| 16. Abstract <br> This study involves the development of safety performance functions (SPFs) for urban and suburban trunkline segments in the state of Michigan. Extensive databases were developed through the integration of traffic crash information, traffic volumes, and roadway geometry information. After these data were assembled, an exploratory analysis of the data was conducted to identify general crash trends. This included an assessment of the base models provided in the Highway Safety Manual (HSM), as well as a calibration exercise, which demonstrated significant variability in terms of the goodness-of-fit of the HSM models across various site types. Michigan-specific SPFs were estimated, including simple statewide models that consider only annual average daily traffic (AADT), as well as regionalized models which take into account regional differences in traffic patterns and roadway geometry. More detailed models were also developed, which considered additional geometric factors such as lane width, right and left shoulder widths, median width, driveway density, on-street parking driveway density by land use, school count, posted speed limit, and intersection and crossover density. Crash modification factors (CMFs) were also estimated, which can be used to adjust the SPFs to account for differences related to these factors. Separate SPFs were estimated for two-way arterials and oneway arterials. Additionally, severity distribution functions (SDFs) were estimated, which can be used to predict the proportion of injury crashes experienced. The SDFs may include various geometric, operation, and traffic variables that will allow the estimated proportion to be specific to an individual segment. Ultimately, the results of this study provide MDOT with a number of methodological tools that will allow for proactive safety planning activities, including network screening and identification of high-risk sites. These tools have been calibrated such that they can be applied at either the statewide level or within any of MDOT's seven geographic regions, providing additional flexibility to accommodate unique differences across the state. The report also documents procedures for maintaining and calibrating these SPFs over time, allowing for a consideration of general trends that are not directly reflected by the predictor variables. |  |  |

## ACKNOWLEDGEMENTS

The research team would like to acknowledge the Michigan Department of Transportation (MDOT) for sponsoring this research and the Federal Highway Administration for State Planning and Research (SPR) funds used for this project. The authors also acknowledge the contributions of the members of the Research Advisory Panel (RAP).

## DISCLAIMER

This publication is disseminated in the interest of information exchange. The Michigan Department of Transportation (hereinafter referred to as MDOT) expressly disclaims any liability, of any kind, or for any reason, that might otherwise arise out of any use of this publication or the information or data provided in the publication. MDOT further disclaims any responsibility for typographical errors or accuracy of the information provided or contained within this information. MDOT makes no warranties or representations whatsoever regarding the quality, content, completeness, suitability, adequacy, sequence, accuracy or timeliness of the information and data provided, or that the contents represent standards, specifications, or regulations.

## EXECUTIVE SUMMARY

## Problem Statement

Federal legislation requires all states to have in place a Highway Safety Improvement Program (HSIP) that is data-driven and allows for proactive policies and programs aimed at improving highway safety by reducing the frequency and severity of traffic crashes. Given the prevailing focus on implementing roadway safety practices that are data-driven, there has been much research focused on gaining a more thorough understanding of how various factors affect the frequency, type, and severity of traffic crashes on specific roadway segments. Gaining a better understanding of these complex relationships provides traffic safety professionals with the ability to develop wellinformed, targeted policies and programs to reduce traffic crashes and the resultant injuries and fatalities.

An important tool in this process is the American Association of State Highway and Transportation Officials' (AASHTO) Highway Safety Manual (HSM). Part C of the HSM provides a series of predictive models that can be utilized to estimate the frequency of traffic crashes on specific road facilities as a function of traffic volume, roadway geometry, type of traffic control, and other factors. These models, referred to as safety performance functions (SPFs), are useful for estimating the safety impacts of site-specific design alternatives or for prioritizing candidate locations for safety improvements on a network basis. As a part of this process, these SPFs can also be integrated with decision support tools, such as Safety Analyst and the Interactive Highway Safety Design Model (IHSDM).

While the SPFs presented in the HSM provide a useful tool for road agencies, it is recommended that these functions are either calibrated for local conditions or re-estimated using local data to improve their accuracy and precision. A variety of states have conducted research to this end, demonstrating that the accuracy of the SPFs from the HSM varies considerably from state to state, a result that may be reflective of differences in geography, design practices, driver behavior, crash reporting requirements, or other factors. The variation in the performance of HSM SPFs across jurisdictions motivates the need for Michigan-specific SPFs, which will allow the Michigan Department of Transportation (MDOT) to more efficiently invest available safety resources.

## Study Objectives

Ultimately, this project aimed to develop a uniform and consistent approach that can be applied to estimate the safety performance of urban trunkline segments at the aggregate (i.e., total crash), crash type, and crash severity level. The product of this research provides important guidance to allow MDOT to make informed decisions as to planning and programming decisions for safety projects. The specific study objectives addressed as a part of this project in order to meet this goal are as follows:

1. Review and summarize previous and existing efforts to generate Safety Performance Function(s) for agencies.
2. Identify sites for the following urban segment types from existing Safety Analyst output:
a. Urban Trunkline Two-Lane Undivided
b. Urban Trunkline Three-Lane Undivided
c. Urban Trunkline Four-Lane Undivided
d. Urban Trunkline Four-Lane Divided
e. Urban Trunkline Five-Lane Undivided
f. Urban Trunkline Six-Lane Divided
g. Urban Trunkline Eight-Lane Divided
h. Urban Trunkline One-Way
3. Develop SPFs for each of the urban segment types listed above.
4. Define a maintenance cycle and process for updating SPFs

## Data Collection

In order to develop a series of SPFs that will provide an accurate prediction of the safety performance of urban trunkline intersections, it was imperative to develop a robust, high-quality database, which includes traffic crash information, traffic volumes, and roadway geometry. These data were obtained from the following sources:

- Michigan State Police Statewide Crash Database;
- MDOT Sufficiency File;
- Michigan Geographic Data Library (MiGDL) All Roads File;
- MDOT Driveway File;
- WSU Curve Database;
- WSU Intersection Inventory; and
- Google Earth.

In addition to traffic volume, crash data, and a number of roadway geometric variables, crossover count and traffic control information was collected using aerial imagery.

These data were aggregated to develop a comprehensive database of segments over the five-year study period from 2008 to 2012. The final sample was comprised of the following number of locations by site type:

- 489 two-lane undivided (2U) segments;
- 236 three-lane (3T) segments;
- 373 four-lane undivided (4U) segments;
- 439 four-lane divided (4D) segments;
- 239 five-lane (5T) segments;
- 119 six-lane divided (6D) segments;
- 166 eight-lane divided (8D) segments
- 189 One-Way (OW) segments.

## Data Analysis

After the data were assembled, an exploratory analysis of the data was conducted separately for each segment type to identify general crash trends using Michigan-specific data. Subsequently, a series of analytical tools were developed, which will allow MDOT to predict the frequency of crashes at each of the eight types of segments noted above.

First, the base SPFs from the Highway Safety Manual (HSM) were applied to the Michigan data. A calibration exercise illustrated that the models, without calibration, provided inconsistent fit across site types, crash types, and severity levels. After the calibration exercise, a series of Michigan-specific SPFs were developed. These SPFs included a series of statewide simple models which consider only annual average daily traffic (AADT) estimates as well as a series of regionalized models, which account for differences in traffic, environment, and roadway geometry.

Lastly, more detailed SPFs were estimated that considered traffic volume, speed limits, functional class, as well as numerous roadway geometric variables. These detailed statistical models may be utilized to account for the effects of this wide range of factors as they provide the greatest degree of accuracy. Separate SPFs were estimated for two-way and one-way arterials, and for those where at least one of the intersecting streets was one-way, as the factors affecting traffic safety were
found to vary between these site types. The SPFs can be used to estimate the average crash frequency for stated base conditions, which are as follows:

- Tangent, straight (no horizontal curves),
- Flat (0\% grade) roadway segments,
- 12-feet lane,
- 6-feet paved shoulder,
- No illumination,
- No passing lanes,
- No rumble strips,
- No two-way left-turn lane (TWLTL),
- Up to 5 driveways/mile,
- No automated speed enforcement,
- Typical roadside hazard rating (RHR) of 3 (i.e., clear zone about 10 feet; sideslope about 1V:3H, marginally recoverable).

Crash modification factors (CMFs) are then used to adjust the SPF estimate when the attributes of the subject site are not consistent with the base conditions. Several variables were incorporated in the development of the SPFs and CMFs including AADT, MDOT region, lane width, right and left shoulder widths, median width, driveway density, on-street parking driveway density by land use; school count, posted speed limit, and intersection and crossover density. All of the models developed as a part of this project were calibrated such that they can be applied at either the statewide level or within any of MDOT's seven geographic regions.

The SPFs can be used to predict the vehicle-involved crash frequency (i.e. single- and multivehicle crashes), as well as the number of pedestrian- or bicycle-related crashes as a proportion of vehicular crashes. Similar proportion data are provided for collision types, which can be used to disaggregate multi-vehicle crashes into various categories (e.g. rear-end, head-on, angle, etc.).

In addition to the Michigan-specific SPFs and CMFs, severity distribution functions (SDFs) were also developed for predicting the proportion of injury crashes that occur across different injury severity levels. The SDFs can be used with the SPFs to estimate the expected crash frequency for each severity category. The SDFs may include various geometric, operation, and traffic variables that will allow the estimated proportion to be specific to an individual segment.

## Conclusions

Ultimately, the results of this study provide MDOT with a number of methodological tools for performing proactive safety planning activities such as network screening and identification of sites with the largest potential for safety improvement. These tools have been calibrated such that they can be applied at either the statewide level or within any of MDOT's seven geographic regions, providing additional flexibility to accommodate unique differences across the state.

In addition to these tools, this study also provides important insights into various aspects of MDOT's existing data systems. This includes the identification of various quality assurance/quality control issues, as well as the development of methods for effectively integrating available resources for safety analyses.

This report also documents the procedure for maintaining and calibrating these SPFs over time. Calibration will allow MDOT to account for yearly changes in traffic volumes and general trends in crashes over time that are not directly reflected by the predictor variables (e.g., recent declines in crashes at the statewide level). As MDOT continues to build its data system, the use of additional geographically-referenced geometric, operational, and traffic control data will allow for further refinements to these analytical tools.

### 1.0 INTRODUCTION

Recently, significant resources have been invested by transportation agencies to develop decision support tools that allow for proactive safety management. These efforts are consistent with federal requirements that State departments of transportation (DOTs) establish a Highway Safety Improvement Program (HSIP) that "emphasizes a data-driven, strategic approach to improving highway safety on all public roads that focuses on performance" [1].

The American Association of State Highway and Transportation Officials (AASHTO) Highway Safety Manual (HSM) provides a general framework that outlines methods by which DOTs and other road agencies can conduct quantitative safety analyses [2]. These analyses may include: predicting the number of traffic crashes, injuries, and fatalities expected to occur at a given location; estimating the impacts of various crash countermeasures; or evaluating the effectiveness of specific countermeasures or safety programs.

Part C of the HSM provides a series of crash prediction models that can be used to estimate the number of traffic crashes that would occur on specific road segments as a function of traffic volumes, segment length, roadway cross-sectional characteristics, and other factors. These models, which are referred to as safety performance functions (SPFs) can be integrated with various other decision support tools, such as Safety Analyst and the Interactive Highway Safety Design Model (IHSDM). It is important to note the HSM recommends these SPFs are either calibrated for local conditions or re-estimated using local data to improve their accuracy and precision [2]. A variety of states have conducted research to this end, including Colorado, Florida, Georgia, Illinois, Kansas, North Carolina, Oregon, Utah, and Virginia [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15]. Collectively, these studies have shown that the accuracy of the SPFs from the HSM vary considerably from state to state, a result that may be reflective of differences in geography, design practices, driver behavior, differences in crash reporting requirements, or other factors.

This study involved the estimation of SPFs for urban and suburban trunkline segments under the jurisdiction of the Michigan Department of Transportation (MDOT). These SPFs were developed using a robust database that combined traffic volume, roadway geometry, and other support information from a diverse set of integrated databases.

In addition to the SPFs, a spreadsheet tool was developed that automates the processes used to estimate the frequency and severity of crashes by type for each segment category. Ultimately, these resources will allow MDOT to more effectively conduct proactive safety management, including the identification of high-risk locations and the selection of cost-effective countermeasures. These resources also provide a more thorough understanding of those factors affecting safety on Michigan roadways.

### 1.1 Background

The first edition of the HSM includes separate families of SPFs for three specific facility types: (1) Rural Two-Lane, Two-Way Roads; (2) Rural Multilane Highways; and (3) Urban and Suburban Arterials. Chapters 10, 11, and 12 of the HSM provide full details of the SPFs for these respective facility types, which were developed based upon the results of empirical studies [16] [17] [18] [19] [20] [21]. Subsequent research that will be integrated into the second edition of the HSM has analyzed other facility types, which include freeways and interchanges [22], as well as six-lane and one-way urban and suburban arterials [23].

Within each facility type, separate SPFs have been developed for intersections and road segments. For both location types, these SPFs can be used to estimate the total number of crashes expected during a given time period (typically one-year) under "base" conditions. Similar to the nomenclature from the Highway Capacity Manual [24], these base conditions generally refer to roadways with standard design elements (e.g., 12-ft lane widths). The HSM SPFs have been statistically estimated such that any variation from these base conditions is then captured in the form of crash modification factors (CMFs), which provide an estimate of the expected change in crash frequency that would correspond to specific changes in these baseline conditions (e.g., decreasing lane widths from 12 ft . to 11 ft .). The "base" SPFs provided in the HSM have been generally developed using data from the Highway Safety Information System (HSIS) [16] [17] [18] [19] [20] [21]. Table 1 provides a summary of the data used to develop the SPFs for urban and suburban arterial segments, which are presented in Chapter 12 of the HSM.

Table 1 shows that separate models have been developed for five different types of road segments:

- Two-lane undivided arterials (2U)
- Three-lane arterials including a center two-way left-turn lane (TWLTL) (3T)
- Four-lane undivided arterials (4U)
- Four-lane divided arterials (i.e., including a raised or depressed median) (4D)
- Five-lane arterials including a center TWLTL (5T)

Table 1. Data Used in the Development and Validation of SPFs for Urban and Suburban Arterial Segments in the Highway Safety Manual [20] [21]

| Site Type | No. of Sites | State | Site Type | No. of Sites | State |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 2U | 577 | MN | 4D | 140 | MI |
| 3 T | 380 | MN | 5 T | 549 | MI |
| 4U | 741 | MN | 2U | 286 | WA |
| 4D | 540 | MN | 3 T | 47 | WA |
| 5 T | 198 | MN | 4U | 106 | WA |
| 2 U | 590 | MI | 4D | 54 | WA |
| 3 T | 100 | MI | 5 T | 371 | WA |
| 4U | 440 | MI |  |  |  |

Note: (2U) two-lane undivided roads; (3T) three-lane roads w/TWLTL; (4U) fourlane undivided roads; (4D) four-lane divided roads; (5T) five-lane roads w/TWLTL

It should be noted that these models were all developed and validated using data from three states. Given differences in drivers, roadways, and environmental conditions, it is unclear how well these SPFs would predict safety performance for urban trunkline road segments throughout Michigan, though some of the segments were located in Oakland County. Since the publication of the HSM, recent studies have involved the analysis of local data from more than ten states [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15]. Collectively, these studies have indicated that direct application of the SPFs from the HSM does not tend to provide accurate results without either careful calibration or re-estimation using local data. These findings suggest that SPFs should be developed that are unique to Michigan's urban trunkline road segments.

In addition to providing tools to predict the total number of crashes on a given road segment, the HSM also presents methods to obtain estimates of crashes by type and injury severity level. The ability to provide estimates at this disaggregate level is important for several reasons. First, specific safety treatments often have differential effects on crashes by type or severity. For example, the installation of a cable median barrier may decrease the frequency of severe injury crashes, while increasing property-damage-only (PDO) crashes. If reliable estimates are available at the crash type level, road agencies will be able to more precisely estimate potential cost savings that coincide with implementation of a specific treatment. The provision of crash estimates by severity level is similarly important since safety treatments are generally given higher priority at those locations that are more prone to severe crashes.

