MINETA TRANSPORTATION INSTITUTE

LEAD UNIVERSITY OF

Mineta Consortium for Transportation Mobility

Founded in 1991, the Mineta Transportation Institute (MTI), an organized research and training unit in partnership with the Lucas College and Graduate School of Business at San José State University (SJSU), increases mobility for all by improving the safety, efficiency, accessibility, and convenience of our nation's transportation system. Through research, education, workforce development, and technology transfer, we help create a connected world. MTI leads the four-university Mineta Consortium for Transportation Mobility, a Tier 1 University Transportation Center funded by the U.S. Department of Transportation's Office of the Assistant Secretary for Research and Technology (OST-R), the California Department of Transportation (Caltrans), and by private grants and donations.

MTI's transportation policy work is centered on three primary responsibilities:

Research

MTI works to provide policy-oriented research for all levels of government and the private sector to foster the development of optimum surface transportation systems. Research areas include: bicycle and pedestrian issues; financing public and private sector transportation improvements; intermodal connectivity and integration; safety and security of transportation systems; sustainability of transportation systems; transportation / land use / environment; and transportation planning and policy development. Certified Research Associates conduct the research. Certification requires an advanced degree, generally a Ph.D., a record of academic publications, and professional references. Research projects culminate in a peer-reviewed publication, available on TransWeb, the MTI website (http://transweb.sjsu.edu).

Education

The Institute supports education programs for students seeking a career in the development and operation of surface transportation systems. MTI, through San José State University, offers an AACSB-accredited Master of Science in Transportation Management and graduate certificates in Transportation Management, Transportation Security, and High-Speed Rail Management that serve to prepare the nation's transportation managers for the 21st century. With the active assistance of the California Department of Transportation (Caltrans), MTI delivers its classes over a state-of-the-art videoconference network throughout the state of California and via webcasting beyond, allowing working transportation professionals to pursue an advanced degree regardless of their location. To meet the needs of employers seeking a diverse workforce, MTI's education program promotes enrollment to under-represented groups.

Information and Technology Transfer

MTI utilizes a diverse array of dissemination methods and media to ensure research results reach those responsible for managing change. These methods include publication, seminars, workshops, websites, social media, webinars, and other technology transfer mechanisms. Additionally, MTI promotes the availability of completed research to professional organizations and journals and works to integrate the research findings into the graduate education program. MTI's extensive collection of transportation- related publications is integrated into San José State University's world-class Martin Luther King, Jr. Library.

16. Abstract Authors of this research developed a traffic simulation model for the downtown San Jose network and evaluated five different street redesign and travel demand combinations. This model aids understanding of network-wide effects of changes in street design for local and regional agencies who are interested in implementing complete streets and/or one-way to two-way conversion. The base network may be altered to model and evaluate other complete streets (e.g., road diet) and tactical urbanism (e.g., farmer's market on city streets on certain days of the week) scenarios. The 3-dimensional animated videos for each scenario are also created to be used for public outreach by the city to engage the stakeholders in the planning and implementation process. Quantitative measures used for evaluating the scenarios include travel times on key corridors and network-wide delays during the afternoon peak hour. The evaluation shows the current city street network will be able to sustain a modest (between 5% and 10%) increase in single-occupancy automobile travel demand. The network will be overwhelmed if the single-occupancy automobile travel demand were to increase to the level projected per the city's 2040 general plan. This outcome points to the need for strong Travel Demand Management (TDM) measures.

EXECUTIVE SUMMARY

The goal of this project is to improve multimodal mobility and public life in downtown San Jose through "complete-street" strategies, assessed using microscopic traffic simulation models. "Complete streets" are streets designed to accommodate multiple modes of transportation, activities, and users, including pedestrians, cyclists, transit riders, drivers, and local business owners and residents. By promoting alternative modes of travel (walking, bicycling, and public transit), complete streets also help reduce greenhouse gas emissions for the transportation sector. The City of San Jose provided data for the surface street network for the core of the downtown San Jose. This network was modeled in a microscopic simulation environment (PTV VISSIM). Significant effort went into making sure that the existing street network, road user behavior, and its Origin-Destination (O–D) patterns were captured so that reliable information about future scenarios could be obtained from the models.

Examining the literature on evaluation of complete street conversions we found that before/after real-world data, as well as simulation models, have been used for evaluating complete street scenarios. However, most studies (including all simulation-based work) focused only on the evaluation of the streets being converted and did not examine the network-wide impacts of the conversion. Detailed microscopic modeling of the downtown core, along with its O–D patterns, provides a way to assess network-wide impacts of changes to individual corridors.

The team examined the travel demand forecasting model which was developed for the 2040 Envision San Jose General Plan and found that the automobile demand is projected to increase significantly, especially for certain parts of the downtown. The mobility of these residents, visitors, and businesses cannot be accommodated by streets that focus on the single-occupancy automobile mode of transportation. To increase the potential for individuals to use non-single-occupancy-automobile modes of travel, the city will need a significant Travel Demand Management (TDM) plan. The output metrics from the simulation models for the base case (2015 demand) and for various projected scenarios indicated that as long as the automobile travel demand is managed to be at current or modestly higher levels (~5–10%), the conversion of individual one-way streets and/or couplets to two-way streets won't have significantly adverse impacts on overall peak-hour delays compared to the base case. The investigators have provided the city with the simulation models so that they can be used for future evaluations of other scenarios. The modeling software also provided three-dimensional (3-D) animations of the multimodal traffic flow that can be used in public forums for community outreach, consistent with the need for visualization tools that have been identified in the academic literature as well as in federal legislation (e.g., SAFETEA-LU).

I. INTRODUCTION

As major cities grow, it would be easier to meet demand if other modes, requiring less road space per traveler, were better accommodated. It is desirable for streets to be designed for everyone, whether young or old, on foot or on the bicycle, in a car or on a bus; streets embodying this ideal are called "complete streets."[1] Complete streets are streets designed to accommodate multiple modes of transportation, activities, and users, including pedestrians, cyclists, transit riders, drivers, and local business owners and residents. According to a recent Future of Transportation National Survey, 66% of Americans want more transportation options so they have the freedom to choose how to get where they need to go, 73% currently feel they have no choice but to drive as much as they do, and 57% would like to spend less time in the car.[2] These figures indicate the need for a cohesive plan to integrate multimodal use and public life.

