashes is as shown in Figure 5.4. From the figure, it is evident that $66 \%$ of all accidents in Nebraska occurred during daylight conditions, and $33 \%$ occurred during dawn or dusk conditions. The rest (1\%) of the crashes occurred during darkness lighted, darkness unlighted, and unknown light conditions.

Figure 5.4 Crashes During Specific Light Conditions on I-80 in Nebraska
Figure 5.5 shows the specific road conditions during crashes in Nebraska. From the figure, most of the crashes ( $63.5 \%$ ) occurred during snowy road conditions, and about $23.7 \%$ of crashes occurred during dry road conditions. Slippery, icy, muddy, slushy, and wet road conditions contributed $12.8 \%$ to the crashes on the corridor.

Figure 5.5 Crashes During Specific Road Conditions on I-80 in Nebraska

Weather conditions are considered significant to most crashes, especially in mountainous regions of the United States. Figure 5.6 shows the crashes during specific weather conditions on Interstate 80 in Nebraska. From the figure, it could be seen that most of the accidents occurred during clear weather conditions, about $46 \%$. This means that most of the crashes occurred during adverse weather conditions. Snowy conditions resulted in $13 \%$ of crashes, and strong wind conditions in $1.1 \%$.

Figure 5.6 Crashes During Specific Weather Conditions on I-80 in Nebraska
The environmental conditions data in both states were combined. Figure 5.7 shows the light conditions in both states during which crashes occurred.

Figure 5.7 Crashes During Specific Light Conditions on I-80 in Both Wyoming and Nebraska

The combined light conditions in both Wyoming and Nebraska showed that most of the accidents ( $64 \%$ ) occurred during daylight in both states. About $18 \%$ of accidents occurred during dawn or dusk conditions, with darkness unlighted conditions contributing about $15 \%$ of accidents. Comparing the individual state conditions to the combined, it became evident that most of the accidents occurred during daylight conditions.

Figure 5.8 Crashes During Specific Road Conditions on I-80 in Both Wyoming and Nebraska

Figure 5.8 shows that $32.4 \%$ and $28.6 \%$ of the crashes occurred during snowy and icy road conditions, respectively, in both states. Dry road conditions contributed about $30.3 \%$ to the accidents. This result showed that snowy road conditions contributed to most of the accidents in both states.

Figure 5.9 shows that clear weather conditions contributed to $50 \%$ of the accidents in both states. Snowy weather conditions contributed to about $20 \%$ of the crashes with the remaining percentage of crashes due to strong winds, fog, rain, dust, and hail.

Figure 5.9 Crashes During Specific Weather Conditions on I-80 in Both Wyoming and Nebraska

## 6. PERCENT TRUCK AND CRASH RATE RELATIONSHIP STUDY

Crashes usually occur as a result of human, environmental factors such as weather and road conditions and roadway factors such as roadway geometry. The severity of crashes depends on the type of vehicle involved. Truck crashes tend to have more severe impact than passenger car crashes due to their different physical and operational characteristics. According to Peeta et al., passenger car drivers operate differently in the presence of large trucks than they do in the presence of other cars. They stated that passenger cars tend to change lanes frequently in order to avoid being in the presence of large trucks, thereby resulting in crashes (Peeta, Zhang, \& Zhou 2004).

This chapter looks at modeling of the relationship between percent trucks and crash rates in both Wyoming and Nebraska. To establish the relation between percent trucks and crash rates, two analyses were looked at: general statistics and statistical regression model analyses. The general statistics looked at the scatter plot relationship between crash rate and percent trucks. The statistical regression analysis examined both the yearly and monthly models. The yearly model looked at the combined interactive effect of the percent trucks on crash rates in both states. The monthly model incorporated the environmental conditions to examine the effect of percent trucks on crash rates.

### 6.1 Methodology

A scatter plot between the calculated crash rates and percent trucks values for each state were used for the general statistics. The multiple linear regression models were used for the statistical analysis. The parameters used for the analysis included percent trucks, log crash rates, weather, road, light, and winter conditions for the 10 -year study period. The dependent variable is the log crash rate and the predictor variables are the percent trucks, winter, weather, road, and light conditions. The log crash rate was used for the regression analysis to meet model assumptions. Two datasets were used for this research: yearly and monthly models.