While several methodological approaches could conceivably be utilized to provide such disaggregate level estimates, there are three distinct approaches considered in the HSM:

1. In Chapters 10 and 11, the total expected number of crashes are estimated for each location. These totals are then disaggregated based upon aggregate-level proportions provided by default collision type and crash severity distributions [24].
2. In Chapter 12, separate SPFs are provided to estimate the total expected number of crashes by aggregate crash type (e.g., single- and multi-vehicle, pedestrian, and bicycleinvolved). Separate SPFs are also provided for fatal-and-injury (FI) crashes and property-damage-only (PDO) crashes. Chapter 11 of the HSM also presents separate SPFs for FI and PDO crashes.
3. More recently, National Cooperative Highway Research Program (NCHRP) 17-45 has utilized a third approach, which involves the estimation of the total expected number of crashes for each location. In addition to this estimate, the proportions of crashes by collision type and severity level are also estimated as a function of traffic volumes and road segment characteristics using discrete outcome models. The results of this two-step process are then combined to determine the expected number of crashes at each site by type and severity.

Beyond the statistical issues involved with SPF development, it must be noted that the HSM "is written for practitioners at the state, county, metropolitan planning organization (MPO), or local level" [25]. This is important to recognize because it is imperative that a balance is struck between the accuracy of a model and its usefulness to practitioners.

### 1.2 Objectives

This research aims to develop a uniform, consistent approach that can be applied to estimate the safety performance of urban trunkline intersections at the aggregate (i.e., total crash), crash type, and crash severity levels. The study results provide important guidance to allow MDOT to make informed decisions as to planning and programming decisions for safety projects. The specific objectives of this study are as follows:

1. Review and summarize previous and existing efforts to generate Safety Performance Function(s) for agencies.
2. Identify sites for the following urban intersection types from existing Safety Analyst output:
a. Two-Lane Undivided (2U)
e. Five-Lane (5T)
b. Three-Lane (3T)
f. Six-Lane Divided (6D)
c. Four-Lane Undivided (4U)
g. Eight-Lane Divided (8D)
d. Four-Lane Divided (4D)
h. One-Way (OW)
3. Develop SPFs for each of the urban road segment types listed above.
4. Define a maintenance cycle and process for updating SPFs.

### 1.3 Report Structure

This report documents the activities involved in the development of safety performance functions (SPFs) and crash modification factors (CMFs) for Michigan urban and suburban road segments. The report is divided into six chapters. Chapter 2 provides a summary of the state-of-the-art research literature. Chapter 3 describes the data collection, including details of the data sources and activities involved in database development. Chapter 4 provides a preliminary visual analysis of the data, as well as a brief summary of the statistical methods utilized as a part of this study. Chapter 5 presents some preliminary results, which includes simple regression models using only AADT and MDOT region as predictor variables. Chapter 6 presents more detailed SPFs that
consider a variety of geometric factors. The chapter also presents a series of CMFs, as well as details of severity distribution functions (SDFs) that are used to estimate crashes by severity. Chapter 7 discusses calibration and maintenance processes for updating the SPFs over time. This chapter also provides a demonstration of how crash frequency can be estimated for a given intersection. Conclusions and directions for future research are discussed in Chapter 8.

### 2.0 LITERATURE REVIEW

Given the current emphases on data-driven strategic approaches for safety analysis, a priority area at the national level has been the identification of high-risk intersections and road segments. Site identification is a critical component of a safety improvement program, and the effective identification of sites that are candidates for improvements can be costly [26]. Historically, a variety of methods have been used to identify and prioritize candidate sites for safety treatments. These have largely included simple methods such as the ranking of sites based upon system-wide crash frequency or crash rate data. There are several drawbacks to such approaches. For example, considering only crash frequency tends to ignore sites with low traffic volumes while using crash rates tends to disproportionately prioritize very low volume sites [27]. The use of crash rates also implicitly assumes a linear relationship between crashes and traffic volume, which is not necessarily well supported by safety research [28]. However, due to minimal data requirements, these methods are still widely used by DOTs in site screening and crash hot spot identification [29] [30].

A bigger concern is that, given the random nature of crashes on a location-by-location basis, shortterm trends in crash frequency or rate are not necessarily good predictors of long-term crash frequency [29]. This concern relates largely to a phenomenon called regression-to-the-mean (RTM). In practical terms, RTM is demonstrated at roadway locations that experience particularly high short-term (e.g., one year) crash frequencies, followed by a decrease closer to the average of similar sites (i.e., regress to the mean) over the long term [30] [31]. To address such concerns, short-term site-specific crash counts can be combined with estimates from predictive regression models to develop more accurate estimates of long-term (i.e., future) safety performance. An important tool in this process is the AASHTO Highway Safety Manual (HSM) [2]. Part C of the HSM provides a series of predictive models, referred to as SPFs, which can be utilized to estimate the frequency of traffic crashes on specific road facilities as a function of traffic volume, roadway geometry, type of traffic control, and other factors.

### 2.1 Safety Performance Functions (SPFs) and Crash Modification Factors (CMFs)

SPFs establish a basis for evaluating roadway safety by considering the effects of traffic volume (AADT), roadway geometry, and other factors. For road segments, the following is a general formulation used to predict the number of crashes occurring on a given segment, $N_{s p f}$.
$N_{s p f}=\exp (a+b \times \ln (A A D T)+\ln (L))$
where:
$A A D T$ = average annual daily traffic volume (vehicles/day) on roadway segment;
$L=$ length of roadway segment (mi); and
$a, b=$ regression coefficients.

Although the HSM provides default SPF models, it is noteworthy that these models were developed using data from a few states. This makes the transferability of the SPFs a critical issue that needs to be handled by state agencies and DOTs when they attempt to implement these models. While these SPFs can be directly applied, the HSM recommends that the equations are either calibrated using local (i.e., state or regional) data or that jurisdiction-specific SPFs are developed. The calibrated model must sufficiently capture local road and traffic features [32]. Calibration of the SPFs is relatively straightforward, requiring the estimation of a calibration factor, $C$, as shown in the following equation:
$N_{\text {predicted }}=N_{\text {spf }} \times C$,
where:
$N_{\text {predicted }}=$ predicted annual average crash frequency for a specific site;
$N_{s p f}=$ predicted average crash frequency for a site with base conditions; and $C=$ calibration factor to adjust SPF for local conditions.

This calibration factor is simply equal to the ratio of the number of observed crashes within the jurisdiction to the predicted number of crashes as estimated by the SPF. While calibration generally results in improved goodness-of-fit, research has shown that the suggested sample sizes for sites (30-50) and crashes (100 per year) in the HSM do not necessarily minimize predictive error in calibration [33].

In addition to calibration for local factors, it is also important to note that the SPFs from the HSM are estimated for "base" conditions. For example, the SPF for urban and suburban roadway segments assume the following base conditions:

- Tangent, straight (no horizontal curves),
- Flat (0\% grade) roadway segments,
- 12-feet lane,
- 6-feet paved shoulder,
- No illumination,
- No passing lanes,
- No rumble strips,
- No two-way left-turn lane (TWLTL),
- Up to 5 driveways/mile,
- No automated speed enforcement,
- Typical roadside hazard rating (RHR) of 3 (i.e., clear zone about 10 feet; sideslope about 1V:3H, marginally recoverable).

At locations where base conditions are not met, the SPFs are multiplied by crash modification factors (CMFs), which adjust the SPF for non-base conditions as shown in the following equation:
$N_{\text {predicted }}=N_{s p f} \times C \times C M F_{i}$,
where:
$N_{\text {predicted }}=$ predicted annual average crash frequency for a specific site;
$N_{s p f}=$ predicted average crash frequency for a site with base conditions;
$C=$ calibration factor to adjust SPF for local conditions; and
$C M F_{i}=$ crash modification factor for condition $i$.

These CMFs allow for crash estimates at locations that do not fit the "base" conditions. For example, the HSM provides a series of CMFs in Chapter 12 specific to intersections on urban and suburban arterials. Chapter 14 provides a catalog of various intersection CMFs based on prior empirical research. In addition, the Federal Highway Administration (FHWA) maintains the CMF Clearinghouse [34], a web-based database of CMFs that provides supporting documentation to assist users in estimating the impacts of various safety countermeasures.

### 2.2 Summary of State Efforts in SPF Calibration and Development

A recent study summarized the results of a nation-wide survey that was employed to assess the current status of safety analysis procedures at state departments of transportation [35]. The results of this survey demonstrated that most states experienced data-related issues that inhibited their ability to effectively conduct safety analyses. A Florida study cited that the data requirements of the HSM were challenging as many of the factors were not available in the state's roadway characteristics inventory database [36]. Similar results were found in Pennsylvania where several variables suggested in the HSM could not be included in SPFs due to lack of available data [37]. Several other studies have also identified data availability and completeness as hurdles in meeting the input requirements of the HSM and other related tools such as Safety Analyst [36] [37] [38]. A study in Georgia found that data quality and availability significantly affected the quality and reliability of SPFs [35]. Research in Kansas noted that the scarcity of intersection data did not allow for the development of separate models for 3-leg and 4-leg stop-controlled intersections [38]. Similarly, due to the lack of details on traffic control types within the Roadway Characteristic Inventory database, the analysis of unsignalized 3-leg and 4-leg intersections was not possible [39].

Specific areas of concern included a lack of sufficient data on traffic volumes and roadway characteristics, as well as a lack of geo-referenced spatial data [35]. In most states, traffic data is generally available for higher classes of roadways (e.g., interstates, state routes, etc.), but is limited for local and low volume roads [35] [39]. Research in Colorado found that volume data for sidestreets were not generally available for more than one or two years, and in many cases the count data did not coincide with the study period [4]. Thus, it was necessary to normalize available sidestreet AADT data over the study period using growth rates derived from the mainline AADT volumes [4]. A study aiming to prepare Florida roads for deployment of Safety Analyst, upon reviewing the segment database, identified 13,000 segments which were missing volume data and were ultimately excluded from the analysis. Aside from this limitation, researchers collected volume data in different formats, including GIS, Excel, maps, and PDF. In some cases, AADT information had to be estimated through a travel demand model [39].

Table 1. Data Requirement [2]

| Data element | Data Required |  |
| :--- | :---: | :---: |
|  | Required | Desirable |
| Segment length | X |  |
| Presence of median | X |  |
| Presence of center two-way left-tumn lane | X |  |
| Average annual daily traffic (AADT) | X |  |
| Number of driveways by land-use type | X |  |
| Low-speed vs. intermediate or high speed | X |  |
| Presence of on-street parking | X |  |
| Type of on-street parking | X |  |
| Roadside fixed object density |  | X |
| Presence of lighting |  | X |
| Presence of automated speed enforcement |  | X |

Table 1 shows the data elements required and desirable for SPF calibration. Aside from traffic volume information, several studies have documented limitations due to a lack of data, including a driveway count by land type, presence and type of parking, roadside fixed object density, presence of street lighting, and presence of automated speed enforcement [40] [14] [41] [33] [42] [43]. Due to absence of such data, certain studies resorted in manually collecting information through aerial imagery and other useful tools, which required significant effort and time. Due to the amount of effort required for data collection, certain studies only collected additional information for a subset of the facilities, thus not utilizing the entire population of sites for calibration or development [43], while others chose to exclude models from their analysis [41]. Other studies chose to use crash modification factors of 1.0 or default values from data utilized to develop urban and suburban SPFs for non-available variables [14] [41].

Another issue encountered by researchers when calibrating or developing SPFs for urban and suburban arterials was crash reporting thresholds. Research in Florida found that one of the limitations for computing calibration factors for urban roadways was the crash reporting system. The Crash Analysis Reporting System (CARS) database only includes long form reports filed for crashes involving injuries and/or fatalities. Short form reports are filed for property damage only crashes and are not coded in the CARS database. As a consequence, the researchers were able to
develop calibration factors for fatal and injuries crashes, but not total crashes [14]. Similarly, in Oregon, drivers are responsible for filing a crash report if the crash results in property damage only. Aside from this, the crash reporting thresholds are higher in Oregon $(\$ 1,500)$ than the neighboring states of Washington and California (\$700 and \$750, respectively) [7]. This may cause a portion of PDO crashes not to be accounted for during calibration or development of SPFs. Underreporting of PDO crashes is also documented in a study by Shin et al. aiming to calibrate HSM SPFs for the state of Maryland [33]. A study in Riyadh, Saudi Arabia, aiming to calibrate HSM SPFs for urban 4-lane divided roads, examined only fatal and injury crashes. Non-injury crashes are collected by private agencies and are often not complete. The reporting threshold for crashes in Riyadh is $\$ 120$ [44].

Despite these limitations, Table 2 shows a significant number of recent state-level efforts aimed at either calibrating the HSM SPFs or developing state-specific SPFs using local data. The table summarizes recent studies, including details of the types of segments that were considered as a part of each study, the number of sites that were included by type, and the number of years of data that were used for model calibration of estimation.

When examining SPF calibration for local conditions, there was significant variability in terms of whether the base models from the HSM over- or under-predicted crashes within specific states.

Research in Alabama [45] developed calibration factors for two-way two-lane rural roads and 4lane divided roads based on the HSM calibration procedure, as well as utilizing a new methodology that considered the calibration factor as a part of the SPF. Both calibration factors overestimated crashes, however, and the HSM-recommended calibration method seemed to outperform the proposed new calibration method for these two types of facilities. A North Carolina study calibrated the HSM SPFs for five urban and suburban facilities and derived calibration factors ranging from 1.54 for 2-lane undivided segments to 4.04 for 4-lane undivided segments [9].

A study in Maryland [33] estimated mixed results in calibration of HSM SPFs of urban and suburban roadway segments. For total crash and fatal/injury crashes, the calibration factors showed that the HSM crash prediction models under-estimated crashes for 2-lane and 4-lane undivided segments and over predicted crashes for 3-lane and 5-lane with TWLTL segments. Also,

4-lane divided segment total crashes were underestimated while the fatal/injury crashes were overestimated. The researchers stated that the exclusion of Baltimore city may have biased the results of the study, especially during the calibration of the intersection crash prediction models.

Table 2. Summary of studies involving calibration or development of specific SPFs

| Ref. \# | State/ Country | Study Year | Site Type(s) | No. of Sites | No. of Years | $\begin{gathered} \text { Calibrated } \\ \text { HSM } \\ \text { SPFs } \end{gathered}$ | Jurisdiction Specific SPFs |

Research in Louisiana determined that HSM SPFs significantly over-predicted crashes for 2-lane and 4-lane undivided segments and 4-lane divided segments, with calibration factors of 1.91, 1.59, and 2.54 , respectively. On the contrary, crashes for 3-lane and 5-lane with TWLTL segments were
severely underestimated, showing calibration factors of 0.26 and 0.06 . Similarly, a study in Ohio underestimated crashes for all the urban segments in the HSM except 2-lane undivided segments, for which the calibration factor was 1.02 . Statewide HSM model calibration in Missouri generally showed calibration factors less than 1.0, suggesting that Missouri facilities experienced fewer crashes than the national average [42]. The magnitude of these calibration factors was attributed to differences in crash definitions between Missouri and the states used as the basis for the HSM.

A study in Oregon estimated calibration factors for all five urban roadways included in the HSM. The calibration factors for urban segments were all less than 1.0 except for 4D segments. This could be indicative of the lack of 4-lane divided segments in Oregon urban areas; only 5.87 miles of this type of roadway were identified by the research team and used in the calibration data statewide. Thus, this calibration factor likely reflects 1) the small sample size, and 2) the difference between the higher design standards of the four-lane divided facilities in the HSM SPFs data set and the segments in the Oregon calibration set. The results of the calibration could also be attributed to the crash reporting system in Oregon, which allows drivers to not report crashes that result in vehicle damage of less than $\$ 1500$.

Ultimately, it has been postulated that the differences in calibration factors are reflective of differences between individual jurisdictions and those states where the HSM models were developed [6] [9] [48] [51] [5] [11] [37] [50] [16] [18] [45].

Given the significant variability in predictive performance across regions, a number of states have developed SPFs specific to their jurisdictions. Research was conducted in Illinois [6] aiming to develop crash prediction models for crashes by severity level as well as a combination of all fatality and injury crashes. A multivariate analysis was also conducted to determine the importance of the 37 exposure variables considered in the study. Some variables had a larger impact than others, however, most were significant at a $90 \%$ confidence interval. The researchers also developed a Visual BASIC for Applications (VBA) tool to assist the department of transportation with future calibration of the newly developed SPFs as well as screening of the Illinois roadway network.

Safety performance functions were also developed as part of a study in North Carolina [9] for 16 roadway types, including urban 2-lane roads, urban multilane undivided roads, and divided roads. For 2-lane roads, the effect of volume was similar on the severity crash models.