For effective multimodal transportation networks to be implemented, public involvement is a key factor in the planning and decision-making process. This process is should involve two-way communication between citizens and government, allowing public transportation agencies to notice, inform, and include the public while using the feedback to develop relationships within the community and build better transportation projects. Lack of public participation can lead to minimal community support, resistance from stakeholders and elected officials, and outcries from the public that could end up in costly project delays or even lawsuits.[3] Visualizations can be effectively used for describing plans to the public within transportation planning process, as was recognized and mandated by the Safe, Accountable, Flexible, Efficient, Transportation Equity Act: A Legacy for Users (SAFETEA-LU).[4, 5] While SAFETEA-LU has now expired, using visual three dimensional (3-D) animations displaying potential project scenarios, in conjunction with quantitative analysis and results, is a great way to engage and inform the community during public outreach.

This research created a simulation-based framework to evaluate network-wide implications of converting streets into complete streets. In addition to quantitative metrics such as travel-time and vehicular throughput, animated 3-D visualizations were also produced for the modeled scenarios. Best practices for using these visualizations in project implementation are also described.

STUDY AREA: DOWNTOWN SAN JOSE

Located in the heart of Silicon Valley, San Jose is the 3rd largest city in the State of California and the 10th largest city in the USA.[6] Downtown San Jose continuously attracts new residents, visitors, and businesses while experiencing tremendous growth and providing opportunities to technology professionals and others [7]. As a result, downtown San Jose becomes more crowded by the day. Downtown San Jose also houses several key destinations such as Diridon station, a crucial central transit hub for Silicon Valley, and the SAP Center, a major event venue. For a city the size of San Jose to be efficient and livable, urban transport systems should be able to more effectively accommodate resource-efficient modes of travel such as walking, cycling, and transit.[8] Similarly, tactical urbanism—the use of low-cost, low-commitment modifications to the built environment (such as seating, automobile barriers, and food carts), to improve social interaction and public life—can help in creating demand for these more efficient transportation modes, and utilize the urban street space more effectively.

The study area (Figure 1) consists of approximately 5 square miles concentrated in the core of Downtown San Jose. Within the study area, Interstate 280 (I-280) and California State Route 87 (CA 87) serve as important routes of entry and exit into the downtown area.

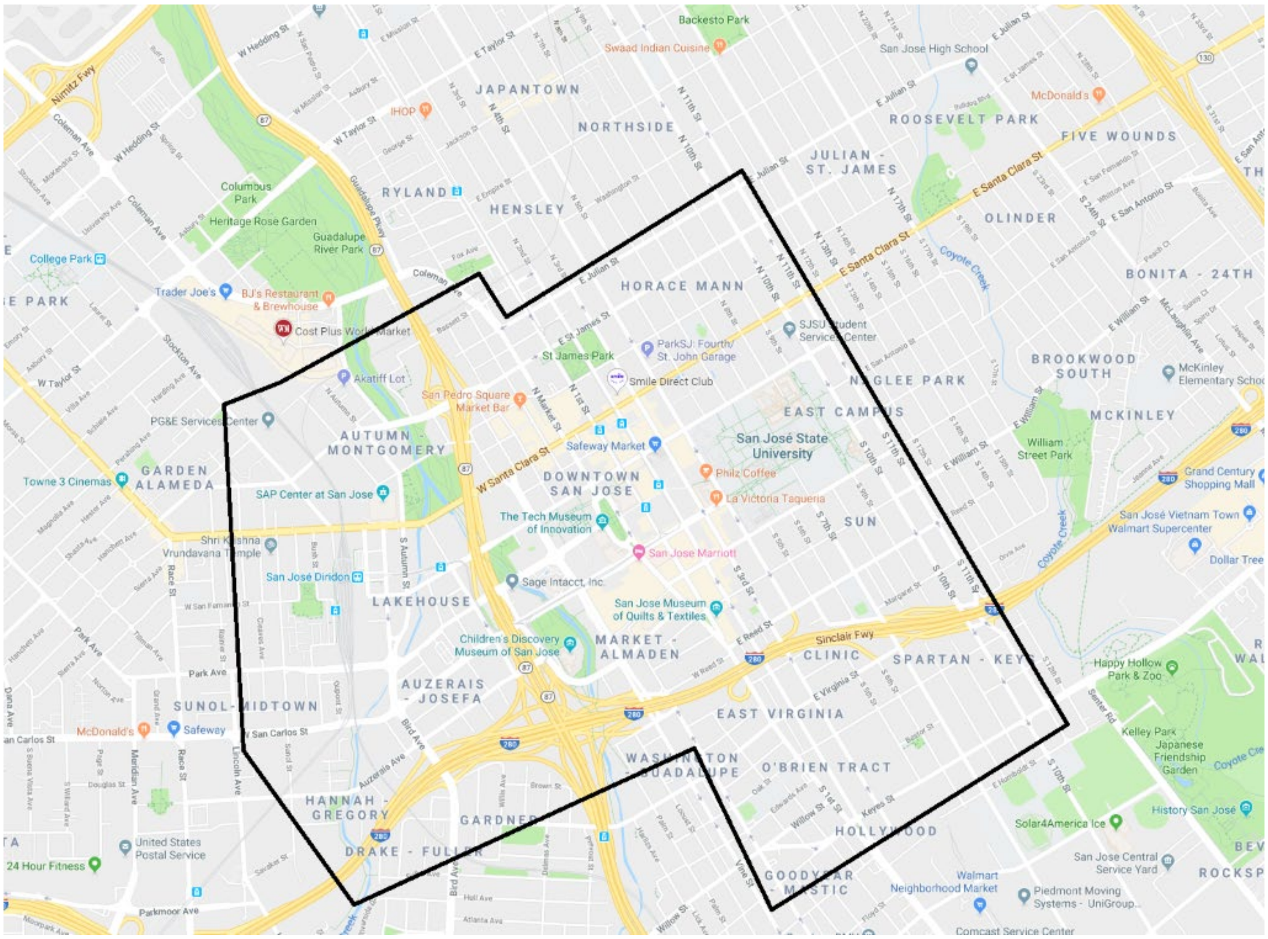

Figure 1. Study Area Map

STUDY OBJECTIVES

Simulation models can aid transportation planners and designers in assessing the impact of various alternatives to existing systems. The use of simulation can help the City of San Jose visualize and evaluate the collective behaviors and patterns of travelers as well as the implications these behaviors have for the whole transportation network. Network performance can be analyzed and compared for before and after scenarios to answer “what-if” questions.

The objectives of this study are:

- To assess complete-street and tactical-urbanism strategies identified by the City of San Jose, through microscopic traffic simulation models.

- To test and refine scenariO–Development techniques and develop a micro-simulation evaluation framework that can help other cities adopt similar strategies.

- To provide a framework to use the 3-D visualization created from the simulation models for public information campaigns.