The parameters for the yearly model included the crash year, log crash rate, percent truck and accident locations (sections). The Interstate was divided into 108 sections in Wyoming and 80 sections in Nebraska for reporting the Annual Average daily Traffic (AADT). Each section also corresponds to the accident location, percent trucks and crash rate. The locations (sections) were included in the model because the crash rates differ along the entire corridor. Yearly crash rates were calculated for both all vehicles and trucks only. The yearly model determines if there is a relationship between percent trucks, crash rate, and year. The yearly model was analyzed by combining data for both states.

The monthly model used monthly crash rates instead of the yearly crash rates. The weather, road, light, and winter condition variables were included in the monthly model. The monthly model examines the relationship between percent trucks, crash rates, weather, winter, road and light conditions in both states.

### 6.2 General Statistics

The VMT data, together with the crash data, were used to calculate the crash rate for each section on the Interstate in both states for all vehicles and truck only crashes for the 10-year study period. Data used for the general statistics were grouped into yearly for both Wyoming and Nebraska. A scatter plot of the crash rates and percent trucks were plotted to examine the relationship. Figure 6.1 shows the plot of percent trucks and crash rates for all vehicles in Wyoming.

Figure 6.1 Percent Truck and Crash Rates for All Vehicles for All Years in Wyoming
The graph shows no correlation between percent truck and crash rates for all vehicles, since the coefficient of determination $\left(\mathrm{R}^{2}\right)$ is almost zero. It could be seen that most of the data are concentrated between the $40 \%$ and $60 \%$ trucks and between $0-8$ crashes per million VMT, with several outliers. This graph shows that the data do not fit the model well because of the large presence of outliers and large amounts of variations within the data. The crash rates ranges from zero to 24 crashes per million VMT. Figure 6.2 shows the plot of percent trucks and the crash rates for trucks only for all years in Wyoming. This graph shows similarities with Figure 6.1 above except that all vehicle crash rates are slightly higher than that of the trucks only crash rates. This graph shows that most of the percent trucks range between $40 \%$ and $60 \%$, with exceptions being the $25^{\text {th }}$ percent and $75^{\text {th }}$ percent. The crash rates ranges from zero to about 20 crashes per million TVMT. Most of the crash rate data lie within zero and six crashes per million TVMT.

Figure 6.2 Percent Truck and Crash Rates for Truck Only for All Years in Wyoming
This graph gives little to no indication of a relationship between percent truck and crash rates, because of the presence of several outliers and the low coefficient of determination $\left(\mathrm{R}^{2}\right)$ value. Figure 6.3 shows the plot of percent truck and crash rates for all vehicles in Nebraska for all years. From the graph, it is evident that the data points of the percent truck are well distributed from the $5 \%$ to the $65 \%$ trucks. The crash rates ranges from zero to four crashes per million VMT with the higher crash rates within the range of zero and two crashes per million VMT. The coefficient of determination $\left(\mathrm{R}^{2}\right)$ is 0.16 , which accounts for $16 \%$ of the variation that percent trucks have on crash rates. Several outliers can be seen in the plot with the extreme one occurring at the 3.5 crashes per million VMT.

Figure 6.3 Percent Truck and Crash Rates for All Vehicles for All Years in Nebraska

Figure 6.4 shows the plot of percent truck and crash rates for truck only for all years in Nebraska. The percent trucks data shows a good distribution ranging from about 5\% to $65 \%$ for all years. The crash rates ranges from below zero to about eight crashes per million TVMT, with most data concentrated between zero and three. Presence of outliers could be seen from four to eight crashes per million TVMT. The R -square value ( 0.15 ), accounts for $15 \%$ of the variations that percent trucks have on the crash rates.