In Pennsylvania [48], researchers developed regionalized crash prediction models to capture regional differences. SPFs were only developed for 2-lane undivided roads, 4-lane undivided roads, and 4-lane divided roads. The presence of center two-way left-turn lanes (TWLTLs) was incorporated within the SPFs for 2-lane undivided roads and 4-lane undivided roads as an indicator variable. The results showed that the degree of curvature was not statistically significant for the 4lane undivided and divided segments, while it was statistically significant with a small impact for the 2-lane undivided segments. District level SPFs were also developed when possible and overall showed an improvement in performance when compared to the HSM SPFs.

Collectively, the domestic and foreign studies have indicated that direct application of the SPFs from the HSM (or other non-local source) does not tend to provide accurate results without either careful calibration or re-estimation using local data. Consequently, the primary purpose of this study was to develop a series of SPFs and other safety tools that can be used by MDOT as a part of their continuing traffic safety efforts.

### 3.0 DATA COLLECTION

Ultimately, the accuracy of an SPF depends largely on the quality of the data from which it is developed. The development of robust SPFs requires a crash database that is comprehensive and includes information on specific crash location, collision type, severity, and other salient factors. Roadway data is also important, including the physical features within the right-of-way. Roadway geometry data that are recommended for use in safety analyses include: lane width; shoulder width and type; horizontal curve length, radius, superelevation, grade, driveway density, and indicator variables for features such as auxiliary turn lanes [2].

In 2008, the Model Minimum Uniform Crash Criteria (MMUCC) guidelines were developed through the National Highway Traffic Safety Administration (NHTSA) in collaboration with the Governor's Highway Safety Association (GHSA), FHWA, Federal Motor Carrier Safety Administration (FMCSA), State DOTs, law enforcement agencies, and other traffic safety stakeholders. The MMUCC consists of a recommended minimum set of data elements for States to include in their crash forms and databases [53]. This set includes 110 data elements, 77 of which are to be collected at the scene, 10 data elements to be derived from the collected data, and 23 data elements to be obtained after linkage to driver history, injury, and roadway inventory data.

As a part of this study, the research team developed a comprehensive checklist of important data elements to be collected for the purposes of SPF development. As a starting point, an inventory file was developed based on yearly MDOT Sufficiency files. This file included location information for the following four types of site locations while Figure 1 indicates the total number of segments for each type considered for SPF development:

- 2-lane undivided roadways (2U)
- 2-lane divided roadways (2D)
- 3-lane undivided roadways (3U)
- 3-lane undivided roadways with presence of a two-way left turn lane (3T)
- 4-lane undivided roadways (4U)
- 4-lane undivided roadways with presence of a two-way left turn lane (4T)
- 4-lane divided roadways (4D)
- 5-lane undivided roadways with presence of a two-way left turn lane (5T)
- 6-lane undivided roadways (6U)
- 6-lane undivided roadways with presence of a two-way left turn lane (6T)
- 6-lane divided roadways (6D)
- 7-lane undivided roadways with presence of a two-way left turn lane (7T)
- 8-lane undivided roadways (8U)
- 8-lane divided roadways (8D)
- 10-lane divided roadways (10D)
- One-Way roadways

Figure 1. Segment Site Types

For the purposes of SPF development, the HSM suggests a minimum sample size of 30 to 50 sites, which collectively experience a minimum of 100 total crashes per year. Several of the facility types did not have a sufficient sample size to be considered for SPF development (2D, 3U, 4T, 6U, 6T, 7T, 8U, and 10D). While the recommended number of sites were identified within most regions and site types, there are several regions where sufficient numbers of sites were not available as shown in Table 3. This was particularly true for 6D and 8D segments, which are mainly present in the Metro area.

Table 3. Sites by MDOT Region and Intersection Type

| Segment | MDOT Region |  |  |  |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Type | Superior | North | Grand | Bay | Southwest | University | Metro | Total |
| One-Way | 6 | 3 | 0 | 48 | 28 | 67 | 37 | 189 |
| 2U | 66 | 48 | 54 | 61 | 105 | 108 | 47 | 489 |
| 3T | 4 | 28 | 26 | 32 | 72 | 68 | 6 | 236 |
| 4U | 45 | 7 | 116 | 20 | 54 | 66 | 65 | 373 |
| 5T | 19 | 22 | 30 | 35 | 49 | 53 | 31 | 239 |
| 4D | 49 | 37 | 51 | 62 | 64 | 80 | 96 | 439 |
| 6D | 0 | 0 | 7 | 2 | 2 | 22 | 86 | 119 |
| 8D | 0 | 0 | 2 | 0 | 0 | 2 | 162 | 166 |

Once segments were identified within each of the seven regions and eight site types, data were collected from existing data sources that were available either publicly or through MDOT. These data sources included the following databases and files:

- Michigan State Police Statewide Crash Database;
- MDOT Sufficiency File;
- Michigan Geographic Data Library (MiGDL) All Roads File;
- MDOT Driveway File;
- Wayne State University (WSU) Curve Database;
- WSU Intersection Inventory (prepared during a previous project); and
- Google Earth.

A quality assurance/quality control (QA/QC) process was implemented to verify the data in these sources using the MDOT PR Finder (http://www.mcgi.state.mi.us/prfinder/) and Google Earth. Further details of each respective data source is provided in the following sections of this report.

### 3.1 Michigan State Police Statewide Crash Database

The Michigan State Police (MSP) crash database contains details of all reported crash records in the state of Michigan. Records in this database are maintained at the crash-, vehicle-, and personlevels. There are a total of nine separate spreadsheets included in the database as illustrated in Figure 2.

## 1 crash

2 crash location
3 unit
4 party
5 harmful event
6 drivers license
7 driver condition
8 commercial vehicle
9 record type

Figure 2. Spreadsheets of the MSP Crash Database

For the purposes of this report, only crash level data was needed from the "1 crash" and " 2 crash location" files. These sheets were linked in Microsoft Access using the "crsh_id" field, as shown in Figure 3.

Figure 3. Joining of the MSP Crash Database Sheets

After joining the two sheets together, the information relevant to the report was exported. The relevant fields are defined below.

- crsh_id- unique identifier for each crash, and was used as the basis for linking the spreadsheets
- date_val-contains the date the crash occurred, which allowed the crash to be assigned to a particular year
- fatl_crsh_ind-identifies the crash as having at least one fatality
- num_injy_a-total number of people sustaining "A level" injuries in the crash
- num_injy_b-total number of people sustaining "B level" injuries in the crash
- num_injy_c-total number of people sustaining "C level" injuries in the crash
- prop_damg_crsh_ind-identifies the crash as being property damage only (PDO)
- crsh_typ_cd-defines the crash as single-vehicle or one of nine multiple-vehicle collision types
- rdwy_area_cd-indicates where on the roadway a crash occurred, allows for differentiation between intersection-related and non-intersection-related crashes.
- ped_invl_ind-indicates that a pedestrian was involved in the crash
- bcyl_invl_ind-indicates that a bicycle was involved in the crash
- intr_id-assigns the crash to a specific segment in the Calibration file
- PR-identifies the Physical Road on which the crash occurred
- MP-identifies the mile point along a Physical Road where a crash occurred

As was previously mentioned, this analysis was focused on "crash" level data. Crashes were defined based on the most significant injury sustained by anyone involved in the incident. Additionally, non-intersection related crashes were selected for the purposes of the analysis; the selection of non-intersection crashes was made possible through a field within the crash data called "mdot_area_type_cd" by selecting the "Mid-block" option. Crashes involving bicycles or pedestrians were separated from vehicle-only crashes for the purpose of the data analysis.

### 3.2 MDOT Sufficiency File

MDOT sufficiency files were made available for the years 2004 through 2014. The sufficiency files contain 122 fields for the state maintained roads in Michigan. The data is broken into segments of varying length. These segments are identified through a SuffiD, a unique ID given to each segment. Additionally, the segments are identified through Physical Road (PR), Beginning Mile Point (BMP), and End Mile Point (EMP) coordinates. These three characteristics are used for geographically mapping the segments in ArcGIS and finding the segments through MDOT PR Finder and Google Earth.

### 3.3 Geographic Position from Michigan Geographic Data Library (MiGDL) All Roads file

In order to facilitate the use of Geographic Information System (GIS) software for this project, a GIS shapefile, allroads_miv13a.shp, was obtained from the Michigan Geographic Data Library through the Michigan Center for Geographic Information (MCGI) website. The file consists of all road segment statewide. Although the file has a total of 36 attribute fields, the following three were of particular use for this project:

- PR-Physical Road ID number
- BMP-Beginning PR mile point for linear referencing system
- EMP-Ending PR segment mile point

### 3.4 MDOT Driveway File

This file contains information about the number of driveways for each segment. Driveway density is calculated by dividing the total number of driveways by the segment length in miles. Driveway density was also separated in categories, namely, from $0-2,2-5,5-10,10-20,20-30$, and 30 and more driveways/mile. Additional information is provided, such as the number of driveways per segment by type of driveway, including residential, commercial, industrial, field, private, other, and undefined.

### 3.5 WSU Curve Database

The curve information for each segment was obtained through a database created by WSU. The information includes number of curves with radii of up to 0.5 miles, length of the curved portion of the segment, fraction of segment length that is curved, and average radii of curves up to 0.5 miles for a segment. The information was organized in cumulative categories, decreasing in order of radii, from 0.5 mile radii to 0.088 mile radii.

### 3.6 WSU Intersection Inventory

An intersection inventory was developed during a prior project performed by WSU and funded by MDOT. The project developed SPFs for four types of intersections, 3ST, 3SG, 4ST, and 4SG, namely 3-leg with stop-control on the minor road, 3-leg signalized, 4-leg with stop control on the
minor road, and 4-leg signalized intersection. The intersection inventory was developed through the utilization of the MDOT Calibration File. The intersections were represented with a PR and mile point (MP) and spatially matched to the segments. This was done to obtain the number of intersections and intersection density for each segment by type of intersection, namely, number of legs and intersection traffic control.

### 3.7 Data Review

Extensive data review was conducted to ensure that the final datasets included only urban and suburban segments categorized into their respective facilities and based upon the number of lanes and whether the two directions of roadway were separated by a painted or physical median. To begin, the rural segments were removed from the dataset. These were identified by the RURAL_URBAN field in the Sufficiency file. Next, the divided segments were separated from the undivided segments using the Direction field. Following that, the NUM_LANES field was used to separate the segments by the number of lanes. The TWLTL field was used to classify the segments that included a TWLTL for the undivided segments. The ROAD_TYPE field was used to separate out the one-way segments. When this process was completed, each segment was classified as one of the following road types: 2U, 3T, 4U, 5T, 4D, 6D, 8D, OW, and Other. The Other classification includes all the segments types with insufficient sample size (segments) for model development, namely 2D, 3U, 4T, 6U, 6T, 7T, 8U, and 10D segments. Due to their insufficient sample size as recommended by the HSM, these facilities were not considered for SPF development.

Each observation (row) of the assembled dataset represents one year of data for a specific segment; segments would have anywhere from one year to eleven years of data. For the purposes of the SPF development, the only segments considered for modeling were those with at least five years of data, selected as a sufficient number of years of data to develop robust SPFs while allowing for segments that experienced construction at the beginning or end of the total 11 year period to be included. A preliminary QA/QC process was used on the undivided facility types to ensure segments were classified appropriately. This involved a thorough QA/QC process on the 4 U and 5T facility types, which had the highest percentage of incorrectly coded segments. Every segment originally assigned a 4 U or 5 T label for which five years of data were available were examined
through the use of the Michigan PR Finder and Google Earth. Segments were categorized according to whether the segment was completely another facility type, mostly (>50\%) another facility type, approximately $50 \%$ the listed type and $50 \%$ another type, mostly ( $>50 \%$ ) the listed type, or completely the listed type. The segments that were completely or mostly of another facility type were reassigned to the appropriate facility type. Segments that were approximately half the listed type of facility were removed from the dataset. Using the historical aerial imagery in Google Earth, segments that experienced construction during any of the last five years were identified and removed from the dataset. Due to changes in the beginning and end mile points of the segments over the years, a number of segments of road were overrepresented. These were identified and only the most recent five years of observations were kept in the datasets. For each PR, any segments that overlapped were flagged in excel using a logic statement that compared the EMP of the previous segment to the BMP of the current segment. Any segments flagged in this way were manually reviewed and the newest five years of data were kept. These duplicates were typically caused by the MPs changing by 0.001 to 0.005 miles.

### 3.8 Manual Data Collection

Divided roadways in Michigan have different PR numbers for the opposing directions of travel. Due to the segmentation of the urban and suburban arterials, it was determined that the divided arterials would be analyzed directionally. This means that for each direction of travel of the divided road, there are five years of observations and data. This decision was made due to two constraints. The segmentation of some arterials did not often guarantee the same beginning and end mile point for the opposing direction of travel segments, thus hindering the linking of the two segments. Additionally, certain matching segments might not have been included in the final dataset due to lack of available data for five consecutive years or due to the presence of construction during one or more of the five years of data. Previous research recommends that due to differences in important geometric features such as grade, number of access points, or curvature, modeling for multilane divided roadways should be done by direction [50].

On certain divided roadways in the state of Michigan, vehicles are prevented from turning left at intersections. Instead, the vehicles have to travel downstream of the intersection and utilize a crossover for turning into the other direction of the roadway, and then making a right turn at the
intended intersection or driveway (J-turn). Crossovers are channelized lanes that divert traffic from one direction of the roadway to the opposite direction, and they can be uncontrolled, yield controlled, stop controlled, or signalized. As a comprehensive database to classify these crossovers did not exist, an extensive review of the divided roadway facilities was conducted. Utilizing the MDOT PR Finder to identify the segments and Google Earth to collect aerial and street view information, the mile point information of each median crossover was collected as illustrated in Figure 4 below:

Figure 4. Screenshot of MDOT PR Finder utilization in the process of identifying crossover

Additionally, crossovers were classified based on whether they diverged or merged traffic from/into the segment of interest, traffic control type, and whether the crossover merged traffic
into the opposite direction of the roadway, a driveway, or another roadway intersecting the segment of interest. Figure 5 illustrates diverging and merging crossovers:

Figure 5. Screenshot of a crossover on a 4D segment

Emergency crossovers were also recorded when they were identified; these were somewhat difficult to identify when signs were not present indicating the crossover was for use by authorized vehicles only. See Figure 6 for an example.

Figure 6. Emergency crossover example

Table 4 summarizes how the median crossover locations were classified based on the characteristics described previously.

Table 4. Classification of crossovers

| Code | Description |
| :--- | :--- |
| O0 | No traffic control, crossover merging traffic only in the opposite direction of roadway |
| O2 | No traffic control, crossover merging traffic on a driveway |
| O4 | No traffic control, crossover merging traffic into an intersecting roadway |
| Y0 | Yield control, crossover merging traffic only in the opposite direction of roadway |
| Y2 | Yield control, crossover merging traffic on a driveway |
| Y4 | Yield control, crossover merging traffic into an intersecting roadway |
| 0 | Stop control, crossover merging traffic only in the opposite direction of roadway |
| 2 | Stop control, crossover merging traffic on a driveway |
| 4 | Stop control, crossover merging traffic into an intersecting roadway |
| 1 | Traffic signal, crossover merging traffic only in the opposite direction of roadway |
| 3 | Traffic signal, crossover merging traffic on a driveway |
| 5 | Traffic signal, crossover merging traffic into an intersecting roadway |
| 9 | Diverging crossover (diverging from the segment of interest) |
| E | Emergency crossover |

Table 5 through Table 12 provide summary statistics for all relevant variables among all segment types considered in this report. Each table presents the minimum, maximum, mean value, and standard deviation for each variable of interest.

Table 5. Descriptive Statistics for Variables of Interest for 2-Lane Undivided Segments

### 4.0 PRELIMINARY ANALYSIS

After the database was assembled, a series of preliminary analyses were conducted to examine general trends across the sample of study locations. This included assessing the univariate relationships between traffic crashes and each prospective predictor variable. Correlation among predictor variables was also examined and provided insights for the subsequent estimation of the SPFs.

Figure 7 through Figure 10 provide summary plots of the crash per mile rate versus AADT for various site and crash types. These figures show that a non-linear relationship generally exists between traffic flow and the number of crashes. Crashes are shown to increase less rapidly at higher volumes, which is consistent with prior research in this area.

When examining these figures, there are several segment locations for various facility types that experienced significantly higher or lower numbers of crashes over the study period. As a part of the data collection process, careful quality assurance and quality control procedures were followed. This included a review of these potential outliers. Ultimately, all of the intersections included in the study were similar in terms of their geometric and traffic control characteristics. No sites were removed on the basis of their crash history during the study period. It is important to note that these figures represent only the effects of traffic volumes. Consequently, the effects of other important predictor variables are not reflected here. As an example, for all facilities, fewer crashes tended to be observed at locations where two or more schools were located nearby, despite the speed limit.