REPORT ORGANIZATION

The report is organized as follows. Chapter 2 presents a literature review of relevant past studies. Chapter 3 outlines the development and coding for the model, detailing the process of data collection, network coding, calibration, and validation for the base conditions (2015 traffic). Chapter 4 describes and compares the results for different scenarios, including both quantitative metrics and 3-D visualizations; it also discusses the use of the latter for public information campaigns. Finally, Chapter 5 contains a summary of conclusions along with recommendations for future work.

II. LITERATURE REVIEW

This chapter reviews traffic simulation applications, and potential advantages and disadvantages that microsimulation offers over more macroscopic modeling. It also discusses complete streets and tactical urbanism within a downtown context, and the development of large-scale microscopic traffic simulation models.

TRAFFIC SIMULATION

Simulation, a way of numerically modeling the behavior of systems over time through the use of computer software, is an increasingly popular and effective tool for analyzing the behavior and interactions of traffic systems. Simulation models can provide an understanding of cause-and-effect relationships and satisfy a wide range of applications, including evaluation of alternative treatments, testing of new designs, training of personnel, and safety analysis. Simulation models are useful in studying models too complicated for analytical treatment and cases where there is a need to view vehicle animation.[9] Modern traffic simulation models can answer “what-if” questions to aid system designers in assessing the impact of various changes on existing systems in a cost-effective way.[10] Based on the simulation model for an underlying transportation network, one can obtain performance measures such as delay, emissions, average speeds, travel time, and others.

SIMULATION MODEL CHOICES

Depending on the desired level of detail to be studied, simulation models can be classified as microscopic, mesoscopic, or macroscopic.

Microscopic models provide a detailed representation of the traffic process, considering the characteristics of individual vehicles and simulating vehicle interactions in the traffic stream based on car-following and lane-changing theories. Microsimulation offers benefits in clarity, accuracy, and flexibility. It can provide a comprehensive real-time visual display to illustrate traffic operations in a readily understandable manner. Individual vehicles make their own decision on speed, lane changing, and route choice. The dynamic evolution of traffic congestion and the effectiveness of traffic management strategies can be evaluated with microsimulation. These models are typically used for short-term and congestion-related issues. Compared to macroscopic models, a microscopic model is only practical for smaller networks and shorter modeling periods, due to the high number of data inputs, calibration and validation efforts, and computing power for modeling and analysis.[11]

Macroscopic models describe systems and their activities and interactions at a low level of detail. Rather than considering individual vehicles’ behaviors and interactions, macroscopic models consider aggregate variables such as average speeds. These models consider variables such as land use, socioeconomic demographical data, and travel behaviors to perform operational analysis and long-term forecasting. In a macroscopic traffic model, trips are assumed to load simultaneously on a link and to share the same speed and time period. Lower-fidelity models are easier and less costly to develop, execute, and maintain. However, due to the low level of detail, their representation of the real-world system may be less accurate. Macroscopic models are more appropriate for regional or large-scale systems, and can provide predictions of current and future travel patterns and demand.[12]

A mesoscopic model is a hybrid of microscopic and macroscopic models. These models do represent vehicles and some of their behaviors individually, but model some features of the system only in the aggregate, simplifying interactions. For example, such a model might represent individual vehicles' decisions to change lanes, but model this decision as being made in response to aggregate traffic flow, rather than to the vehicle's proximity to other individual vehicles.[13, 14]

Models can also be classified as deterministic or stochastic. Deterministic models have no random variables and perform the same way for a given set of initial conditions. Stochastic models have processes that include probability functions, introducing randomness into the model, and their exact outcomes will differ each time the model is run, though they may be qualitatively similar.

ADVANTAGES AND DISADVANTAGES OF TRAFFIC SIMULATION

Traffic simulation models are powerful tools because they provide relatively inexpensive, fast, and risk-free evaluation environments. They not only account for a variety of different scenarios that cannot be practically tested in real-world conditions, but also provide various network performance measures, becoming a very useful and widely accepted tool in transportation engineering applications.

Park, Yun, & Choi provided a case study reviewing four discrete-time microscopic traffic models and evaluating their performances.[15] One of the models was CORSIM, which is a microscopic simulation model developed for the Federal Highway Administration (FHWA) and is used mainly in modeling urban traffic conditions.[16,17] CORSIM does not have a robust multimodal functionality. In addition, because it relies on link-based, as opposed to route-based, input volumes it is difficult to use for obtaining network-level measures. Paramics, developed by Quadstone Limited, is a suite of high-performance tools for microscopic traffic simulation. This software allows application program interfaces (APIs). However, these APIs are not built into the model and need to be created by the user. The program lacks automatic vehicle diffusion for vehicles that get stuck at a simulated network location (e.g., trying to change a lane), potentially creating large discrepancy and high variability in data output. SIMTRAFFIC, created by Trafficware Inc., is companion software to SYNCHRO, a signal optimization tool, and only able to run SYNCHRO input files.[18] This software focuses on checking and fine-tuning traffic signal operation. PTV VISSIM, created by PTV Vision, is a microscopic behavior-based simulation model developed to model urban transportation operations.[19] A weakness of this program is its lack of a built-in actuated controller program (overcome through an add-on RBC interface) and its inability to produce HCM compatible output. CORSIM and SIMTRAFFIC have network limits, while PTV VISSIM and Paramics do not. In evaluating these programs for modeling signalized intersections, Park et al. concluded that PTV VISSIM and Paramics more effectively modeled various signal timing plan use cases compared to SIMTRAFFIC and CORSIM.

We chose PTV VISSIM for this study primarily due to the program's ability to analyze multimodal traffic (i.e., automobile, bicycles, and pedestrians) as well as transit operations under constraints such as lane configuration, traffic composition, traffic signals, transit stops, and other similar criteria, thus making it a useful tool for the evaluation of various alternatives.[20] PTV VISSIM also allows for the interaction of different modes of transportation, including bicycles, transit, automobiles, and pedestrians. This flexibility of being able to model interactions between different modes of transportation is ideal for evaluating the network changes expected in our study.

Shortcomings of traffic simulations include the amount of time needed to develop a good simulation model, difficulty understanding simulation data, and computer limitations, and can also include unrealistically simplified driver behavior.

Table 1, reproduced from Chapter 31 of the Highway Capacity Manual (HCM 2000),[21] summarizes the strengths and flaws of the simulation approach to traffic modeling.