Figure 6.4 Percent Truck and Crash Rates for Truck Only for All Years in Nebraska

### 6.3 Statistical Regression Analysis

The data were assembled in Microsoft Excel and modeled using SAS Statistical Software Version 9.2. The Multiple Linear Regression was used for the analysis of both the yearly and monthly models in both Wyoming and Nebraska. The GLM procedure was used for the analysis, which uses the least squares to estimate parameters in the multiple linear regression models. It also handles models relating one or several continuous or categorical dependent variables. This analysis seeks to establish a relationship between the log crash rate dependent variable and predictor variables such as percent trucks, year, and locations, etc. for the yearly model. Equation 6.1 shows the general form of the multiple linear regression model used for this analysis.

$$
\operatorname{Ln}\{Y i\}=\beta o+\beta_{1} X_{1}+\beta_{2} X_{2}+\cdots+\beta p X p+\varepsilon i
$$

Equation 6.1 Multiple Linear Regression Model
where:
$\mathrm{Y} i$ is the dependent variable ( $\log$ crash rate);
$\beta_{1}, \ldots, \beta_{p}$ are the regression coefficients;
$\mathrm{X}_{1} \ldots, \mathrm{X}_{\mathrm{p}}$ represents the predictor variables in the model;
$\mathcal{E} i$ - Error term N $\left(0, \sigma^{2}\right)$.

The assumptions for the model are normality, equal variance, and independence. Two datasets were performed with the GLM procedure; the yearly and monthly models. The yearly data model included variables such as log crash rate, percent trucks, location, year, and state. The crash rate was transformed using the natural logarithm to meet the model assumptions. The $\log$ crash rate is the response variable, and the categorical factors are state, location, and year. The percent truck variable is a continuous covariate. The monthly data model has the same variables as the yearly model but has also included the environmental factors such as road, weather, light, and winter conditions.

The parameters with p-value less than 0.05 are deemed to be significant to the model and pvalues greater than the 0.05 cutoff are not significant. For a good model fitting, a large Rsquare value is needed, and a small R-square value means the model does not have a good fitting. The R-square value ranges from zero to one, with values closer to one indicating a good model fit. The R-Square measures how well the regression line approximates the real data points.

### 6.4 Combined Yearly Data Model

The yearly data from both states were merged in Microsoft Excel and the merged data imported into SAS for modeling. The input variables for the modeling were log crash rate (response variable) percent trucks (continuous covariate); this is the continuous predictor variable that controls the model. The year, location, and state are the categorical factors; these factors show a finite number of levels. Binary values were assigned to the state variable, with Wyoming assigned a value of 0 and Nebraska a value of 1 . The model was run for log crash rates for all vehicles and trucks only. Location and year were used as classification variables giving a total of 1,880 observations. The presence of outliers was evident in the residual plot. However, this did not change the results even after the removal of some of the outliers from the model. The SAS output for the combined yearly data model can be found in Appendix B.

Table 6.1 shows results for the combined model for all vehicles. The initial interaction model was significant with an R-Square value of 0.8392 , which accounts for $83.92 \%$ ( $\mathrm{p}<0.0001$ ) of variations that the effect of percent trucks have on crash rates. The interaction between PTrucks and year in the initial model was removed since the p-value ( 0.2788 ) was greater than the cutoff of 0.05 levels. The model was re-run until all the p-values were less than 0.05 levels. The final model showed significance $(\mathrm{p}=0.0002)$ for the interaction between PTrucks and location (state), which means that the effect of percent trucks on the response log crash rate changes at different locations in both states. The state and year interaction also showed significance ( $\mathrm{p}<0.0001$ ), which indicates that the effect on the estimated $\log$ crash rate differs between the two states and varies from year to year. The final model has an R-Square value of 0.8380 , which accounts for $83.8 \%(\mathrm{p}<0.0001)$ of the variations that percent trucks have on crash rate.