Figure 9. Relationship between Vehicle-Only Crashes/Mile and AADT for 4D, 6D, and 8D Segments

Figure 10. Relationship between Vehicle-Only Crashes/Mile and AADT for One-way Segments

Figure 11 through Figure 14 show the relationship between the rate of pedestrian crashes/mile and AADT, while Figure 15 through Figure 18 show the relationship between the rate of bicycle crashes/mile and AADT. For several of the facilities, more crashes involving non-motorized users occurred on roads with lower levels of AADT. This could reflect the fact that pedestrians and bicyclists prefer to ride on roads with less traffic, thus making these types of facilities more prone to experiencing non-motorized crashes.

### 4.1 Development of Safety Performance Functions

After examining these general relationships between crashes and traffic volume within each of the four site types, a series of SPFs were developed with varying degrees of complexity. These SPFs take the form of generalized linear models. As crash data are comprised of non-negative integers, traditional regression techniques (e.g., ordinary least-squares) are generally not appropriate. Given the nature of such data, the Poisson distribution has been shown to provide a better fit and has been used widely to model crash frequency data. In the Poisson model, the probability of segment $i$ experiencing $y_{i}$ crashes during a one-year period is given by:
$P\left(y_{i}\right)=\frac{\operatorname{EXP}\left(-\lambda_{i}\right) \lambda_{i}^{y_{i}}}{y_{i}!}$,
where $P\left(y_{i}\right)$ is probability of segment $i$ experiencing $y_{i}$ crashes and $\boldsymbol{\lambda}_{i}$ is the Poisson parameter for segment $i$, which is equal to the segments expected number of crashes per year, $E\left[y_{i}\right]$. Poisson models are estimated by specifying the Poisson parameter $\boldsymbol{\lambda}_{i}$ (the expected number of crashes per period) as a function of explanatory variables, the most common functional form being $\lambda_{i}=$ $\exp \left(\beta X_{i}\right)$, where $X_{i}$ is a vector of explanatory variables and $\beta$ is a vector of estimable parameters.

A limitation of this model is the underlying assumption of the Poisson distribution that the variance is equal to the mean. As such, the model cannot handle overdispersion, wherein the variance is greater than the mean. Overdispersion is common in crash data and may be caused by data clustering, unaccounted temporal correlation, model misspecification, or ultimately by the nature of the crash data, which are the product of Bernoulli trials with unequal probability of events [54]. Overdispersion is generally accommodated through the use of negative binomial models (also referred to as Poisson-gamma models).

The negative binomial model is derived by rewriting the Poisson parameter for each segment as $\lambda_{i}=\exp \left(\beta X_{i}+\varepsilon_{i}\right)$, where $\operatorname{EXP}\left(\varepsilon_{i}\right)$ is a gamma-distributed error term with a mean of one and variance $\alpha$. The addition of this term allows the variance to differ from the mean as $\operatorname{VAR}\left[y_{i}\right]=E\left[y_{i}\right]+\alpha E\left[y_{i}\right]^{2}$. The negative binomial model is preferred over the Poisson model since the latter cannot handle overdispersion and, as such, may lead to biased parameter estimates [55]. Consequently, the HSM recommends using the negative binomial model for the development of SPFs.

If the overdispersion parameter ( $\alpha$ ) is equal to zero, the negative binomial reduces to the Poisson model. Estimation of $\lambda_{i}$ can be conducted through standard maximum likelihood procedures. While alternatives, such as the Conway-Maxwell model, have the advantage of accommodating both overdispersion and underdispersion (where the variance is less than the mean) [56], the negative binomial model remains the standard in SPF development.

The overdispersion parameter from the negative binomial model is also utilized in the empirical Bayes (EB) method for evaluating the effectiveness of safety improvements as described in the HSM. The $\alpha$ parameter is used to determine the weighted adjustment factor, $w$, which is then used to estimate the expected number of crashes at a given location when combining observed crash data with the number of crashes predicted by an SPF. The formula for this weighting factor is:
$w=\frac{1}{1+\left(\alpha \times N_{s p f}\right)}$,
where:
$\alpha=$ overdispersion parameter, and
$N_{S p f}=$ predicted number of crashes by SPF.

Upon determining $w$, the expected number of crashes can then be determined as follows:
$N_{\text {expected }}=w \times N_{\text {spf }}+(1-w) \times N_{\text {observed }}$,
where:
$N_{\text {expected }}=$ expected number of crashes determined by the EB method,
$w=$ weighted adjustment factor, and
$N_{\text {observed }}=$ observed number of crashes at a site.

For further details of the EB method, refer to the HSM [2].

As a part of this study, SPFs were examined at four levels of detail:

- Uncalibrated HSM - The segment models from Chapter 12 of the HSM were applied directly using traffic volume data for the study sites.
- Calibrated HSM - The predicted number of crashes based upon the SPFs from the HSM were calibrated based upon the observed crashes at the study sites.
- Michigan-Specific Models with AADT and Regional Indicators - A series of Michigan-specific models were developed using only AADT information. A simple statewide model was estimated, as well as a similar model that included a series of binary indicator variable for each MDOT region.
- Fully Specified Michigan-Specific Models - A series of detailed models were subsequently developed in consideration of AADT, regional indicator variables, and a diverse range of geometric variables.

The uncalibrated and calibrated HSM models are discussed in Section 4.2 while the Michiganspecific SPFs are presented in Chapter 5.

### 4.2 Comparison of Uncalibrated and Calibrated HSM Models

The base SPFs from Chapter 12 of the HSM were first applied to the datasets for each of the five segment types for which the HSM SPFs exist, namely 2U, 3T, 4U, 4D, and 5T. These base models only require the AADT as an input value. While these models generally apply to base conditions
(i.e., 12 -ft lanes, 6 -feet paved shoulders, tangent and flat sections, no lighting, no two-way-left-turn-lane, etc), they were applied directly to the study datasets without adjusting for those locations where the base conditions were not present (e.g., sites with lanes narrower than 12 ft ). Separate estimates were obtained for total crashes, property damage only (PDO) crashes, and fatal/injury (FI) crashes.

After applying these models, the resulting estimates for each study location were then compared to the observed values. The ratio of the total observed crashes to the estimated crashes (from the base SPFs) for the entire sample is used to estimate a calibration factor, which provides a measure of how close the base SPFs from the HSM fit the Michigan data. The calibration factor for each of the three models (i.e., total, PDO, and FI) and each of the five site types (2U, 3T, 4U, 4D, and 5T) are presented in Table 13.

Table 13. Calibration Factors for HSM Models

|  | Segment Types | $\mathbf{2 U}$ | $\mathbf{3 T}$ | $\mathbf{4 U}$ | $\mathbf{5 T}$ | 4D |
| :--- | :--- | :---: | :---: | :---: | :---: | :---: |
| Single- | Total | 3.498 | 4.224 | 2.133 | 1.099 | 1.971 |
|  | PDO | 4.372 | 5.472 | 2.301 | 1.31 | 2.092 |
|  | Fatal-Injury | 1.302 | 1.506 | 1.059 | 0.628 | 1.396 |
| Multi- | Total | 1.529 | 1.874 | 1.943 | 1.466 | 0.579 |
|  | PDO | 1.555 | 2.061 | 2.431 | 1.530 | 0.621 |
|  | Fatal-Injury | 1.260 | 1.443 | 1.156 | 1.066 | 0.104 |

By briefly scanning the calibration factors derived from the HSM models, it is evident that the accuracy of the base SPFs from the HSM vary widely by site type, crash type, and crash severity level. It is also very clear that the parameter estimates of the Michigan specific models are noticeably different from the parameters for the HSM models. These differences are reflective of several factors, including state-specific differences (e.g., driver characteristics, road design standards, weather, etc.), as well as the fact that only AADT was considered (and not geometric or road use characteristics).

### 5.0 MICHIGAN-SPECIFIC SAFETY PERFORMANCE FUNCTIONS

Having established that the base SPFs from the HSM do not provide consistent fit across segment types, crash types, and crash severity levels, the research team developed a series of Michiganspecific SPFs. This chapter presents a number of simple models, which can be applied without any roadway geometry data. These SPFs were developed in two general forms:

- Michigan-Specific Models with AADT - A series of Michigan-specific models were developed using only annual average daily traffic (AADT) as a predictor variable.
- Michigan-Specific Models with AADT and Regional Indicators - Similar models were estimated that included AADT as well as a series of binary indicator variables for each MDOT region.

These models are considered valid only for the range of AADT values with which they were estimated. These AADT values can be found in Table 14. Minimum AADT values were rounded down to the nearest 100 while maximum AADT values were rounded up to the nearest 100 .

Table 14. Model AADT Ranges

| Facility Type | Min AADT | Max AADT |
| :--- | ---: | ---: |

### 5.1 SPFs with AADT only and SPFs with AADT and Regional Indicator Variables

This section presents the results of separate SPFs for FI crash rates, PDO crash rates, and total crash rates for each of the eight site types. Results are presented in Table 14 through Table 28. For each site type, the results are first presented for the general statewide model and followed by a model that has been calibrated at the regional level. The regionally calibrated models account
for general differences in safety performance across the seven MDOT regions. For these models, the parameter estimates are provided for AADT and each region. In each model, the Metro region serves as the baseline and indicator variables are then used to adjust the estimates to fit other regions. Graphical representation of the SPFs are provided in Figure 19 to Figure 33. These figures are also provided for both the statewide and regional SPFs.

Table 14 and Figure 19 present the SPFs for 2-lane undivided (2U) segments. For these locations, the effect of AADT on the FI crash rate is almost elastic, as shown from the AADT coefficient and the relationship between crashes/mile and AADT. The AADT effect on PDO crashes and total crashes is less pronounced, indicating that the majority of crashes are PDO crashes.

Table 15. SPF for Crashes on 2U Segments with AADT Only

| Variable | Fatal \& Injury Crashes |  |  | Property Damage Only Crashes |  |  | All Crash Severities |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Value | Std. <br> Error | statistic | Value | Std. <br> Error | statistic | Value | Std. <br> Error | statistic |
| Intercept | -9.128 | 0.477 | -19.124 | -4.199 | 0.291 | -14.439 | -4.502 | 0.272 | -16.545 |
| AADT | 0.966 | 0.052 | 18.613 | 0.601 | 0.032 | 18.665 | 0.655 | 0.030 | 21.761 |
| Inverse Dispersion Parameter | 14.280 | - |  | 2.850 | 0.022 |  | 3.190 | 0.019 |  |

Figure 19. Total Annual Crashes per Mile for 2U Segments

Table 15 and Figure 20 present the SPFs with regional indicators for 2-lane undivided segments. AADT has a higher effect on fatal and injury crash rates as compared to PDO or total crash rates. For PDO and total crash rate models, the only region indicator that is statistically significant is Grand Region, where crash rates are higher than in the Metro region. In the case of the fatal and injury crash rate model, the only statistically significant regions are Superior, North, and Southwest, all of which have lower crash rates compared to the Metro region.

Table 16. SPF for Crashes on 2U Segments with AADT and Regional Indicators

| Variable | Fatal and Injury Crashes |  |  | Property Damage Only Crashes |  |  | All Crash Severities |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Value | Std. <br> Error | statistic | Value | Std. <br> Error | tstatistic | Value | Std. <br> Error | statistic |
| Intercept | -8.016 | 0.528 | -15.177 | -3.960 | 0.324 | -12.241 | -4.145 | 0.303 | -13.697 |

Figure 20. Total Annual Crashes per Mile for 2U Segments with Regional Indicators

Table 16 and Figure 21 present the relationship of crash rate and AADT for 3-lane undivided segments with a TWLTL. For all three severity models, AADT has a pronounced effect on crash rate as observed by the coefficients for AADT within the model results. As shown in Table 17, none of the regional indicators are statistically significant. Additionally, Superior region had not experienced fatal or injury crashes on 3T segments during the study period.

Table 17. SPF for Crashes on 3T Segments with AADT Only

| Variable | Fatal \& Injury Crashes |  |  | Property Damage Only Crashes |  |  | All Crash Severities |  |  |

*Note: Metro Region Effect serves as baseline reference category

Figure 22. Total Annual Crashes per Mile for 3T Segments with Regional Indicators

Table 18 and Figure 23 depict the relationship of crash rate and AADT for 4-lane undivided segments. AADT had a stronger influence on the FI crash rate than on total or PDO crash rate.

Table 19. SPF for Crashes on 4U Segments with AADT Only

| Variable | Fatal \& Injury Crashes |  |  | Property Damage Only Crashes |  |  | All Crash Severities |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Figure 23. Total Annual Crashes per Mile for 4U Segments

Table 19 and Figure 24 show the results for the regionally calibrated model for 4-lane undivided segments. The AADT effects on crash rates follow the same trends as in all three severity models. The Bay region experienced the lowest crash rate for total crashes and PDO crashes. For the FI severity model, the Superior region had the lowest crash rate, while Grand region had the highest.

Table 20. SPF for Crashes on 4U Segments with AADT and Regional Indicators

| Variable | Fatal and Injury Crashes |  |  | Property Damage Only Crashes |  |  | All Crash Severities |  |  |

*Note: Metro Region Effect serves as baseline reference category

Figure 24. Total Annual Crashes per Mile for 4U Segments with Regional Indicators

Table 20 and Table 21 show the results for the AADT only and the AADT with regional effects models for all three crash severities for 5-lane segments with TWLTL. The AADT effects on crashes was similar for the two sets of models, having an emphasized effect on FI crashes. For total crashes, the Superior region had the lowest crash rate and the Grand region had the highest. On the other two severity models, some regional effects were not statistical significant; however, for FI crash rate models the Superior region had the lowest crash rate and the Grand region had the highest crash rate. For the PDO crash rate model, the Metro region had the lowest crash rate.

Table 21. SPF for Crashes on 5T Segments with AADT Only

Figure 25. Total Annual Crashes per Mile for 5T Segments

Table 22. SPF for Crashes on 5T Segments with AADT and Regional Indicators

*Note: Metro Region Effect serves as baseline reference category

Figure 26. Total Annual Crashes per Mile for 5T Segments with Regional Indicators

Table 22 and Table 23 describe the relationship between AADT and crash rate for different crash severities among 4-lane divided segments. The AADT effects on crash rates are similar for the AADT only and the AADT with regional calibration models. Regional effects are not
statistically significant for FI crash rate models. For the other two severity models, total crash rate and PDO crash rates are highest in Superior region and lowest in North region.

Figure 30. Total Annual Crashes per Mile for 6D Segments with Regional Indicators

Table 26 shows the AADT only model results for total, FI, and PDO crash rates for 8-lane divided segments. Regional effects are not statistically significant; however, this is indicative of the distribution of 8D segments, which are for the most part located in the Metro Region. Therefore, it is not possible to deduce any information regarding regional effects on crash rates for this type of facility.

Table 27. SPF for Crashes on 8D Segments with AADT Only

| Variable | Fatal \& Injury Crashes |  |  | Property Damage Only Crashes |  |  | All Crash Severities |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Figure 31. Total Annual Crashes per Mile for 8D Segments

Table 27 shows the statewide AADT only model results for one-way segments. It can be observed that AADT has an elastic effect on crashes for total and PDO crash rate models.

Table 28. SPF for Crashes on One-Way Segments with AADT Only

Figure 32. Total Annual Crashes per Mile for One-Way Segments

Table 28 shows the AADT with regional effects model for one-way segments. The AADT has an elastic effect on all three severity crash rates. The Bay Region had the lowest crash rate for total, FI, and PDO models. The Superior Region had the highest total and PDO crash rate, while the Metro Region had the highest FI crash rate.