Table 1. HCM Simulation Model Analysis

Simulation Strengths	Simulation Shortcomings
Other analytical approaches may not be appropriate	
Can experiment off-line without using an on-line trial-and-error approach	Simulation models require considerable input characteristics and data, which may be difficult or impossible to obtain
Can experiment with new situations that do not exist today	Simulation models may require verification, calibration, and validation, which, if overlooked, make such models useless or not dependable
Can provide insight into what variables are important and how they interrelate	Development of simulation models requires knowledge in a variety of disciplines, including traffic flow theory, computer programming and operation, probability, decision making, and statistical analysis
Can provide time and space sequence information as well as means and variances	The simulation model may be difficult for analysts to use because of the lack of documentation for unique computer facilities
Can study system in real-time, compressed time, or expanded time	Some users may apply simulation models and not understand what they represent
Can conduct potentially unsafe experiments without risk to system users	Some users may apply simulation models and not know or appreciate model limitations and assumptions
Can replicate base conditions for equitable comparison of improvement alternatives	
Can study the effects of changes on the operation of a system	
Can handle interacting queuing processes	
Can transfer unserved queued from one time period to the next	
Can vary demand over time and space	
Can model unusual arrival and service patterns that do not follow more traditional mathematical distributions	

SIMULATION STUDY STEPS

Successfully using a mathematical model requires understanding its operations and input data. Lieberman and Rathi[22] suggested the following process to build and apply traffic simulation models:

1. Define the problem and model objectives.
2. Define the system to be studied.
3. Develop the model.
4. Calibrate the model.
5. Verify the model.
6. Validate the model.
7. Document activities.

The first step in any study is to identify and describe the scope of the problem. This step includes stating the model's purpose and identifying the information desired from the model, such as travel time, travel volume, and queue lengths.

The second step is to identify the geographical boundary of the physical area being modeled , data input, and traffic control environment (e.g., signals, stop signs etc.). The elements in this step include city streets, state highways, highway geometrics, peak hour factor, intersection volumes, and speed data.

The third step, model development, identifies the type of model that should be used, depending on the level of complexity needed to satisfy the objectives. At this point, a model type (whether microscopic, macroscopic, or mesoscopic, and whether deterministic or stochastic) and appropriate software for running that model are also selected. Calibration criteria and a logical structure for integrating model components (such as street network and traffic controls) are established.

The fourth step is to calibrate the model. The real-world data needed for calibration is collected and introduced into the model. Details such as signal timing, satellite imagery, vehicle composition, speeds, and traffic are all needed to complete the simulation model. A small section of the modeled area is tested against real-world data to calibrate the model. This step entails adjusting simulation factors such as perception time, headway allocations, and traffic control device locations, and determines whether the calibration is accurate and adequate.

The fifth step, verification of the model, includes a visual check to monitor for any unrealistic and unusual network behavior. It may be that the software replicates a model component properly as designed, but that its performance deviates from the theoretical expectations or empirical observations; if this occurs, one must go back to step four, model calibration.

The sixth step is to validate the model by collecting, reducing, and organizing data from the model to compare to actual data. At this step, statistical tests establish whether the model describes the real system at an acceptable level of accuracy. Validation is extremely crucial because a model that cannot replicate known data cannot be trusted as a proxy for unknown data. Therefore, in addition to the statistical test results, one must be attentive to the proper representation of vital processes within the overall model, errors in the input data, reasonable output developed from simulation trials, and potential “bugs” in the model and algorithms utilized. A detailed inspection of the animation is an excellent tool for observing the traffic setting and interpreting the simulation output. Validation often occurs alongside calibration and verification.

The seventh and final logical step described by Liberman and Rathi, to be carried out simultaneously with all the others, is proper documentation. This includes summarizing the steps taken to create the model, creating a user manual, and documenting algorithms and software used. Documentation provides future users with a guide with which they can critique and understand the model and its analysis.

DEVELOPMENT OF LARGE-SCALE MICROSCOPIC TRAFFIC SIMULATION MODEL

Large-scale traffic simulation models require detailed data from many sources, as well as proper calibration and validation. Small errors in microscopic models are greatly magnified in large networks.[23]

Jha et al.[24] developed and calibrated a microscopic traffic simulation model, using MITSIMLab, for the entire metropolitan area of Des Moines, Iowa. Origin–Destination (O–D) Zone aggregations was used to generate 19,000 to 21,000 O–D pairs (number of trips from a zone (origin) to another zone (destination)). Parameters and inputs to be calibrated for this model included parameters of the driving behavior model, parameters of the route choice model, O–D flows, and habitual travel times. Although ideally these should all be calibrated jointly, the scale of the model led them to calibrate the driving behavior parameters separately from the others. An iterative process was used to calibrate the remaining parameter and inputs. The paper concluded that its calibration and validation results were promising.

More recently, Bartin et al.[25] calibrated and validated a large-scale traffic simulation network with a case study in New Jersey. Their model was developed using PARAMICS and calibrated and validated using throughout, queue lengths, and travel times at selected key locations in the network. Bartin et al. described the calibration and validation process as an iterative process including error-checking, demand estimation, capacity calibration, route choice calibration, and system performance calibration. Their paper details the modeling effort required to build a large-scale traffic simulation model, including the available data requirements, generating and O–D matrix, where displays the number of trips going from each origin to each destination and the results of the calibration and validation process.

Edara, Sharma and McGhee[26] developed a large-scale traffic simulation model for hurricane evacuation, for a case study of Virginia's Hampton roads region, using PTV VISSIM. Their approach to the O–D demand matrix utilized the Abbreviated Transportation Model (ATM), which is based on tract and population data from the 2000 U.S. Census.

COMPLETE STREETS

The term "complete streets" refers to roads designed to accommodate multiple modes, activities and users, including pedestrians, cyclists, transit riders, drivers, and local business owners and residents. An example of a downtown street before and after conversion to a complete street is shown in Figure 2.[27] In the 'before' illustration the bus stop is obstructed by an illegally parked car; in the 'after' illustration, a bus bulb has provided to address this issue. This is one example of how complete street conversion supports more efficient modes of travel. There are several studies, documented in the subsequent section of this chapter, that reported benefits of complete street conversions; however, the literature has also noted that the benefits depend heavily on the local context.[28]

Figure 2. Illustration of Before (Top) and After (Bottom) Complete Street Conversion[29]

Road Diet

A road diet conversion is a type of complete street conversion in which the number of lanes and effective width of a road are reduced, so that the road space can be used for other purposes and travel modes.[30] Road diet reconfigurations typically consist of converting an undivided four-lane roadway to a three-lane undivided roadway made up of two through lanes and a center two-way left-turn lane, as seen in Figure 3. Research on an urban arterial street noted that while road diet conversion may increase travel time due to capacity reduction, the benefits associated with the reduction in traffic crashes overwhelmingly exceed the costs of additional delay.[31] In addition to reducing overall crashes, road diets improve safety by reducing vehicle speed differential and vehicle interactions. When traffic is reduced to one lane per direction, the speed differential is limited by the lead vehicle.[32] Litman[33] has also mentioned that post-road diet conversion, off-peak traffic may move slower but peak-period traffic may move faster. Nixon et al.[34] have noted the need to study the impact of road diet programs both on the road diet location itself and on the surrounding streets.