Table 6.1 Results for Initial and Final Model for All Vehicles

| Predictor Variable | Initial Model |  | Final Model |  |
| :--- | :--- | :--- | :--- | :--- |
|  | Type I <br> P-value | Type III <br> P-value | Type I <br> P-value | Type III <br> P-value |
| PTrucks | $<.0001$ | 0.1394 | $<.0001$ | 0.1818 |
| State | $<.0001$ | 0.0012 | $<.0001$ | 0.0013 |
| Location (State) | $<.0001$ | $<.0001$ | $<.0001$ | $<.0001$ |
| Year | $<.0001$ | 0.5849 | $<.0001$ | $<.0001$ |
| PTrucks*Location(State) | $<.0001$ | 0.0003 | $<.0001$ | 0.0002 |
| PTrucks*Year | 0.0009 | 0.2788 | - | - |
| State*Year | $<.0001$ | $<.0001$ | $<.0001$ | $<.0001$ |

Results for the initial and final model for the trucks only are shown in Table 6.2. The RSquare value for the initial interaction model is 0.5867 , which accounts for $58.67 \%$ ( $\mathrm{p}<0.0001$ ) of the variation that percent trucks have on crash rate. The final model has an RSquare value of 0.5233 which means that $52.33 \%$ ( $\mathrm{p}<0.0001$ ) of the total variation accounts for a relationship between percent trucks and crash rate. Results from the initial model indicate that the interaction between PTrucks and year has the largest p-value (0.1802) greater than the 0.05 significant levels. This interaction variable was first removed and the model rerun. The final model indicates that the interaction between state and year showed significance ( $\mathrm{p}<0.0001$ ), which means that the effect on the response log crash rate changes from year to year and differs between the two states.

Table 6.2 Results for Initial and Final Model for Trucks Only

| Predictor Variable | Initial Model |  | Final Model |  |
| :--- | :--- | :--- | :--- | :--- |
|  | Type I <br> P-value | Type III <br> P-value | Type I <br> P-value | Type III <br> P-value |
|  | $<.0001$ | 0.0367 | -.0001 | 0.0376 |
| State | $<.0001$ | 0.1834 | $<.0001$ | $<.0001$ |
| Location(State) | $<.0001$ | 0.0412 | $<.0001$ | $<.0001$ |
| Year | $<.0001$ | 0.5017 | $<.0001$ | $<.0001$ |
| PTrucks*Year | $<.0001$ | 0.1802 | - | - |
| PTrucks*Location(State) | 0.0839 | 0.1001 | - | - |
| State*Year | 0.0727 | 0.0727 | $<.0001$ | $<.0001$ |

### 6.4.1 Yearly Regression Model Result Discussion

The all vehicles model showed a higher R-Square value ( 0.838 ), which accounts for about $84 \%$ ( $\mathrm{p}<0.0001$ ) of the variations in percent truck to crash rates. This means that the model fits the data well since the value is closer to one. Results for the interaction between PTrucks and location (state) showed that the effect of PTrucks on the response log crash rate changes at different locations. The state and year interaction also indicate that the effect on the log crash rate differs between the two states and varies from year to year.

The R-Square value for truck model falls within the range of $52.33 \%$ and $58.67 \%$, which accounts for the variation that percent trucks have on crash rate. The interaction between state
and year showed significance, which indicates that the effect on the log crash rate changes from year to year and differs from state to state. This means that the effect on log crash rate in Wyoming will be different from that of Nebraska from year to year.

### 6.5 Monthly Data Regression Model

The variables used for the model included log crash rate, percent trucks, and environmental factors such as light, road, winter, and weather conditions. The environmental factors showed conditions when an accident occurred on a particular day. The worst (non-ideal) conditions under each environmental factor was used for the modeling, with the worst conditions for the light and road variables being dark and wet conditions, respectively. The worst weather condition used was snow condition. The actual values of these worst (non-ideal) conditions were used. The months of October through March were termed as winter months and a value of 1 was assigned; and the months from April through September were termed as non-winter months (summer) and a value of 0 was assigned. These environmental factors were merged with the $\log$ crash rate, year, and percent truck to run the monthly model. The states of Wyoming and Nebraska were assigned a value of 0 and 1 , respectively. When preliminary analyses were performed, it became evident that both states could not be combined for analysis due to the differences that exist in the environmental conditions in both states. Another reason for this is the difference between the monthly and yearly effects on the log crash rate. The results for the monthly model can be found in Appendix C.