Table 29. SPF for Crashes on One-Way Segments with AADT and Regional Indicators

| Variable | Fatal and Injury Crashes |  |  | Property Damage Only Crashes |  |  | All Crash Severities |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Value | Std. <br> Error | tstatistic | Value | Std. <br> Error | tstatistic | Value | Std. <br> Error | tstatistic |
| Intercept | -9.627 | 1.897 | -5.076 | -8.366 | 0.946 | -8.848 | -7.903 | 0.885 | -8.933 |
| AADT | 0.996 | 0.202 | 4.933 | 1.012 | 0.101 | 10.030 | 0.985 | 0.094 | 10.428 |
| Superior Region Effect | -0.836 | 0.633 | -1.321 | 1.130 | 0.220 | 5.136 | 0.933 | 0.214 | 4.361 |
| North Region Effect | - | - | - | -0.501 | 1.037 | -0.483 | -0.752 | 1.034 | -0.727 |
| Grand Region Effect | - | - | - | - | - | - | - | - | - |
| Bay Region Effect | -1.235 | 0.304 | -4.069 | -0.545 | 0.145 | -3.748 | -0.642 | 0.138 | -4.660 |
| Southwest Region Effect | -0.585 | 0.294 | -1.991 | 0.276 | 0.145 | 1.907 | 0.158 | 0.138 | 1.141 |
| University Region Effect | -0.042 | 0.200 | -0.210 | 0.306 | 0.119 | 2.569 | 0.257 | 0.112 | 2.289 |
| Inverse Dispersion Parameter | 1.140 | 0.310 |  | 1.470 | 0.082 |  | 0.649 | 0.073 |  |

*Note: Metro Region Effect serves as baseline reference category

Figure 33. Total Annual Crashes per Mile for One-Way Segments with Regional Indicators In addition to providing estimates of crashes by site type and region, it is also useful to predict how many crashes may be expected by type at a specific location. To this end, Table 29 provides details of the crash type distribution for each of the eight site types by severity level (FI versus PDO). Table 30 to Table 36 provide similar distributions for each of the MDOT regions.

Table 30. Statewide Distribution of Crashes by Collision Type

| Manner of Collision | Statewide Proportion of Crashes by Severity Level for Specific Segment Types |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

### 5.2 Michigan Specific SPFs for Pedestrian- and Bicycle-Involved Crashes

Pedestrian and cyclist volumes were not readily available for this study; however, the research team attempted to develop models for pedestrian and bicycle crashes based on vehicular AADT for total, FI, and PDO crashes as shown in Table 39 and Table 40.

Table 38. Michigan Specific AADT Only Pedestrian Crash Models

|  | Segment Types | Intercept <br> (a) | AADT (b) | Overdispersion factor (k) |
| :---: | :---: | :---: | :---: | :---: |

*The variable was not significant at $95 \%$ confidence interval

Each of the models show that a majority of crashes increase with respect to traffic volumes. However, even in the highest volume cases, segments were generally expected to experience only a fraction of a crash per year. This is demonstrated by the crash proportions on Table 31 through Table 36. Bicycle FI crash proportions were relatively high for one-way segments in the Superior and Southwest Regions, and the pedestrian FI crash proportion was high for 6-lane divided segments in the University Region. In any case, these models provide a general starting point for pedestrian and bicycle safety analyses. As additional data becomes available, these models may be expanded to better understand the effects of geometric and traffic control factors on the crash
risk for pedestrians and bicyclists. The lack of a reliable exposure measure to represent the amount of pedestrian or bicyclist activity on a given segment is also a limitation which may be addressed through future programs aimed at collecting data for non-motorized users.

Another point worth noting is that most of the parameters in the property damage only (PDO) models are not statistically significant. This is reflective, at least in part, of the fact that pedestrianor bicycle-involved crashes that result in no injury are very rare and most crashes of this type tend to go unreported.

### 6.0 FULLY-SPECIFIED SPFS WITH AADT, REGIONAL INDICATORS, AND GEOMETRIC VARIABLES

After estimating the models considering only traffic volumes and MDOT region, more detailed models were specified that considered the full database developed by the research team. These fully-specified models were developed in a format similar to those presented in Chapter 12 of the HSM. This section briefly outlines the format of these SPFs, which are estimated in combination with CMFs where sufficient data are available. Separate models are estimated for intersections of two-way streets and one-way streets as the factors contributing to crashes in each setting are found to vary, as are the magnitudes of the relevant predictors.

The predicted average crash frequency for each roadway segment on a particular facility is computed as the sum of predicted average crash frequency of all crash types that occurred on the segment. The predicted average crash frequency is computed using the predictive model, where a model is the combination of a SPF and several CMFs. The SPF is used to estimate the average crash frequency for the stated base conditions. The CMFs are used to adjust the SPF estimate when the attributes of the subject site are not consistent with the base conditions. The predicted average crash frequency of a roadway segment is calculated as shown below.
$N_{r}=N_{b r}+N_{\text {pedr }}+N_{\text {biker }}$
with,
$N_{b r}=N_{m v r}+N_{s v r}$
$N_{\text {mvr }}=N_{\text {spfmv }} \times\left(C M F_{1} \times \ldots \times C M F_{p}\right)$
$N_{s v r}=N_{s p f s v} \times\left(C M F_{1} \times \ldots \times C M F_{p}\right)$
$N_{\text {pedr }}=N_{b r} \times f_{\text {ped }}$
$N_{\text {biker }}=N_{b r} \times f_{\text {bike }}$
where,
$N_{r}=$ predicted average crash frequency of an individual segment for the selected year;
$N_{b r}=$ predicted average crash frequency of an individual segment (excluding vehiclepedestrian and vehicle-bicycle collisions);
$N_{\text {pedr }}=$ predicted average crash frequency of vehicle-pedestrian collisions for a segment ;
$N_{\text {biker }}=$ predicted average crash frequency of vehicle-bicycle collisions for a segment;
$N_{m v r}=$ predicted average crash frequency of multiple-vehicle crashes (excluding vehiclepedestrian and vehicle-bicycle collisions) for a segment ;
$N_{s v r}=$ predicted average crash frequency of single-vehicle crashes (excluding vehiclepedestrian and vehicle-bicycle collisions) for a segment ;
$N_{\text {spfmv }}=$ predicted average crash frequency of multiple-vehicle crashes (excluding vehiclepedestrian and vehicle-bicycle collisions) for base conditions ;

$$
\begin{aligned}
N_{s p f m v} & =\begin{array}{l}
\text { predicted average crash frequency of single-vehicle crashes (excluding vehicle- } \\
\\
\text { pedestrian and vehicle-bicycle collisions) for base conditions; } ;
\end{array} \\
f_{\text {ped }}= & \text { pedestrian crash adjustment factor } ; \\
f_{b i k e}= & \text { bicycle crash adjustment factor } ; \\
C M F_{1} & \times \ldots \times C M F_{p}=\text { crash modification factors at site with geometric design features } p .
\end{aligned}
$$

SPFs and CMFs are provided for the various site types on urban and suburban highways listed in Table 41.

Table 40. List of Facility Types with SPFs

| Site Type | Site Types with SPFs |
| :--- | :--- |
| Two-way Streets | Two-lane undivided arterials with $55 \mathrm{miles} /$ hour posted speed <br> (2U55E) <br> Two-lane undivided arterials with less than 55 miles/hour posted <br> speed (2U55L) |
|  | Three-lane arterials including a center TWLTL (3T) |
|  | Four-lane undivided arterials (4U) |
|  | Four-lane divided arterials (including a raised or depressed median) |
|  | (4D) |
|  | Five-lane arterials including a center TWLTL (5T) |
|  | Six-lane divided arterials (including a raised or depressed median) |
|  | (6D) |
|  | Eight-lane divided arterials (including a raised or depressed median) |
|  | (8D) |
| One-way Streets | Two-lane one-way arterials (2O) |
|  | Three-lane one-way arterials (3O) |
|  | Four-lane one-way arterials (4O) |

### 6.1 Model Development - Two-Way Arterials

The following regression model form was used to predict the average crash frequency along an individual roadway segment.

$$
\begin{gathered}
N_{j}=\left(N_{s p f m v} I_{m v} C M F_{d w}+N_{s p f s v} I_{s v} C M F_{f o}\right) \times C M F_{l w} \times C M F_{l s w} \times C M F_{r s w} \times C M F_{m w} \\
\times C M F_{p k} \times C M F_{l g t} \times C M F_{s p d}
\end{gathered}
$$

with,
$N_{s p f m v}=n \times L \times e^{b_{m v}+b_{m v 1} \ln (A A D T)+b_{c o m} \frac{A A D T_{c o m}}{A A D T}+b_{r 1} I_{r 1}+b_{r 2} I_{r 2}+b_{r 3} I_{r 3}+b_{r 4} I_{r 4}+b_{r 5} I_{r 5}+b_{r 6} I_{r 6}}$
$N_{s p f s v}=n \times L \times e^{b_{s v}+b_{s v 1} \ln (A A D T)+b_{c o m} \frac{A A D T_{c o m}}{A A D T}+b_{r 1} I_{r 1}+b_{r 2} I_{r 2}+b_{r 3} I_{r 3}+b_{r 4} I_{r 4}+b_{r 5} I_{r 5}+b_{r 6} I_{r 6}}$
$C M F_{l w}=e^{b_{l w}\left(W_{l}-12\right)}$
$C M F_{l s w}=e^{b_{l s w}\left(W_{l s w}-1.0\right)}$
$C M F_{m w}=e^{b_{m w}\left(\sqrt{W_{m}}-\sqrt{16}\right)}$
$C M F_{d w}=e^{b_{d w c}\left(n_{d w c}-10\right)} \times e^{b_{d w i}\left(n_{d w i}-3\right)} \times e^{b_{d w r}\left(n_{d w r}-8\right)} \times e^{b_{d w o}\left(n_{d w o}-10\right)}$
where,
$N_{j}=$ predicted annual average crash frequency for model $j(j=m v, s v)$;
$N_{m v}=$ predicted annual average multiple-vehicle crash frequency;
$N_{s v}=$ predicted annual average single-vehicle crash frequency;
$I_{m v}=$ multiple-vehicle crash indicator variable ( $=1.0$ if multiple-vehicle crash data, 0.0 otherwise) ;
$I_{s v}=$ single-vehicle crash indicator variable (=1.0 if single-vehicle crash data, 0.0 otherwise) ;
$n=$ number of years of crash data;
$A A D T=$ annual average daily traffic, veh/day;
$A A D T_{\text {com }}=$ commercial vehicle average annual daily traffic, veh/day;
$I_{r 1}=$ Superior region indicator variable ( $=1.0$ if site is in Superior region, 0.0 if it is not);
$I_{r 2}=$ North region indicator variable ( $=1.0$ if site is in North region, 0.0 if it is not);
$I_{r 3}=$ Grand region indicator variable ( $=1.0$ if site is in Grand region, 0.0 if it is not);
$I_{r 4}=$ Bay region indicator variable ( $=1.0$ if site is in Bay region, 0.0 if it is not);
$I_{r 5}=$ Southwest region indicator variable ( $=1.0$ if site is in Southwest region, 0.0 if it is not);
$I_{r 6}=$ University region indicator variable ( $=1.0$ if site is in University region, 0.0 if it is not);
$C M F_{l w}=$ lane width modification factor;
$C M F_{l s w}=$ left shoulder width crash modification factor;
$C M F_{r s w}=$ right shoulder width crash modification factor;
$C M F_{m w}=$ median width crash modification factor;
$C M F_{p k}=$ on-street parking crash modification factor;
$C M F_{f o}=$ roadside fixed objects crash modification factor;
$C M F_{d w}=$ driveway count crash modification factor;
$C M F_{\text {lgt }}=$ lighting crash modification factor;
$C M F_{s p d}=$ automatic speed enforcement crash modification factor;
$W_{l}=$ average lane width, ft ;
$W_{l s w}=$ average left shoulder width, ft;
$W_{m}=$ median width, ft ;
$n_{d w c}=$ commercial driveway density, driveways/mile
$n_{d w i}=$ industrial driveway density, driveways/mile
$n_{d w r}=$ residential driveway density, driveways/mile
$n_{d w o}=$ other type driveway density, driveways/mile
$b_{i}=$ calibration coefficient for variable $i$.

The inverse dispersion parameter, $K$ (which is the inverse of the over-dispersion parameter $k$ ), is allowed to vary with the segment length. The inverse dispersion parameter is calculated using the following equation:

$$
K=L \times e^{\delta, j} ; j=m v, s v
$$

where,
$K=$ inverse dispersion parameter.
$\delta=$ calibration coefficient for inverse dispersion parameter.

### 6.1.1 Model Calibration

The predictive model calibration process consisted of the simultaneous calibration of multiplevehicle and single-vehicle crash models and CMFs using the aggregate model represented by the equations above. The simultaneous calibration approach was needed because some CMFs were common to multiple-vehicle (MV) and single-vehicle (SV) crash models. The database assembled for calibration included two replications of the original database. The dependent variable in the first replication was set equal to the multiple-vehicle crashes. The dependent variable in the second replication was set equal to the single-vehicle crashes. The results of the multivariate regression model calibration are presented in the following tables.

Table 42 and Table 43 summarize the results for fatal and injury and PDO crashes, respectively, on two-way roadway segments. The t-statistics indicate a test of the hypothesis that the coefficient value is equal to 0.0 . Those $t$-statistics with an absolute value that is larger than 2.0 indicate that the hypothesis can be rejected with the probability of error in this conclusion being less than 0.05. For those few variables where the absolute value of the $t$-statistic is smaller than 2.0 , it was decided that the variable was important to the model and its trend was found to be consistent with previous research findings (even if the specific value was not known with a great deal of certainty as applied to this database). The indicator variables for some regions in the state were found to be significant. For the same conditions, the Grand Region experienced the highest number of fatal and injury crashes and PDO crashes, while the Superior Region experienced the least fatal and injury crashes. This is likely due to the differences between regions such as vertical grade, crash reporting, and weather.

The non-linear mixed modeling (NLMIXED) procedure in the SAS software was used to estimate the proposed model coefficients. This procedure was used because the proposed predictive model is both nonlinear and discontinuous. The log-likelihood function for the NB distribution was used to determine the best-fit model coefficients.

Table 41. Calibrated coefficients for fatal and injury crashes on two-way segments

| Coefficient | Variable | Type | Value | Std. Dev | t-statistic |
| :---: | :---: | :---: | :---: | :---: | :---: |

The relationship between crash frequency (FI plus PDO crashes) and traffic demand for base conditions, as obtained from the calibrated models, is illustrated in Figure 34.

a) Multiple-Vehicle Crashes

b) Single-Vehicle Crashes

Figure 34. Graphical Form of the Segment SPF for Crashes on Two-way Streets
The crash frequency obtained can be multiplied by the proportions in Table 44 to estimate the predicted average multiple-vehicle crash frequency by collision type category.

Table 43. Distribution of multiple-Vehicle crashes by collision type

|  | Proportion of Crashes by Severity Level for Specific Segment Types |  |  |  |  |  |  |  |  |

### 6.1.2 Vehicle-Pedestrian Crashes

The number of vehicle-pedestrian collisions per year for a segment is estimated as:
$N_{\text {peds }}=N_{b s} \times f_{\text {ped }}$
$N_{b s}=$ predicted average crash frequency of an individual segment (excluding vehiclepedestrian and vehicle-bicycle collisions);
$N_{\text {peds }}=$ predicted average crash frequency of vehicle-pedestrian collisions for a segment;
$f_{\text {ped }}=$ pedestrian crash adjustment factor.

The pedestrian crash adjustment factor is estimated by dividing the vehicle-pedestrian crashes by the sum of single-vehicle and multiple-vehicle crashes for each segment type. Table 45 presents the values of $\mathrm{f}_{\text {ped }}$. All vehicle-pedestrian collisions are considered to be fatal-and-injury crashes.