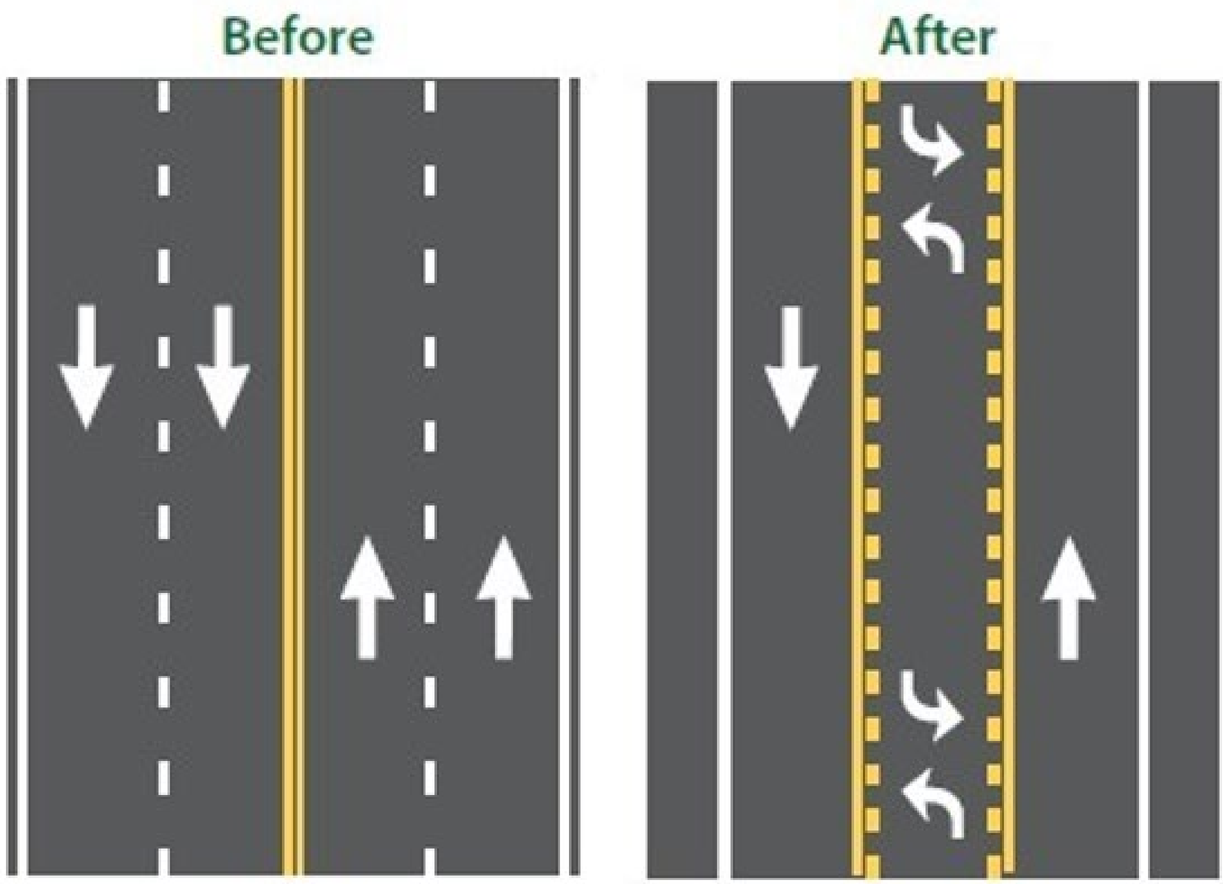

Figure 3. Typical Road Diet Basic Design[35]

One-way to Two-way Street Conversions

One-way streets to two-way street conversions allow for better local access and reduced speeds.[36] The most common reasons for converting one-way to two- way streets include the improvement of confusing circulation patterns, increased business exposure and access to passing motorists, slower traffic speeds, and improved pedestrian and bicycle safety.[37] Sisiopiku and Chemmannur[38] studied the conversion of one-way street pairs to two-way streets in downtown Birmingham using Synchro and CORSIM. A comparison of the pre- and post-conversion conditions indicated no major negative impacts on traffic circulation, such as unfavorable delays or spillbacks. Chiu, Zhou, and Hernandez[39] used a multiple resolution simulation and assignment approach, entailing integration of two traffic simulation assignment methods—a dynamic traffic assignment and a microscopic traffic simulation model—to estimate traffic and environmental impacts resulting from downtown traffic flow conversions. Their study included a case study in El Paso, concluding that two-way configurations do not always improve traffic performance; however, they also showed that if carefully analyzed and designed, opportunities exist in order to make a two-way configuration a desirable option.

Complete Street Effects on Neighboring Streets

In one of the previous sections (“Road Diet”), several studies demonstrating the benefits of complete streets conversions were cited and documented. However, studies cited in that section, with the exception of Nixon et al.[40] focused only on the corridor being converted without analyzing the effects on the surrounding network. However, understanding network-wide effects are critical for understanding whether traffic and safety issues have merely been passed on to adjacent streets.

In addition to the previously cited Nixon et al. study, there have been a few others recently that have attempted to examine the effects of complete street conversion on surrounding network. Smart Growth America showcased a project in Seattle, Washington where the redesign of Stone Way North reduced speeds, increased bicycle traffic, and decreased collisions while peak traffic volumes city-wide remained consistent and no traffic diversion to parallel streets occurred.[41] Zhu et al.[42] studied the effects of complete streets on travel behavior in the Los Angeles area, by comparing complete to incomplete streets. The study reported that three out of six sites had lower total traffic volume on the complete streets compared with the incomplete streets. Two other sites showed the opposite to be the case, and, on one of the sites, there was no significant difference in traffic volumes between complete and incomplete streets. Their study suggests that the differences between complete and incomplete streets are site-specific and results can vary greatly depending on the location and function of the complete streets. These studies in addition to the Nixon et al.,[43] indicate that a pre-implementation assessment of network effects of complete street conversion may be useful for agencies considering these changes.