### 6.5.1 Monthly Data Model - Wyoming

The all vehicles model for Wyoming included data such as the log crash rate, percent trucks, road, light, and winter for 2008. A graph of the log crash rate and year variable was plotted, and the results show that apart from 2008, which had the highest crash rate, the rest of the years had approximately the same crash rate levels. Due to that, 2008 was isolated from the crash years and used to represent the yearly variable. The road and light variables are continuous regressors, which means actual values were used. Winter variables have binary values, with the non-winter period assigned a value of 0 and otherwise a value of 1 . Although few outliers were found to be present in the model, further checks reveal that the overall result will not be affected. For the truck model, the variables used were "lyear," winter, road, April, PTrucks, and log crash rate. These "lyear" and April variables explain the yearly and monthly effects on $\log$ crash rates. The "lyear" represents low crash rate years (2005 and 2009), which were assigned a value of 1 and otherwise a value of 0 . The April variable represented the weather variables, because of their high crash rates.

Table 6.3 shows the results for the monthly all vehicles model in Wyoming. The initial model included all the parameters and their interactions with percent trucks. The p-values greater than the 0.05 significance levels were removed starting with the largest value and the model re-run until all the p -values were less than 0.05 level. The initial model has an R-Square value of 0.8493 , which accounts for $84.93 \%$ ( $\mathrm{p}<0.0001$ ) of the variation that percent trucks have on the $\log$ crash rate. The winter and PTrucks interaction was first removed and the model re-run because of its large p-value ( 0.9504 ). The next predictor variable to be removed from the
model was the year08 and PTrucks interaction. Filtering continues until all p-values greater than 0.05 were removed. The final model shows all the predictor variables with p -values less than the 0.05 cutoff. The final model has an R-Square value ( 0.8486 ), which indicates that the model accounts for $84.86 \%$ ( $\mathrm{p}<0.0001$ ) of the variation that percent trucks have on the log crash rate. The positive estimate ( 0.0162 ) of the road and PTrucks interaction shows that the effect of PTrucks on the response $\log$ crash rate changes with the road conditions. This means that there is a likelihood of the log crash rate increasing during wet road conditions.

Table 6.3 Results for Initial and Final Models for All Vehicles in Wyoming

| Predictor Variable |  | Initial Model |  | Final Model |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
|  |  | P-value | Estimate | P-value |  |
| Intercept | -0.90052 | 0.0671 | -0.62181 | 0.0033 |  |
| road | 0.718541 | 0.2212 | 0.683162 | 0.009 |  |
| year08 | 1.01217 | 0.2688 | 1.263385 | $<.0001$ |  |
| light | -0.10488 | 0.9265 | -0.8461 | 0.0051 |  |
| winter | 0.200265 | 0.5038 | 0.177913 | 0.0265 |  |
| PTrucks | -0.01308 | 0.1822 | -0.0185 | 0.0001 |  |
| winter*PTrucks | -0.0003 | 0.9504 | - | - |  |
| road*PTrucks | 0.015135 | 0.1578 | 0.01622 | 0.0003 |  |
| light*PTrucks | -0.0138 | 0.4988 | - | - |  |
| year08*PTrucks | 0.003149 | 0.7654 | - | - |  |

Results for the trucks only model can be found in Table 6.4. The initial model has an RSquare value of 0.6486 , which accounts for $64.86 \%$ ( $p<0.0001$ ) of the variation that percent trucks have on the log crash rate. The "lyear" and PTrucks interaction was first removed and the model re-run because of its large p-value ( 0.511 ) in the model. Filtering continues until all the p-values for the predictor variables are less than the 0.05 significant levels. Results from the final model has an R-Square value ( 0.6373 ) which accounts for $63.73 \%$ ( $p<0.0001$ ) of the variation that percent trucks have on crash rate. The positive estimate (1.1379) for the road and PTrucks interaction indicates that the effect of PTrucks on the response log crash rate changes with the road conditions. This means that an increase in percent trucks will result in an increase in the estimated log crash rate during wet road condition. The positive estimate for the winter and PTrucks interaction shows that the effect of PTrucks on the response log crash rate changes with the winter conditions. This means that increasing PTrucks increases the estimated log crash rate during the winter season from October to March and decreases during non-winter months from April to September.