Table 44. Pedestrian crash adjustment factors

| Segment Type | Total <br> Crashes | Pedestrian | Total MV and SV <br> Crashes* | $\boldsymbol{f}_{\text {ped }}$ |
| :--- | :--- | :--- | :--- | :--- |
| 2U55E | 8 | 5611 | 0.0014 |  |
| 2U55L | 25 | 3695 | 0.0068 |  |
| 3T | 16 | 2812 | 0.0057 |  |
| 4U | 38 | 3004 | 0.0095 |  |

| 8D | 31 | 0.0104 |  |  |

*Excludes pedestrian and bicycle crashes

### 6.1.3 Vehicle-Bicycle Crashes

The number of vehicle-bicycle collisions per year for a segment is estimated as:

$$
\begin{aligned}
& N_{\text {bikes }}=N_{b s} \times f_{\text {bike }} \\
& N_{b s}= \text { predicted average crash frequency of an individual segment (excluding vehicle- } \\
& \text { pedestrian and vehicle-bicycle collisions); } \\
& N_{\text {bikes }}= \text { predicted average crash frequency of vehicle-bicycle collisions for a segment; } \\
& f_{\text {bike }}= \text { bicycle crash adjustment factor. }
\end{aligned}
$$

The bicycle crash adjustment factor is estimated by dividing the vehicle-bicycle crashes by the sum of single-vehicle and multiple-vehicle crashes for each segment type. Table 46 presents the values of $f_{\text {bike }}$. The vehicle-bicycle collisions by severity are estimated using the following equation.

$$
\begin{aligned}
& N_{\text {bikes }, f s}=N_{\text {bikes }} \times P_{f s} \\
& N_{\text {bikes }, \text { pdo }}=N_{\text {bikes }} \times\left(1-P_{f s}\right)
\end{aligned}
$$

$$
\begin{aligned}
N_{\text {bikei,fi }} & =\begin{array}{l}
\text { predicted average fatal and injury crash frequency of vehicle-bicycle collisions } \\
\text { for a segment } ;
\end{array} \\
N_{\text {bikei,pdo }}= & \begin{array}{l}
\text { predicted average property damage only crash frequency of vehicle-bicycle } \\
\text { collisions for a segment; }
\end{array} \\
P_{f i} & =\text { proportion of fatal and injury vehicle-bicycle crashes. }
\end{aligned}
$$

Table 45. Bicycle crash adjustment factors

| Segment Type | Bicycle Crashes |  |  | Total MV <br> and SV <br> Crashes*  |  | $f_{\text {bike }}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| 5 T | 103 | 89 | 0.86 | 17703 |  | 0.0058 |
| 6D | 25 | 23 | 0.92 | 3810 |  | 0.0066 |
| 8D | 31 | 28 | 0.90 | 31 |  | 0.0046 |

*Excludes pedestrian and bicycle crashes

### 6.1.4 Crash Modification Factors

The CMFs for geometric design features of segments are presented below. The CMFs are used to adjust the SPF for segments to account for differences between the base conditions and the local site conditions. Several CMFs were calibrated in conjunction with the SPFs. These were calibrated using the FI crash data because of known issues with the PDO crash data, such as underreporting. If the coefficient used in the CMFs was not significant or when the data was not available, CMFs were adopted from previous research. Collectively, CMFs describe the relationship between various geometric factors and crash frequency. Many of the CMFs found in the literature were typically derived from (and applied to) the combination of multiple-vehicle and single-vehicle crashes. That is, one CMF is used to indicate the influence of a specified geometric feature on total crashes. In contrast, the models developed for this project include several CMFs that are calibrated for a specific crash type.

CMFiw- Lane Width. The estimated coefficient that is used in the lane width CMF is statistically insignificant but it is similar to the one found in Lord et al. Thus, the CMF is adopted from the work of Lord et al [57]. The base condition for this CMF is a $12-\mathrm{ft}$ lane width. The lane width used in this CMF is an average for all through lanes on the segment. This CMF applies to both MV and SV segment crashes (not including vehicle-pedestrian and vehicle-bicycle crashes). The lane width CMF is described using the following equation:

$$
C M F_{l w}=e^{-0.0219\left(W_{l}-12\right)}
$$

CMF $_{\text {lsw- }}$ Left Shoulder Width. The base condition for this CMF is a $1.0-\mathrm{ft}$ inside shoulder width and it is applicable to divided roadway segments only. The shoulder width used in this CMF is an average of two roadbeds on the segment. This CMF applies to both MV and SV segment crashes (not including vehicle-pedestrian and vehicle-bicycle crashes).

$$
C M F_{l s w}=e^{-0.022\left(W_{l s w}-1.0\right)}
$$

CMFrsw- Right Shoulder Width. Although efforts are made in this study to develop a right shoulder width CMF, a meaningful CMF could not be developed. The outside shoulder width CMF from the work from Lord et al. was adopted and is described in the below equation [57]. The base condition for this CMF was a 1.5 -ft outside shoulder width. The shoulder width used in this CMF is an average of two roadbeds on the segment. This CMF applies to both MV and SV segment crashes (not including vehicle-pedestrian and vehicle-bicycle crashes).

$$
C M F_{r s w}=e^{-0.0285\left(W_{r s w}-1.5\right)}
$$

where,

$$
W_{r s w}=\text { average right shoulder width, ft. }
$$

CMF mw- Median Width. The estimated coefficient that is used in the median width CMF is statistically insignificant and therefore the CMF from the work of Bonneson and Pratt was adopted [58]. The base condition for this CMF was a $16-\mathrm{ft}$ median width for restrictive medians and a 12ft median width for nonrestrictive medians. Restrictive medians can include raised-curb or depressed medians. This CMF applies to both MV and SV segment crashes (not including vehiclepedestrian and vehicle-bicycle crashes).

For restrictive medians: $C M F_{m w}=e^{-0.041\left(\sqrt{W_{m}}-\sqrt{16}\right)}$

For nonrestrictive medians: $C M F_{m w}=e^{-0.0255\left(W_{m}-12\right)}$
$\mathbf{C M F}_{\text {pk }}$ On-street Parking. This CMF is adopted from the HSM and is applicable to two-way roadway segments with five or fewer lanes. The base condition for this CMF is the absence of onstreet parking on the roadway segment. The CMF for on-street parking is determined using the following equation.

$$
C M F_{p k}=1+p_{p k} \times\left(f_{p k}-1.0\right)
$$

Where,
$f_{p k}=\quad$ factor from Table 47;
$p_{p k}=\quad$ proportion of curb length with on-street parking $=\left(0.5 L_{p k} / L\right)$;
$L_{p k} \quad=\quad$ sum of curb length with on-street parking for both sides of the road combined (miles); and
$L \quad=\quad$ length of roadway segment (miles).

The CMF for on-street parking applies to all collision types other than vehicle-pedestrian and vehicle-bicycle. The sum of curb length with on-street parking ( $\mathrm{L}_{p k}$ ) can be determined from field measurements or video log review to verify parking regulations. Estimates can be made by deducting from twice the roadway segment length allowances for intersection widths, crosswalks, and driveway widths.

Table 46. Values of $f_{p k}$ used in determining the CMF for on-street parking

|  | Type of Parking and Land Use |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Roadway | Residential | Commercial | or | Residential | Commercial |
| Segment | or Other | Industrial/Institutional | or Other | Industrial/Institutional |  |
| 2U | 1.465 | 2.074 | 3.428 | 4.853 |  |
| 3T | 1.465 | 2.074 | 3.428 | 4.853 |  |
| 4U | 1.100 | 1.709 | 2.574 | 3.999 |  |
| 4D | 1.100 | 1.709 | 2.574 | 3.999 |  |
| 5T | 1.100 | 1.709 | 2.574 | 3.999 |  |

CMFfo- Roadside Fixed Objects. The roadside fixed-object CMF is adopted from the work of Lord et al. and is applicable to single-vehicle crashes only [57]. It is described using the following equation.

$$
C M F_{f o}=1.0+\frac{0.01 D_{f o}}{e^{0.131\left(o_{f o}\right)}}
$$

The base condition for the roadside fixed-object CMF is absence of roadside objects. The change in the roadside fixed-object CMF with an increase in the offset distance for a segment with 50 roadside objects per mile is shown in Table 48.

Table 47. Roadside fixed-object CMF

| Offset to Fixed Objects $\left(\boldsymbol{O}_{\boldsymbol{f o}}\right)(\mathbf{f t})$ | CMF (Proposed) |
| :--- | :--- |
| $\mathbf{0}$ | 1.50 |
| $\mathbf{2}$ | 1.38 |
| $\mathbf{5}$ | 1.26 |
| $\mathbf{1 0}$ | 1.13 |
| $\mathbf{1 5}$ | 1.07 |
| $\mathbf{2 0}$ | 1.04 |
| $\mathbf{2 5}$ | 1.02 |
| $\mathbf{3 0}$ | 1.01 |

CMF $_{\boldsymbol{d} w}$ - Driveways. The driveway CMF is applicable to multiple-vehicle crashes only. Commercial driveways provide access to establishments that serve retail customers. Industrial/institutional driveways serve factories, warehouses, schools, hospitals, churches, offices, public facilities, and other places of employment. Residential driveways serve single- and multiple-family dwellings. Other driveways include field, private, and undefined driveways. The base condition for the driveway CMF is 10 commercial driveways per mile, three industrial driveways per mile, eight residential driveways per mile, and 10 other type driveways per mile. The driveway CMF is described using the following equation.

$$
C M F_{d w}=e^{0.014\left(n_{d w c}-10\right)} \times e^{0.005\left(n_{d w i}-3\right)} \times e^{0.002\left(n_{d w r}-8\right)} \times e^{0.003\left(n_{d w o}-10\right)}
$$

CMF ${ }_{\text {lgt }}$ Lighting. The CMF for lighting is adopted from the HSM and is applicable only to roadway segments with five or fewer lanes. The base condition for lighting is the absence of roadway segment lighting. The CMF is determined using the following equation.
$C M F_{\text {lgt }}=1.0-\left(1.0-0.72 \times p_{\text {inr }}-0.83 \times p_{p n r}\right)$
Where,
$p_{\text {inr }}=$ proportion of total nighttime crashes for unlighted roadway segments that involve a fatality or injury;
$p_{p n r}=\quad$ proportion of total nighttime crashes for unlighted roadway segments that involve property damage only; and
$p_{n r}=\quad$ proportion of total crashes for unlighted roadway segments that occur at night.
This CMF applies to all collision types other than vehicle-pedestrian and vehicle-bicycle. Table 49 presents default values for the nighttime crash proportions $\mathrm{p}_{n r}$, $\mathrm{p}_{\mathrm{inr}}$, and $\mathrm{p}_{\mathrm{pnr}}$.

Table 48. Nighttime crash proportions for unlighted roadway segments

| Roadway Type | Segment | Proportion of Total Nighttime Crashes by Severity Level |  | Proportion of Crashes that Occur at Night |
| :---: | :---: | :---: | :---: | :---: |
|  |  | FI pinr | PDO P ${ }_{\text {n }}$ | P ${ }_{\text {r }}$ |
| 2U |  | 0.424 | 0.576 | 0.316 |
| 3 T |  | 0.429 | 0.571 | 0.304 |
| 4U |  | 0.517 | 0.483 | 0.365 |
| 4D |  | 0.364 | 0.636 | 0.410 |
| 5T |  | 0.432 | 0.568 | 0.274 |

CMF $_{\text {spd-A }}$ Automated Speed Enforcement. The CMF for automated speed enforcement is adopted from the HSM and it applies to all roadway segment types and all collision types (other than vehicle-pedestrian and vehicle-bicycle). Automated speed enforcement systems use video or photographic identification in conjunction with radar or lasers to detect speeding drivers. These systems automatically record vehicle identification information without the need for police officers at the location. The base condition for automated speed enforcement is that it is absent. A CMF of 0.83 for the reduction of all types of FI crashes from implementation of automated speed enforcement is recommended. This CMF is assumed to apply to roadway segments between intersections with fixed camera sites where the camera is always present or where drivers have no way of knowing whether the camera is present or not. No information is available on the effect of automated speed enforcement on noninjury crashes. With the conservative assumption that automated speed enforcement has no effect on noninjury crashes, the value of the CMF for automated speed enforcement would be 0.95 .

### 6.2 Model Development - One-Way Arterial Segments

The following regression model form was used to predict the average crash frequency along an individual roadway segment.
$N_{j}=\left(N_{s p f m v} I_{m v} C M F_{p k} C M F_{d w}+N_{s p f s v} I_{s v} C M F_{f o}\right) \times C M F_{r s w}$
with,
$N_{s p f m v}=n \times L \times e^{b_{m v}+b_{m v 1} \ln (A A D T)+b_{r 1} I_{r 1}+b_{r 2} I_{r 2}+b_{r 3} I_{r 3}+b_{r 4} I_{r 4}+b_{r 5} I_{r 5}+b_{r 6} I_{r 6}}$

$$
N_{s p f s v}=n \times L \times e^{b_{s v}+b_{s v 1} \ln (A A D T)+b_{r 1} I_{r 1}+b_{r 2} I_{r 2}+b_{r 3} I_{r 3}+b_{r 4} I_{r 4}+b_{r 5} I_{r 5}+b_{r 6} I_{r 6}}
$$

$$
C M F_{d w}=e^{b_{d w c}\left(n_{d w c}-10\right)}
$$

where,
$N_{j}=$ predicted annual average crash frequency for model $j(j=m v, s v)$;
$N_{m v}=$ predicted annual average multiple-vehicle crash frequency;
$N_{s v}=$ predicted annual average single-vehicle crash frequency;
$I_{m v}=$ multiple-vehicle crash indicator variable ( $=1.0$ if multiple-vehicle crash data, 0.0 otherwise) ;
$I_{s v}=$ single-vehicle crash indicator variable ( $=1.0$ if single-vehicle crash data, 0.0 otherwise) ;
$n=$ number of years of crash data;
$A A D T=$ annual average daily traffic, veh/day;
$I_{r 1}=$ Superior region indicator variable ( $=1.0$ if site is in Superior region, 0.0 if it is not);
$I_{r 2}=$ North region indicator variable ( $=1.0$ if site is in North region, 0.0 if it is not);
$I_{r 3}=$ Grand region indicator variable ( $=1.0$ if site is in Grand region, 0.0 if it is not);
$I_{r 4}=$ Bay region indicator variable ( $=1.0$ if site is in Bay region, 0.0 if it is not);
$I_{r 5}=$ Southwest region indicator variable ( $=1.0$ if site is in Southwest region, 0.0 if it is not);
$I_{r 6}=$ University region indicator variable ( $=1.0$ if site is in University region, 0.0 if it is not);
$C M F_{r s w}=$ right shoulder width crash modification factor;
$C M F_{p k}=$ on-street parking crash modification factor;
$C M F_{f o}=$ roadside fixed objects crash modification factor;
$C M F_{d w}=$ driveway count crash modification factor;
$n_{d w c}=$ commercial driveway density, driveways/mile
$b_{i}=$ calibration coefficient for variable $i$.

The inverse dispersion parameter, $K$ (which is the inverse of the over-dispersion parameter $k$ ), is allowed to vary with the segment length. The inverse dispersion parameter is calculated using the following equation:

$$
K=L \times e^{\delta, j} ; j=m v, s v
$$

where,

$$
K=\text { inverse dispersion parameter. }
$$

$\delta=$ calibration coefficient for inverse dispersion parameter.

The predictive model calibration process consisted of the simultaneous calibration of multiplevehicle and single-vehicle crash models and CMFs using the aggregate model represented by the equations above. The database assembled for calibration included two replications of the original database. The dependent variable in the first replication was set equal to the multiple-vehicle crashes. The dependent variable in the second replication was set equal to the single-vehicle
crashes. Table 50 and Table 51 summarize the modeling results for one-way arterial segments for FI and PDO, respectively.

Table 49. Calibrated coefficients for FI crashes on one-way arterials.

| Coefficie nt | Variable | Facility | Estimate | Std. Error | t-statistic |

| Observations |  | 181 segments ( $2 \mathrm{O}=33 ; 3 \mathrm{O}=117 ; 4 \mathrm{O}=31$ ) |  |  |  |

The relationship between crash frequency (FI plus PDO crashes) and traffic demand for base conditions, as obtained from the calibrated models, is illustrated in Figure 35.

a) Multiple-Vehicle Crashes

b) Single-Vehicle Crashes

Figure 35. Graphical form of the segment SPF for crashes on one-way streets

Table 52 shows the proportion of injury crashes for SV and MV crashes by severity level. The values from this can be multiplied by the output of $\mathrm{N}_{\text {spfmv }}$ and $\mathrm{N}_{\text {spfsv }}$ for multi- and single-vehicle crashes, respectively. Note that all one-way segments have a very small sample size. Hence, the proportions should be used with caution.

Table 51. Proportion of injury crashes for single- and multi-vehicle crashes for one-way segments

| Severity | $\mathbf{2 O}$ |  | $\mathbf{3 O}$ |  | 4O |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  |  | SV | MV | SV | MV | SV |

The crash frequency obtained can be multiplied by the proportions in Table 53 to estimate the predicted average multiple-vehicle crash frequency by collision type category.

Table 52. Distribution of multiple-vehicle crashes by collision type

| Manner of Collision | Proportion of Crashes by Severity Level <br> for Specific Segment Types |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |

*Technically, these crashes should not happen but may occur due to wrong-way driving.

### 6.2.1 Vehicle-Pedestrian Crashes

The number of vehicle-pedestrian collisions per year for a segment is estimated as:
$N_{\text {peds }}=N_{b s} \times f_{\text {ped }}$
$N_{b s}=$ predicted average crash frequency of an individual segment (excluding vehiclepedestrian and vehicle-bicycle collisions);
$N_{\text {peds }}=$ predicted average crash frequency of vehicle-pedestrian collisions for an segment;
$f_{\text {ped }}=$ pedestrian crash adjustment factor.