TACTICAL URBANISM

The phrase “tactical urbanism” refers to low-cost, temporary interventions, such as temporary street closures for farmers markets and/or public pedestrian plazas, intended to improve local neighborhoods and city gathering places.[44] More specifically, the Street Plans Collaborative defines “tactical urbanism” as an approach to urban change that features the following five characteristics:

1. A deliberate phased approach to instigating change;
2. The offering of local solutions for local planning challenges;
3. Short-term commitment and realistic expectations;
4. Low risks, with a possibility of high reward; and
5. The development of social capital between citizens and the building of organizational capacity between public-private institutions, non-profits, and their constituents.

Examples of tactical urbanism include ad hoc conversion of on-street parking spaces to dining or seating areas, filling of awkward corners where the excess pavement is unused, and others.[45] Tactical urbanism projects can also serve as pilot studies by generating data and public feedback for the temporary changes in street design. This allows cities to test out and improve upon ideas before they invest in more costly, permanent solutions.

Pop-up Bikeways

Pop-up bikeways are temporary bikeways installed as a result of community interest and/ or in order to gather community feedback on new bike infrastructure. The Scott Street Pop-up Bikeway Demonstration in May 2016 resulted from residents and business owners in West San Carlos and South Bascom Urban Villages of San Jose calling for streets to safer be for people walking and biking. Community members and partners created a two–Day demonstration project showing what a safer Scott Street could look like.[46] The twO–Day project featured temporary shared-lane markings (sharrow) on the street created with sidewalk chalk, as shown in Figure 4; free bike repair; bicycle safety classes; free yoga; and games for families.

Figure 4. Scott Street Pop-up Bikeway Demonstration (Source: City of San Jose)

To evaluate the long-term goal of having a series of protected bikeways, the City of San Jose had another “pop-up” bikeway in 2017. From August 7 to August 13, the City created a protected bikeway, shown in Figure 5, and 4^{th} Street and bikers were encouraged to fill out brief surveys about their experience.[47] Overall, the survey results indicated that most respondents had an overall positive impression of the bikeway, including 61% of those respondents who experienced the bikeway by automobile.[48]

Figure 5. Different Complete Street Treatments in Downtown San Jose[49]

CONCLUSIONS FROM LITERATURE REVIEW

This chapter reviewed background information on the development of traffic simulation models in general and on complete street strategies. Complete streets are integral components of multi-modal transport systems and more livable communities. Microsimulation allows for detailed modeling and visualization of transportation networks. As Nixon et al. emphasized,[50] complete street conversions can have network-wide impacts; some recent research has started examining the network-wide impacts post-implementation. The simulation approach allows for studying the network-wide impacts of complete street strategies. Studying network-wide impacts is critical to assess the potential migration of safety and traffic issues onto neighboring streets. Our study aims to provide network output evaluation metrics on complete street conversions in order to help agencies select optimal strategies for their downtown plans prior to implementation.

III. NETWORK MODELING

The investigators worked with the City's transportation planning and traffic engineering division to create the model for downtown San Jose. Towards that end, the city identified the downtown core area to be modeled in PTV VISSIM. To replicate downtown San Jose's most congested period, the downtown core network was modeled according to the weekday afternoon peak hour travel demand. This chapter explains the network modeling procedure, including data collection, model building, and calibration and validation. The peak hour counts for different transportation modes were obtained from the city. Figure 6 shows the map for the downtown core (blue shade) and downtown frame (purple shade). Based on our discussions with the City of San Jose staff, only the downtown core was modeled.

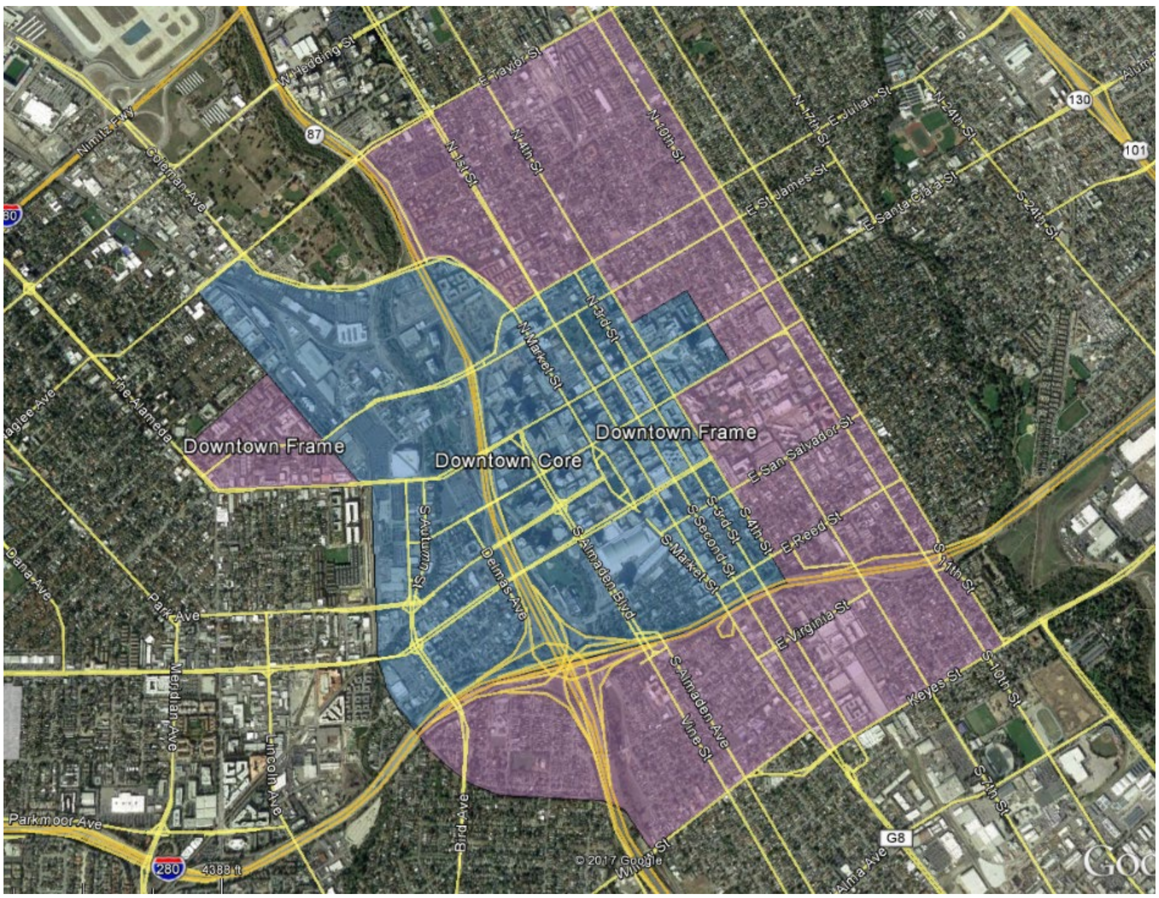

Figure 6. Map with Downtown San Jose Core and Frame

CREATING THE NETWORK

Road Network

PTV VISSIM has built-in satellite imagery from Microsoft's Bing Maps, which was used as a basis for tracing the traffic network for the San Jose downtown core. Specific lane geometry, including for automobile lanes and bike lanes, was verified through satellite images and street views in Google Maps. Cars and heavy goods vehicles (HGV), i.e.