### 6.5.2 Monthly Data Model - Nebraska

The Nebraska all vehicles model includes parameters such as the log crash rate, percent trucks, road, light, winter (April), "hyear" (high crash years), "myear" (median crash years), and "lyear" (low crash years). A graph of crash rates and years was plotted which showed a cubic curve with years 2000-2002 having high crash years (hyear); years 2003-2005 represent the median crash years (myear) and years 2006-2009 represent the lowest crash years (lyear). These variables were included in the model to explain the yearly effects that have continuous covariates.

The truck model variables are "cmonth," "hyear," "lyear2," weather, road, PTrucks, and log crash rate. The "cmonth" variable represented the cold months from December to February when crashes occur. A value of 1 was assigned for the "cmonth" and a value of zero assigned for all other months. The "hyear" variable stands for high crash years (2000, 2008, and 2009) and "lyear2" represents the low crash years (2002, 2004, and 2005). A value of one was assigned for the high and low crash years (2000, 2002, 2004, 2005, 2008, 2009), and a value of zero for the other years. These variables explain the year and month effects on log crash rates in Nebraska.

Results for the monthly all vehicles model are shown in Table 6.5. Results from the initial model showed that the PTrucks and "hyear" interaction have the largest p-value (0.7842), and thus was first removed from the model and the model re-run. Filtering continues until all pvalues greater than 0.05 levels are removed from the model. The R-Square value for the initial model is 0.6571 , which accounts for about $66 \%$ of the variation that percent trucks have on $\log$ crash rates. The final model reveals that no interaction predictor variables remain in the model. The R-Square value for the final model was 0.6517 , which accounts for about $65 \%$ of the variation that percent trucks have on the log crash rates. The positive estimate $(0.00795)$ for the PTrucks predictor variable indicates that a $1 \%$ increase in PTrucks causes an increase in the estimated $\log$ crash rates by $2.2 \%$.

Table 6.5 Results for Initial and Final Models for All Vehicles in Nebraska

| Predictor Variable | Initial Model |  | Final Model |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Estimate | P-value | Estimate | P-value |
| Intercept | -0.80217 | 0.0196 | -1.01557 | $<.0001$ |
| PTrucks | -0.00386 | 0.8066 | 0.00795 | $<.0001$ |
| road | 0.8649 | 0.0528 | 1.17524 | 0.0002 |
| hyear | 0.39769 | 0.0009 | 0.37649 | $<.0001$ |
| myear | 0.24973 | 0.0464 | 0.17991 | 0.006 |
| april | -0.11591 | 0.4659 | -0.2118 | 0.0122 |
| PTrucks*road | 0.01750 | 0.3745 | - | - |
| PTrucks*hyear | -0.00142 | 0.7842 | - | - |
| PTrucks*myear | -0.00352 | 0.566 | - | - |
| PTrucks*april | -0.00433 | 0.5339 | - | - |

Table 6.6 shows results for the truck only model. Results for the initial model showed an RSquare value ( 0.8262 ), which accounts for $82.62 \%$ ( $p<0.0001$ ) of the variation that percent trucks have on log crash rates. The interaction between road and PTrucks with the largest pvalue ( 0.9220 ) is first removed and the model re-run. Filtering continues until all the p-values are less than 0.05 significant levels. The final model shows predictor variables with p-values less than the cutoff of 0.05 . The final model has an R-Square value ( 0.8188 ), which accounts for $81.88 \%$ ( $\mathrm{p}<0.0001$ ) of the variation that percent trucks have on log crash rates. The positive estimate for the interaction between PTrucks and "lyear2" (low years) indicates that the effect of PTrucks on the response log crash rate changes from 2002 to 2005. The weather and "cmonth" interaction indicates that the effect on the response log crash rate changes with the weather conditions and differs during the cold months from December to February. The positive estimate ( 0.0104 ) for the "lyear2" and weather interaction indicates that the effect on the response log crash rate changes with the weather conditions and differs with low crash years from 2002 to 2005.