The pedestrian crash adjustment factor is estimated by dividing the vehicle-pedestrian crashes by the sum of single-vehicle and multiple-vehicle crashes for each segment type. Table 54 presents the values of $f_{\text {ped }}$. All vehicle-pedestrian collisions are considered to be fatal-and-injury crashes.

## Table 53. Pedestrian crash adjustment factors

| Segment Type | Total <br> Crashes | Pedestrian | Total MV and SV <br> Crashes* | $\boldsymbol{f}_{\text {ped }}$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 2 O | 0 | 204 | 0.0000 |  |
| 3O | 4 | 676 | 0.0060 |  |
| 4 O | 2 | 368 | 0.0005 |  |

*Excludes pedestrian and bicycle crashes

### 6.2.2 Vehicle-Bicycle Crashes

The number of vehicle-bicycle collisions per year for a segment is estimated as:
$N_{\text {bikes }}=N_{b s} \times f_{\text {bike }}$
$N_{b s}=$ predicted average crash frequency of an individual segment (excluding vehiclepedestrian and vehicle-bicycle collisions);
$N_{\text {bikes }}=$ predicted average crash frequency of vehicle-bicycle collisions for a segment; $f_{\text {bike }}=$ bicycle crash adjustment factor.

The bicycle crash adjustment factor is estimated by dividing the vehicle-bicycle crashes by the sum of single-vehicle and multiple-vehicle crashes for each segment type. Table 55 presents the values of $f_{\text {bike }}$. The vehicle-bicycle collisions by severity are estimated using the following equation.

$$
\begin{aligned}
& N_{\text {bikes }, f s}=N_{\text {bikei }} \times P_{f s} \\
& N_{\text {bikes }, \text { pdo }}=N_{\text {bikes }} \times\left(1-P_{f s}\right) \\
& \text { Where, }
\end{aligned}
$$

$$
\begin{aligned}
N_{\text {bikes }, f s}= & \begin{array}{l}
\text { predicted average fatal and injury crash frequency of vehicle-bicycle collisions } \\
\text { for a segment; }
\end{array} \\
N_{\text {bikes }, \text { pdo }}= & \begin{array}{l}
\text { predicted average property damage only crash frequency of vehicle-bicycle } \\
\\
\text { collisions for a segment; }
\end{array} \\
P_{f s}= & \text { proportion of fatal and injury vehicle-bicycle crashes. }
\end{aligned}
$$

Table 54. Bicycle crash adjustment factors

| Segment Type | Bicycle Crashes |  |  | Total MV  <br> and SV <br> Crashes*  |  | $f_{\text {bike }}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

*Excludes pedestrian and bicycle crashes

### 6.2.3 Crash Modification Factors

The CMFs for geometric design features of one-way street roadway segments are presented below. The CMFs are used to adjust the SPF for segments to account for differences between the base conditions and the local site conditions.

CMFrsw- Right Shoulder Width. The sites considered in this study had no right shoulders and so a CMF could not be developed. Recently, Lord et al. found that the right shoulder width has a significant influence on the safety of one-way streets. Thus, the right shoulder width CMF from the work of Lord et al. was adopted in this study [57]. The base condition for this CMF is no shoulders. This CMF applies to both MV and SV segment crashes (not including vehiclepedestrian and vehicle-bicycle collisions). The right shoulder width CMF is described using the following equation.
$C M F_{r s w}=\frac{e^{-0.0201\left(W_{r s w}-4\right)}}{e^{0.0804}}$
where,

$$
W_{\text {rsw }}=\text { right shoulder width, } \mathrm{ft} .
$$

$\mathbf{C M F}_{\mathbf{p k}^{-}}$On-street Parking. This CMF is adopted from the work of Lord et al [57]. The base condition for this CMF is the absence of on-street parking on the roadway segment and is applicable to multi-vehicle crashes only. The CMF for on-street parking is determined using the following equation.
$C M F_{p k}=\left(1+\left(\frac{0.5 L_{p k_{p a r}}}{L}\right) \times\left(b_{p k_{p a r}}-1.0\right)\right) \times\left(1+\left(\frac{0.5 L_{p k_{a n g}}}{L}\right) \times\left(b_{p k_{a n g}}-1.0\right)\right)$
where,

$$
\begin{aligned}
L_{p k_{p a r}} & =\begin{array}{l}
\text { sum of curb length with on-street parallel parking for both sides of road } \\
\text { combined, mi; }
\end{array} \\
L_{p k_{a n g}} & =\begin{array}{l}
\text { sum of curb length with on-street angle parking for both sides of road } \\
\text { combined, mi; and }
\end{array} \\
b_{p k} & =\begin{array}{l}
\text { factor from Table } 56 \\
L
\end{array}=\quad \text { length of roadway segment (miles). }
\end{aligned}
$$

Table 55. Values of $\boldsymbol{b}_{\boldsymbol{p} k}$ used in determining the CMF for on-street parking.

|  | Type of Parking |  |
| :--- | :--- | :--- |
| Road Type | Parallel Parking $\left(b_{p k_{p a r}}\right)$ | Angle Parking $\left(b_{p k_{a n g}}\right)$ |
| 2 O | 1.112 | 4.364 |
| 3 O | 1.359 | 4.364 |
| 4 O | 1.359 | 4.364 |

CMF $_{\boldsymbol{d} w}$ - Driveways. The driveway CMF is applicable to multiple-vehicle crashes only. Commercial driveways provide access to establishments that serve retail customers. The base condition for the driveway CMF is 10 commercial driveways per mile. The driveway CMF is described using the following equation.
$C M F_{d w}=e^{0.011\left(n_{d w c}-10\right)}$

CMFfo- Roadside Fixed Objects. The roadside fixed-object CMF is adopted from the work of Lord et al. and is applicable to single-vehicle crashes only [57]. It is described using the following equation.
$C M F_{f o}=1.0+\frac{0.01 D_{f o}}{e^{0.0938\left(o_{f o}\right)}}$
The base condition for the roadside fixed-object CMF is absence of roadside objects. The change in the roadside fixed-object CMF with the increase in the offset distance for a segment with 50 roadside objects per mile is shown in Table 57.

Table 56. Roadside fixed-object CMF

| Offset to Fixed Objects $\left(\boldsymbol{O}_{\boldsymbol{f} \boldsymbol{o}}\right)(\mathbf{f t})$ | CMF (Proposed) |
| :--- | :--- |
| $\mathbf{0}$ | 1.50 |
| $\mathbf{2}$ | 1.41 |
| $\mathbf{5}$ | 1.31 |
| $\mathbf{1 0}$ | 1.20 |
| $\mathbf{1 5}$ | 1.12 |
| $\mathbf{2 0}$ | 1.08 |
| $\mathbf{2 5}$ | 1.05 |
| $\mathbf{3 0}$ | 1.03 |

### 6.3 Development of Severity Distribution Functions

This section documents the development of SDFs for two-way arterials. Although efforts were made to develop SDFs for one-way streets as well, meaningful results were not obtained due to the small sample size. For this reason, a fixed proportion by severity is recommended in Table 52. Section 6.3.1 describes the functional form. Section 6.3.2 covers the model development. Section 6.3.3 describes how the models may be used to predict the proportion of crashes by severity level, and Section 6.3.4 summarizes how the models can be used to predict crashes by type.

### 6.3.1 Functional Form

A SDF is represented by a discrete choice model. In theory, it could be used to predict the proportion of crashes in each of the following severity categories: Fatal = K, Incapacitated injury = A, Non-incapacitated injury = B, or Possible injury = C. The SDF can be used with the safety performance functions to estimate the expected crash frequency for each severity category. It may include various geometric, operation, or traffic variables that would allow the estimated proportion to be specific to an individual segment.

The multinomial logit (MNL) model was used to predict the probability of crash severities. Given the characteristics of the data, the MNL model was the most suitable model for estimating a SDF. A linear function was used to relate the crash severity with the geometric and traffic variables. SAS's NLMIXED procedure was used for the evaluation of the MNL model.

The probability for each crash severity category is given by the following equations:

$$
\begin{aligned}
P_{K} & =\frac{e^{V_{K}}}{1+e^{V_{K}}+e^{V_{A}}+e^{V_{B}}} \\
P_{A} & =\frac{e^{V_{A}}}{1+e^{V_{K}}+e^{V_{A}}+e^{V_{B}}} \\
P_{B} & =\frac{e^{V_{B}}}{1+e^{V_{K}}+e^{V_{A}}+e^{V_{B}}} \\
P_{C} & =1-\left(P_{K}+P_{A}+P_{B}\right)
\end{aligned}
$$

where, $P_{j}=$ probability of the occurrence of crash severity $j$;
$V_{j}=$ systematic component of crash severity likelihood for severity $j$.

### 6.3.2 Modeling Development

The database assembled for calibration included crash severity level as a dependent variable and the geometric and traffic variables of each site as independent variables. Each row (site characteristics) is repeated to the frequency of each severity level. Thus, a segment with ' $n$ ' crashes will be repeated ' $n$ ' number of times. It should be noted that the segments without injury (including fatal) crashes are not included in the database. The total sample size of the final dataset for model calibration was equal to the total number of injury (plus fatal) crashes in the data. During the model calibration, the "possible injury" category was set as the base scenario with coefficients restricted to zero.

A model for estimating the systematic component of crash severity $V_{j}$ for two-way arterial segments is described by the following equations.

$$
\begin{aligned}
V_{K} & =A S C_{K}+b_{\text {ter }, K} \times I_{\text {ter }}+b_{d i v, K} \times I_{d i v}+b_{\text {psl, },} \times P S L \\
V_{A} & =A S C_{A}+b_{\text {ter }, A} \times I_{t e r}+b_{d i v, A} \times I_{d i v}+b_{\text {psl, A }} \times P S L \\
V_{B} & =A S C_{B}+b_{\text {ter }, B} \times I_{t e r}+b_{d i v, B} \times I_{d i v}+b_{p s l, B} \times P S L
\end{aligned}
$$

where,
$I_{\text {ter }} \quad=$ terrain indicator variable ( $=1.0$ if level, 0.0 if it is rolling);
$I_{\text {div }}=$ divided road indicator variable (=1.0 if divided, 0.0 otherwise);
PSL $=$ posted speed limit on the segment, miles per hour;

$$
\begin{array}{ll}
A S C_{j} & =\text { alternative specific constant for crash severity } j ; \text { and } \\
b_{k, j} & =\text { calibration coefficient for variable } k \text { and crash severity } j .
\end{array}
$$

The final form of the regression models is described here, before the discussion of regression analysis results. However, this form reflects the findings from several preliminary regression analyses where alternative model forms were examined. The form that is described represents that which provided the best fit to the data while also having coefficient values that were logical with constructs that were theoretically defensible and properly bounded.

Table 58 summarizes the estimation results of the MNL model. An examination of the coefficient values and their implication on the corresponding crash severity levels are documented in a subsequent section. In general, the sign and magnitude of the regression coefficients in Table 58 are logical and consistent with previous research findings.

## Table 57. Parameter estimation for the SDF

| Coefficie nt | Variable | Fatality (K) |  | Incapacitating injury (A) |  | NonIncapacitating injury (B) |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Value | tstatistic | Value | $\begin{aligned} & \text { t- } \\ & \text { statistic } \end{aligned}$ | Value | tstatistic |
| ASC | Alternative specific constant | -4.930 | -7.49 | -2.631 | -8.28 | -1.427 | -6.99 |
| $b_{\text {ter }}$ | Terrain <br> (1=level; <br> $0=$ rolling $)$ | -0.656 | -2.54 | -0.256 | -1.69 | -0.130 | -2.53 |
| $b_{\text {div }}$ | Divided road (1=divided; $0=$ others) | -0.355 | -1.99 | -0.354 | -4.16 | -0.130 | -2.53 |
| PSL | Posted limit, mph speed | 0.042 | 3.49 | 0.018 | 3.28 | 0.013 | 3.74 |
| Observations |  | 10,021 crashes ( $\mathrm{K}=173$; $\mathrm{A}=809$; B=2,340; $\mathrm{C}=6,699$ ) |  |  |  |  |  |

Note: Possible injury is the base scenario with coefficients restricted at zero.

### 6.3.3 Predicted Probabilities

This section describes the change in probability of each crash severity for a given change in particular variable.

Terrain. This variable indicates the type of terrain. Approximately 95\% of the segments were on level terrain, and the remaining 5\% were on rolling terrain. The negative coefficient in Table 58 indicates that the probability of $\mathrm{K}, \mathrm{A}$, and B crash severities for the segments on level terrain was lower than the segments on rolling terrain. As seen in Table 59, the likelihood of a fatal and injury crash changes from $34.1 \%$ on level terrain to $38.5 \%$ on rolling terrain.

Table 58. Crash severity distribution based on terrain type

| Road Type | Crash Severity |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  | K | A | B | C |
| Level | $1.6 \%$ | $7.7 \%$ | $24.8 \%$ | $65.9 \%$ |
| Rolling | $2.8 \%$ | $9.3 \%$ | $26.3 \%$ | $61.5 \%$ |

Road Type. The effect of road type on crash severity was also considered in the calibrated model. About 33 percent of crashes occurred on divided roads while the remaining crashes occurred on undivided or TWLTL segments. The model coefficients in Table 58 indicated that a crash on a divided road segment is less severe than a crash on either undivided segments or segments with a TWLTL. As seen in Table 60, the likelihood of fatal and severe injury crashes (i.e., K, A, and B) is 31.5 percent on divided segments and 35.7 percent on undivided or TWLTL segments. This was expected because the chance of opposite direction crashes, which are very severe in nature, is reduced on divided segments.

Table 59. Crash severity distribution based on road type.

| Road Type | Crash Severity |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  | K | A | B | C |
| 2U/3T/4U/5T | $1.8 \%$ | $8.2 \%$ | $29.0 \%$ | $61.1 \%$ |
| 4D/6D/8D | $1.3 \%$ | $6.5 \%$ | $27.8 \%$ | $64.4 \%$ |

Speed Limit. The speed limit variable indicates the posted speed limit on a particular segment. The speed limit of all segments considered in the SDF model calibration ranged from 25 mph to 70 mph . The average speed limit was 45 mph . The positive sign for a posted speed limit in Table 58 shows that as speed limit increases, the likelihood of a fatal injury also increases. As seen in Table 61, the likelihood of a fatal crash increases from 0.7 percent at 25 mph to 3.7 percent at 70 mph . This is not unexpected because speed limit is highly correlated to crash severity.

Table 60. Crash severity distribution based on posted speed limit.

| Posted Speed Limit <br> (mph) | Crash Severity |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  | $\mathbf{K}$ | $\mathbf{A}$ | $\mathbf{B}$ | C |
| 25 | $0.7 \%$ | $5.8 \%$ | $20.6 \%$ | $72.8 \%$ |
| 30 | $0.9 \%$ | $6.2 \%$ | $21.6 \%$ | $71.3 \%$ |
| 35 | $1.0 \%$ | $6.7 \%$ | $22.6 \%$ | $69.7 \%$ |
| 40 | $1.3 \%$ | $7.2 \%$ | $23.5 \%$ | $68.0 \%$ |
| 45 | $1.5 \%$ | $7.7 \%$ | $24.5 \%$ | $66.3 \%$ |
| 50 | $1.8 \%$ | $8.2 \%$ | $25.5 \%$ | $64.5 \%$ |
| 55 | $2.2 \%$ | $8.7 \%$ | $26.5 \%$ | $62.7 \%$ |
| 60 | $2.6 \%$ | $9.3 \%$ | $27.4 \%$ | $60.7 \%$ |
| 65 | $3.1 \%$ | $9.8 \%$ | $28.3 \%$ | $58.7 \%$ |
| 70 | $3.7 \%$ | $10.4 \%$ | $29.2 \%$ | $56.7 \%$ |

### 6.3.4 Estimation of Crashes by Type

The predicted average crash frequency obtained can be multiplied by the proportions in Table 62 through Table 69 to estimate the predicted average multiple-vehicle crash frequency by collision type category.