trucks, were prohibited from Class 1 and 2 bike lanes, except at links approaching an intersection. In PTV VISSIM, links are used to model street segments while connectors are used to join links with each other, e.g., at intersections. The complete network consisted of 1,051 links and 2,242 connectors for a total of 3,293 links and connectors, shown in Figure 4. Note that since the evaluation of complete street strategies in the downtown is the purpose of the model, no freeways mainline segments were included in the model based on our discussion with the stakeholders. Off-ramps and on-ramps to the regional freeways that connected with the downtown core served as origins and destinations in the PTV VISSIM model.

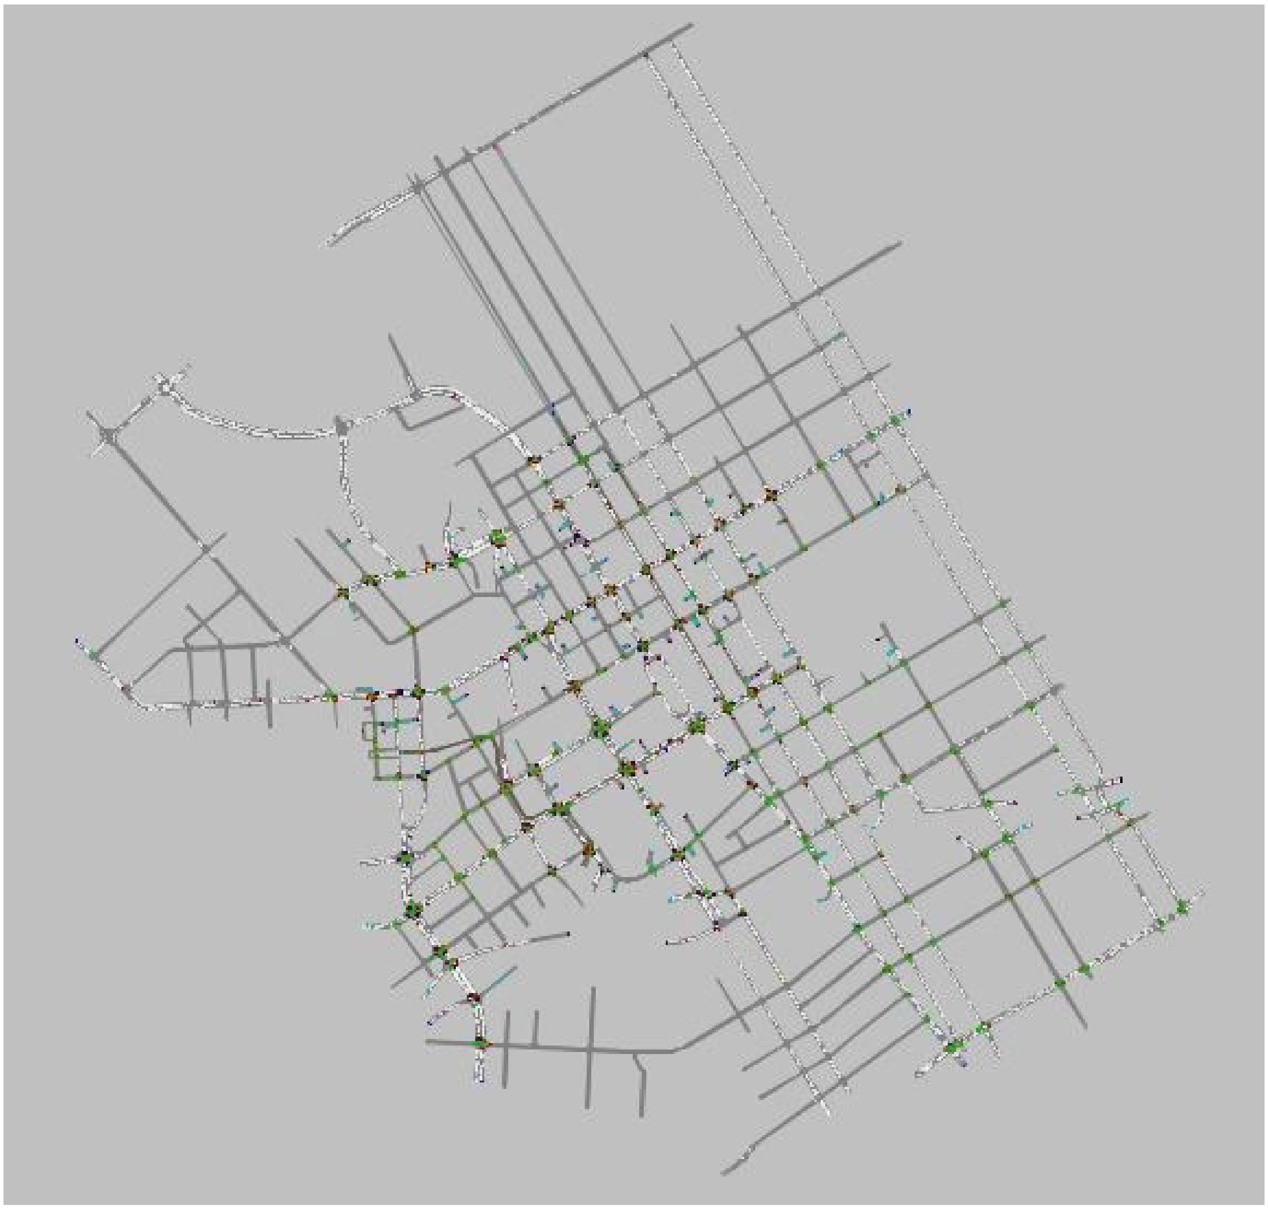

Figure 7. PTV VISSIM Model for the Downtown Core

Vehicle Data and Composition

To create an accurate existing baseline PM-peak traffic model, the City of San Jose provided intersection turning movement data for downtown surface streets and a list of parking lots within the downtown area. The number of parking spaces in a lot was used as an estimate of volume inputs at the parking lot's exit. In addition, off-ramp volumes provided, by Caltrans in terms of annual daily traffic (ADT), were converted to the peak hour volumes using Equation 1 for preliminary volume inputs.

$$\text{Peak Hour Volume}=(\text{ADT})*(\text{K}-\text{factor}) \tag{1}$$

where

ADT: Annual daily traffic

K-factor: Proportion of daily traffic occurring during the peak hour

The methodology for determining input volumes in PTV VISSIM involved these steps:

1. Convert off-ramp ADT to peak hour volumes using Equation 1, assuming a K-factor of 10%

2. For parking lots, use 50% of available parking spaces as PM peak hour volume input.

Based on the discussions with the City of San Jose staff, vehicle compositions maintained their PTV VISSIM default values of 98% cars and 2% HGVs.