### 6.5.3 Monthly Model Result Discussion

The results for the monthly all vehicle models in Wyoming show an R-Square value, which accounts for about $84 \%$ of variations that percent trucks have on log crash rates. The positive estimate ( 0.01622 ) of the road and PTrucks interaction indicates that the effect of PTrucks on the response $\log$ crash rate changes with the road conditions. This means that increasing PTrucks causes an increase in the log crash rate during wet road condition. The R-Square value accounts for about $63.73 \%$ ( $\mathrm{p}<0.0001$ ) in the truck only model, which indicates the variations that percent trucks have on log crash rates. The PTrucks and road interaction variable shows a positive estimate (1.13795), which indicates that the effect of PTrucks on the response $\log$ crash rate changes with the road conditions. This means that increasing PTrucks causes an increase in the log crash rate during wet road conditions. The PTrucks and winter interaction indicate that the effect of PTrucks on the response log crash rate changes with the winter conditions.

The monthly all vehicles model in Nebraska showed an R-Square value (0.65) which accounts for $65 \%$ of the variation that percent trucks have on $\log$ crash rates. The positive estimate ( 0.0079 ) for the PTrucks indicates that a $1 \%$ increase in PTrucks causes an increase in the estimated crash rate by $2.2 \%$. The positive estimates of the road and year predictor variable indicates that the effect on the log crash rates change from year 2003 to year 2009 during wet road condition.

The R-Square value for the truck only model in Nebraska accounts for about $82 \%$ ( $\mathrm{p}<0.0001$ ) of variations that percent trucks have on log crash rates. The positive estimate $(0.0256)$ for the interaction between PTrucks and "lyear2" (low years) indicates that the effect of PTrucks on the response $\log$ crash rate changes from year 2002 to year 2005. The weather and "cmonth" interaction indicates that the effect on the response log crash rate changes with the weather conditions and differs during the cold months from December to February. The positive estimate $(0.0104)$ for the "lyear2" and weather interaction indicates that the effect on the response $\log$ crash rate changes with the weather conditions and differs with low crash years from 2002 to 2005.

## 7. CONCLUSIONS AND RECOMMENDATIONS

This section will summarize the results from the analysis of truck volume and crash rates, the economic impact of crashes, and the percent trucks and crash rates relationship study on Interstate 80 in the states of Wyoming and Nebraska. Recommendations for future studies of this research area will be presented.

### 7.1 CONCLUSIONS

### 7.1.1 Truck Volume and Crash Rate Analysis

The truck volume results indicate that truck traffic on I-80 section in Nebraska increased by $50 \%$ more than in Wyoming. This phenomenon could be explained by the fact that most freight traffic might use other routes such as Interstate 70 (I-70) and I-76 to link I-80 in Nebraska instead of traveling through Wyoming. The changing truck traffic from year to year in both states is confirmed by the interaction between state and year of the combined yearly model, which means that the effect of PTrucks on the log crash rate changes from year to year and differs between the two states. High truck volumes in Nebraska resulted in low percent trucks, which contributed to lower crash rates for both trucks and all vehicles. Low truck volumes resulted in high percent trucks and higher crash rates for both all vehicles and trucks only in Wyoming. This result is confirmed by the positive estimate of the PTrucks predictor variable in the monthly model, which means that the effect of increasing PTrucks results in an increase of the log crash rate.

### 7.1.2 Economic Impact of Crashes

The economic cost associated with the overall crash severity in Wyoming in terms of fatalities, injury, and property damage cost about $\$ 1.8$ billion, $\$ 108$ million, and $\$ 57$ million, respectively for the 10 -year study period. The fatal truck crashes accounted for about $19 \%$ in overall economic loss in the state of Wyoming. The economic cost of all accidents in the state of Nebraska during the 10 -year study period amounted to $\$ 1.1$ billion, $\$ 269$ million, and $\$ 89$ million in terms of fatalities, injury, and property damage, respectively. Fatal truck crashes contributed about $29 \%$ of the overall economic loss.