Table 61. Statewide Distribution of Multiple-Vehicle Crashes by Collision Type

| Manner of Collision | Statewide Proportion of Multi-Vehicle Crashes by Severity Level for Specific Segment Types |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |

### 7.0 CALIBRATION, MAINTENANCE, AND USE OF SPFS

### 7.1 SPF Calibration Overview

When applied to different jurisdictions or over different time periods, SPFs need to be calibrated to reflect differences due to temporal or spatial trends. This calibration is achieved through the estimation of a calibration factor $C_{x}$. The recommended crash prediction algorithm takes the following form:
$N_{\text {predicted }}=N_{s p f, x} \times\left(C M F_{1 x} \times C M F_{2 x} \times \ldots \times C M F_{y x}\right) \times C_{x}$,
where:
$N_{\text {predicted }}=$ predicted average crash frequency for a specific year for a site of type x;
$N_{s p f, x}=$ predicted average crash frequency determined for base conditions of the SPF developed for site type x ;
$C M F_{y x}=$ Crash modification factors specific to SPF for site type x , and
$C_{x}=$ calibration factor to adjust SPF for local conditions for site type x.

Calibration capabilities are built into existing software support packages, such as the IHSDM, which includes a calibration utility within its Administration Tool to assist agencies in implementing the calibration procedures described in the HSM. The IHSDM also allows state agencies to develop and implement their own SPFs, in addition to modifying the crash severity and crash type distribution values [59].

### 7.2 SPF Calibration Procedure

Calibration can be used to account for changes in safety performance over time, which may be reflective of effects outside of the factors included in the SPFs developed as a part of this study. The calibration process is relatively straight-forward and can be applied following the steps outlined in Appendix A from Part C of the HSM. This procedure is briefly described on the following pages.

1. Identify the facility type for which the applicable SPF is to be calibrated. For the case of the Michigan specific SPFs documented in this report, eight specific facility types are identified. This study considered undivided (2U, 3T, 4U, 5T), divided (4D, 6D, 8D), and OW roadway segments.
2. Select sites for calibration of the predictive model for each facility type. The HSM procedure recommends using 30-50 sites for a given facility type. The HSM also recommends that for jurisdictions attempting calibration that do not have enough sites of a particular type to use all sites within that jurisdiction of said type. For calibration purposes, sites should be selected without regard of historical crash experience at, as selecting sites based on crash experience will potentially result in high or low calibration values. The selected sites should represent a total of at least 100 crashes. Sites should be selected so that they are representative of segments for the entire area for which the calibration will be applied but do not need to be stratified by traffic volume or other site characteristics. The HSM states that site selection for calibration need only occur once, as the same sites may be used for calibration in subsequent years.
3. Obtain data for each facility type available to a specific calibration period. For annual calibration, one year of data should be used. Crashes of all severity levels should be included in the calibration. The HSM recommends that elements a through $j$ are required for calibration of urban and suburban arterials, while items k through m are desired elements.

- Observed crashes on each segment
- Segment length
- Number of through traffic lanes
- Presence of median
- Presence of center TWLTL
- AADT
- Number of driveways by land use type
- Low-speed vs. intermediate or high speed
- Presence of on-street parking
- Type of on-street parking
- Roadside fixed object density
- Presence of lighting
- Presence of automated speed enforcement

For calibration of Michigan-specific models, the following data elements should be acquired in order to perform calibration:

- Observed crashes on each segment
- MDOT region of the segment
- Segment length
- Lane width
- Left shoulder width
- Right shoulder width
- Median width
- On-street parking
- Driveway density
- Roadside fixed object offset
- Lighting
- Automated speed enforcement

4. Apply the SPF to determine the total predicted average crash frequency for each site during the calibration period as a whole. This is done using the equations in sections 6.0 and 6.1 of this report.
5. Calculate the number of expected fatal and injury multiple-vehicle crashes prior to the application of CMFs, $N_{\text {spfmv }}$
6. Calculate the number of expected fatal and injury single-vehicle crashes prior to the application of CMFs, $N_{s p f s v}$
7. Calculate the CMFs for fatal and injury vehicular crashes, $C M F_{1} \times \ldots \times C M F_{p}$
8. Sum $N_{s p f m v}$ and $N_{s p f s v}$, and apply the CMFs to calculate $N_{b i}$ for fatal and injury crashes
9. Calculate the number of expected PDO multiple-vehicle crashes prior to the application of CMFs, $N_{\text {spfmv }}$
10. Calculate the number of expected PDO single-vehicle crashes prior to the application of CMFs, $N_{s p f s v}$
11. Calculate the CMFs for PDO crashes, $C M F_{1} \times \ldots \times C M F_{p}$
12. Sum $N_{s p f m v}$ and $N_{s p f s v}$, and apply the CMFs to calculate $N_{b i}$ for PDO crashes
13. Add the fatal and injury $N_{b i}$ with the PDO $N_{b i}$ to obtain the predicted total of all automobile-only crashes
14. Apply the pedestrian and bicycle proportions to the total automobile-only $N_{b i}$, to obtain the predicted number of pedestrian and bicycle involved crashes
15. Add the pedestrian and bicycle crashes to $N_{b i}$ to obtain the predicted amount of total crashes
16. Compute calibration factors to use with each SPF. The purpose of the calibration factor is to scale the SPF to more accurately match the segments it is being used on. If an SPF predicts fewer total crashes than actually occur for the sum of all crashes of the calibration data set, a calibration factor greater than one is required. If the SPF predicts more crashes than actually occur for the calibration year, then a calibration factor less than one is needed to reduce the predicted crashes. The calibration factors for segments of a particular facility type, $C_{i}$, are computed with the following equation:

$$
C_{i}=\frac{\Sigma_{\text {observed crashes }}}{\Sigma_{\text {predicted crashes }}}
$$

### 7.3 Example Calibration

To illustrate this point, consider the following example: A set of 30 calibration sites experience a total of 100 crashes during the calibration year. The appropriate SPF predicts that the calibration sites should experience 105.099 crashes during the calibration year. The calibration factor of this facility type is calculated by

$$
C_{i}=\frac{100}{105.099}=0.951
$$

This calibration factor can then be applied when predicting crashes for segments of the appropriate facility type. This concept is illustrated in Table 70.

Table 69. Example Calibration

| Hypothetical Segment | Hypothetical Observed Crashes | Hypothetical Predicted Crashes | Calibrated Predictions |
| :---: | :---: | :---: | :---: |
| 1 | 4 | 2.983 | 2.839 |
| 2 | 3 | 3.283 | 3.124 |
| 3 | 3 | 2.983 | 2.839 |
| 4 | 2 | 3.583 | 3.409 |
| 5 | 1 | 3.283 | 3.124 |
| 6 | 0 | 3.883 | 3.695 |
| 7 | 6 | 4.183 | 3.980 |
| 8 | 3 | 3.583 | 3.409 |
| 9 | 4 | 3.283 | 3.124 |
| 10 | 2 | 3.583 | 3.409 |
| 11 | 1 | 3.583 | 3.409 |
| 12 | 2 | 3.883 | 3.695 |
| 13 | 3 | 2.533 | 2.410 |
| 14 | 5 | 4.483 | 4.266 |
| 15 | 1 | 2.983 | 2.839 |
| 16 | 8 | 3.283 | 3.124 |
| 17 | 9 | 3.133 | 2.981 |
| 18 | 0 | 3.433 | 3.267 |
| 19 | 3 | 2.683 | 2.553 |
| 20 | 6 | 4.783 | 4.551 |
| 21 | 3 | 4.183 | 3.980 |
| 22 | 5 | 4.183 | 3.980 |
| 23 | 3 | 3.283 | 3.124 |
| 24 | 0 | 3.283 | 3.124 |
| 25 | 4 | 3.583 | 3.409 |
| 26 | 6 | 4.483 | 4.266 |
| 27 | 4 | 2.683 | 2.553 |
| 28 | 4 | 2.983 | 2.839 |
| 29 | 5 | 3.583 | 3.409 |
| 30 | 0 | 3.433 | 3.267 |
| Total | 100 | 105.099 | 100 |
| Calibration Factor |  | 0.951 |  |

### 7.4 Long Term Maintenance and SPF Re-estimation

In the future, MDOT may wish to re-estimate the SPFs developed in this research. In order to accomplish this task, data should be collected and organized as described in Section 3 of this report. Data available in Safety Analyst may be sufficient to estimate SPFs when used in conjunction with crash data from the Michigan State Police. In lieu of the discontinuation of the Sufficiency File maintained by MDOT, manual data collection may be necessary if available data sources do not contain geometric data. This research found the following variables to significantly influence crashes within at least one of the segment site types:

- AADT
- Commercial vehicle percent
- Lane width
- Median width
- Right shoulder width
- Posted speed limit
- Driveway density
- Count of schools
- Intersection density
- Crossover density

These characteristics provide a starting point for data collection to re-estimate the SPFs;; however, changes in driver behavior and roadway characteristics may lead to additional characteristics becoming significant in the future. In addition to roadway characteristics, this research found variation in estimated crash frequency between MDOT regions, making the inclusion of MDOT region classification a relevant characteristic. Note that a newly proposed regional scheme is scheduled for implementation by MDOT in the near future.

Once the dataset has been assembled, statistical analysis software must be utilized to estimate the effects of each roadway characteristic on each facility type. Negative binomial models, the standard for SPF development, should be used. A functional form of the model must be identified. Recall that separate models have been developed for single-vehicle and multiple-vehicle crashes at FI and PDO severity levels. For a given severity level, the general equation for the predicted number of crashes is shown below.

$$
\begin{aligned}
& N_{j}=\left(N_{s p f m v} I_{m v}+N_{s p f s v} I_{s v}\right) \times C M F_{l w} \times C M F_{l s w} \times C M F_{r s w} \times C M F_{m w} \times C M F_{p k} \times C M F_{f o} \\
& \times C M F_{d w} \times C M F_{l g t} \times C M F_{s p d}
\end{aligned}
$$

The equation for multiple vehicle and single vehicle crashes based on the natural log of AADT and the MDOT regional indicators are shown below.
$N_{s p f m v}=n \times L \times e^{b_{m v}+b_{m v 1} \ln (A A D T)+b_{c o m} \frac{A A D T_{c o m}}{A A D T}+b_{r 1} I_{r 1}+b_{r 2} I_{r 2}+b_{r 3} I_{r 3}+b_{r 4} I_{r 4}+b_{r 5} I_{r 5}+b_{r 6} I_{r 6}}$
$N_{s p f s v}=n \times L \times e^{b_{s v}+b_{s v 1} \ln (A A D T)+b_{c o m} \frac{A A D T_{c o m}}{A A D T}+b_{r 1} I_{r 1}+b_{r 2} I_{r 2}+b_{r 3} I_{r 3}+b_{r 4} I_{r}+b_{r 5} I_{r 5}+b_{r 6} I_{r 6}}$
Ultimately, the results of the statistical analysis will yield parameter estimates, or coefficients, as well as significance levels and information regarding the accuracy of the parameter estimation. The parameter estimates will serve as the "b" values in the SPF equations, provided they are significant at a 95 percent confidence interval or their inclusion can otherwise be justified using engineering judgement. The equation above illustrates that AADT is generally log-transformed, which has been shown to provide improved fit.

The effects of other roadway characteristics such as lane width or speed limit are accounted for through the creation of CMFs. In Section 3, it was mentioned that the "base" scenario is represented with a CMF of 1.0 for a specific roadway characteristic. Based on engineering judgement, it may be desirable to transform the data collected for any specific roadway feature so that a particular case is used as the base scenario. For example, in this research it was determined that the base condition for the driveway CMF is 10 commercial driveways per mile, three industrial driveways per mile, eight residential driveways per mile, and 10 other type driveways per mile. Therefore, all segments which have the aforementioned number of driveways for each type, would have a CMF of 1.0. The driveway CMF is described using the following equation:

$$
C M F_{d w}=e^{0.014\left(n_{d w c}-10\right)} \times e^{0.005\left(n_{d w i}-3\right)} \times e^{0.002\left(n_{d w r}-8\right)} \times e^{0.003\left(n_{d w o}-10\right)}
$$

Re-estimation/long-term maintenance of the SPFs will require careful data collection and analysis. The resulting SPFs can only be as good as the data they are based upon. The SPFs presented in this report are the result of extensive data collection and analysis, and ultimately serve as a guideline for the re-estimation of Michigan-specific SPFs in the future.

### 8.0 CONCLUSIONS

This project involved the development of a uniform, consistent approach that can be applied to estimate the safety performance of urban trunkline segments at an aggregate (i.e., total crash), crash type, and crash severity level. The study results provide important guidance to allow MDOT to make informed decisions when planning and programming safety projects.

This report documents the processes involved in developing safety performance functions (SPFs) and crash modification factors (CMFs) for eight types of arterial roadway segments in Michigan. These tools were developed using a robust database which combined traffic crash, volume, and roadway geometric data. These data were obtained from the following sources:

- Michigan State Police Statewide Crash Database;
- MDOT Sufficiency File;
- MiGDL All Roads File;
- MDOT Driveway File;
- WSU Curve Database;
- WSU Intersection Inventory; and
- Google Earth.

Through the MDOT Sufficiency File and Driveway File, important information on traffic volume, roadway geometric information, speed, and driveway count by type of land use were provided. Additionally, curvature information was extracted through a database created by WSU. Crash information was obtained through the Michigan State Police Crash Database and crashes were linked to each roadway segment through the utilization of a linear referencing system. Crossover information was collected manually using Google Earth and included a count of crossovers as well as type of traffic control. These data were aggregated to develop a comprehensive database of segments including five years of crash, volume, and roadway characteristics for each segment. The final sample was comprised of the following number of locations by site type:

- 489 two-lane undivided (2U) segments;
- 236 three-lane (3T) segments;
- 373 four-lane undivided (4U) segments;
- 439 four-lane divided (4D) segments;
- 239 five-lane (5T) segments;
- 119 six-lane divided (6D) segments;
- 166 eight-lane divided (8D) segments
- 189 One-Way (OW) segments.

After the data were assembled, an exploratory analysis of the data was conducted separately for each segment type to identify general crash trends using Michigan-specific data. The results indicated that a non-linear relationship generally existed between traffic flow and the number of crashes, especially for undivided and one-way segments. With respect to pedestrian and bicycle crashes, it was found that more crashes involving pedestrians or bicyclists occur at lower major road AADT volumes.

In order to provide MDOT with a tool to calculate predicted crash frequency on a particular segment, a series of SPFs were developed. First, the base SPFs from the Highway Safety Manual (HSM) were applied to the Michigan segment data. A calibration exercise illustrated that the models, without calibration, provided inconsistent fit across site types, crash types, and severity levels.

After the calibration exercise, a series of Michigan-specific SPFs were developed. These included a series of simple statewide models, which consider only AADT estimates, as well as regionalized models, which account for differences in traffic, environment, and roadway geometry. In addition to these SPFs, crash type distributions were also developed at a statewide and regional level. While AADT-only SPFs are provided for total, fatal/injury, and property damage only crashes within each of the eight segment types, preliminary models are also provided for pedestrian- and bicycleinvolved crashes.

Lastly, more detailed SPFs were estimated that considered traffic volume, speed limits, functional class, and numerous roadway geometric variables such as shoulder and median width; driveway density by land type; intersection and crossover density; and horizontal curvature. These detailed statistical models account for the effects of this wide range of factors, as they provide the greatest degree of accuracy. The models have been calibrated such that they are able to account for the effects of traffic volumes, roadway geometry, regional differences, and other effects.

Within each site type, separate SPFs are also provided to allow for the prediction of vehicleinvolved crash frequency (i.e. single- and multi-vehicle crashes), as well as pedestrian- or bicyclerelated crashes as a percentage of the vehicular crashes. Distributions are also provided to allow
for disaggregation of multi-vehicle crashes into various collision type categories (e.g. rear-end, head-on, angle etc.).

In addition to the SPFs, which were developed for specific base conditions, CMFs were also developed, which can be used to adjust the SPF estimate when the characteristics of a segment are not consistent with the base conditions. Several variables are incorporated in the development of the SPFs and CMFs including AADT, MDOT Region, lane, right and/or left shoulder,median width, on-street parking, driveway density by land use; school count, posted speed limit, and intersection and crossover density. All of the models developed as a part of this project are calibrated such that they can be applied at either the statewide level or within any of MDOT's seven geographic regions.

In addition to the Michigan-specific SPFs and CMFs developed as a part of this study, SDFs were developed which can be used to predict the proportion of injury crashes which result in different injury severity levels. The SDFs can be used with the SPFs to estimate the expected crash frequency for each severity category. The SDFs may include various geometric, operation, and traffic variables that allow the estimated proportion to be specific to an individual segment.

This report also documents a procedure for maintaining and calibrating these SPFs over time. Calibration will allow for MDOT to account for yearly changes in traffic volumes and general trends in crashes over time that are not directly reflected by the predictor variables. As MDOT continues to build its data system, the use of additional geographically-referenced geometric, operational, and traffic control data will allow for further refinements to these analytical tools.