### 7.1.3 Environmental Conditions

Accidents are caused by many factors, including environmental factors such as light, road, winter, and weather conditions. Most of the accidents/crashes occur during daylight conditions than during dark conditions in both Nebraska and Wyoming. The probable reason could be that drivers tend to drive with caution to avoid potential hazards during dark conditions Snowy ("wet") road conditions contributed to most of the accidents in both Wyoming and Nebraska compared with dry road conditions. This result is confirmed by the monthly model analysis for both Wyoming and Nebraska, which indicates that the effect of PTrucks on the log crash rate increases during "wet" road conditions. Wyoming experienced more truck crashes during winter than Nebraska. This result is confirmed by the monthly
trucks only model for Wyoming. The positive estimate of the PTrucks and winter interaction indicates that the likelihood of truck crash rate increases with an increase in PTrucks during the winter months from October through March.

### 7.1.4 Percent Truck and Crash Rate Relationship Study

The high R-square value for the yearly all vehicle model indicates that the model fits the data well. The positive estimate of the interaction between PTrucks and location (state) indicates that the effect of PTrucks on the log crash rate changes at different locations in each state. This means that crash rates increase with an increasing PTrucks at various locations in each state. The remaining predictor variable, the interaction between state and year, indicates that the effect on the log crash rate changes from year to year and differs from the two states. The yearly truck only model has only one interaction predictor variable that remained in the final model: state and year interaction. The positive estimate of the interaction variable indicates that the effect on the log crash rate changes from year to year and differs from state to state. This means the effect on truck crash rates differs from state to state and changes from year to year.

The result for the all vehicle monthly model for Wyoming shows a positive estimate (0.0162) for the interaction between road and PTrucks, which indicates that the effect of PTrucks on the response log crash rate changes with the road conditions; this means that increasing PTrucks causes an increase in the log crash rate increases during wet road conditions in Wyoming. The positive estimate with a value of 1.1379 for the PTrucks and road interaction for the truck only model indicates that the effect of PTrucks on the log crash rate changes with the road conditions. This means that an increase in PTrucks causes an increase in log truck crash rates during wet road conditions. The positive estimate for the PTrucks and winter interaction indicates that the effect of PTrucks on the log crash rate changes with the winter conditions. This means that there is a likelihood of truck crash rates increasing as PTrucks increase during the winter months from October through March in Wyoming.

Results from the Nebraska monthly model for all vehicles show that five predictor variables remained in the final model: PTrucks, road, April, "myear," and "hyear" condition. The positive estimate of the PTrucks indicates that an increase in PTrucks results in an increase of all vehicle crash rates. The estimate of the road condition in the model has a positive value of 1.1752, which means that the chance of all vehicle crash rates is increased when the road condition is "wet." The positive estimate of the April predictor variable denotes the winter conditions, which indicates that the chance of increasing crash rates occurs during the month of April. The positive estimates of the "hyear" and "myear," indicates that the likelihood of an all vehicle crash rate increases from 2000 to 2005.

The monthly truck only model in Nebraska has three remaining interaction predictor variables in the final model: PTrucks and "hyear," weather and "cmonth," and weather and "lyear2" interactions. The positive estimate ( 0.0257 ) of the interaction between PTrucks and "hyear" indicates that the effect of PTrucks on the log crash rate changes from 2002 to 2005. This means that an increase in PTrucks results in increasing crash rates from 2002 to 2005. The
positive value for the estimate of the interaction between weather and "cmonth" indicates that the effect on the log crash rate changes with the weather conditions and differs during the cold months from December to February. This means that during the cold months and weather conditions, the crash rate increases with an increasing PTrucks. The interaction between "lyear2" and weather conditions indicates that the effect on the log crash rate changes with the weather conditions, which differ from 2002 to 2005.

### 7.2 RECOMMENDATIONS AND FUTURE WORK

Further research should be performed using other advanced statistical models to include other variables such as road geometry. Driver surveys should be undertaken on I-80 in both Wyoming and Nebraska to collect information about driver perception on the level of service (LOS) and safety. This survey should be used to quantify the impact that high percent trucks have on the perception of safety of drivers of other vehicles within the traffic stream.

Extensive education of the traveling public is encouraged to create awareness about the dangers of unsafe driving and its consequences. It is recommended that transportation agencies examine the possibility of providing truck-lane restriction countermeasures at high crash locations on the freeway to improve safety and reduce crashes.