Speed Data

PTV VISSIM requires speed distributions to be defined for all vehicle classes. Speed survey data was provided for key corridors in downtown San Jose. Using this data, a minimum speed, 15th percentile speed, 85th percentile speed, and a maximum desired speed was set for each corridor (see Figure 5 for an example input for the speed profile in PTV VISSIM for one of the links).

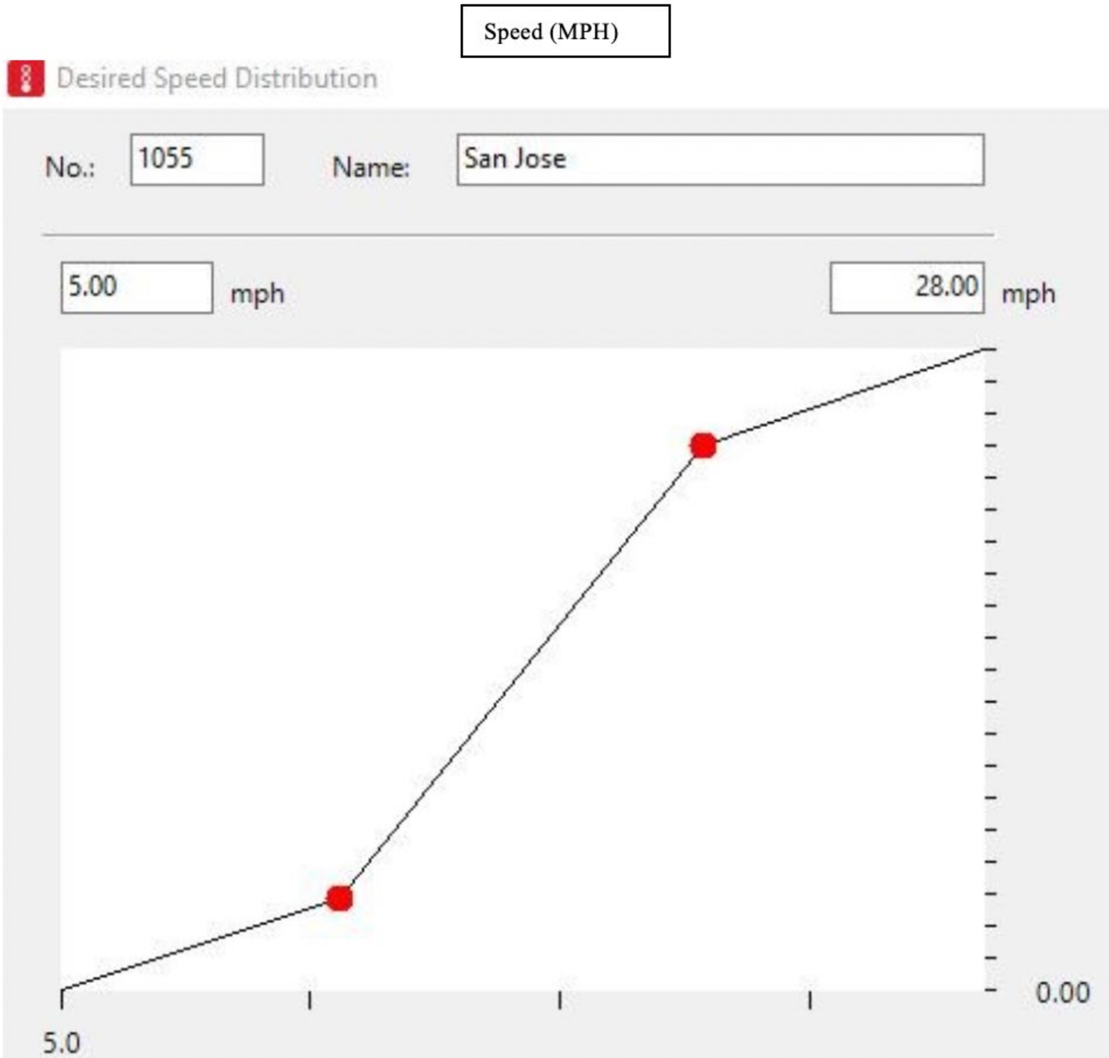

Figure 8. Speed Distribution for Vehicles with Speed in MPH on X-axis and Percentiles on the Y-axis

Conflict Areas

Conflict areas are overlapped links and connectors within the PTV VISSIM network. The priority of movement on these conflict areas need to be defined clearly to prevent vehicles, cyclists, and pedestrians from appearing to be colliding or moving over each other in simulation. These movement priorities were assigned at merge points for vehicles exiting the parking lots and at intersections for left and right turn movements yielding to through traffic. Priorities of movement through the conflict areas, i.e., areas of PTV VISSIM network where there is overlap between two links/connectors, are assigned such that it replicates the real-world behavior of traffic. For example, in case of a permitted left-turn (i.e., where left-turn movement needs to yield to a simultaneously allowed opposing through movement) at a signalized intersection, the priority was assigned to opposing through movement. It ensures that the left-turning vehicle in the simulation environment will wait for the opposing through vehicle to pass through. Conflict area priorities were also assigned at locations where the tramline intersected the road, giving priority to the tram transit vehicles.

Signal Timing Data

After setting up the network geometry, vehicle inputs and composition, speed data, and conflict areas, the next step involved setting up the traffic signals with signal timing sheets provided by the City of San Jose. All signals were modeled by a Ring Barrier Controller (RBC) interface in PTV VISSIM which can model actuated signal timing patterns, as well as coordination if there is any. Signal heads and signal controllers were created and assigned to each other through the PTV VISSIMRBC interface. This type of controller fulfilled our needs of modeling protected left turns (i.e., exclusive left-turn phase with no conflicting movement allowed at the same time), vehicle extensions, and vehicle detections. Figure 6 shows an example of a standard signal timing template. Coordination was added to the corridors where the signal systems operate on a coordinated signal timing plan during the afternoon peak-hour period.

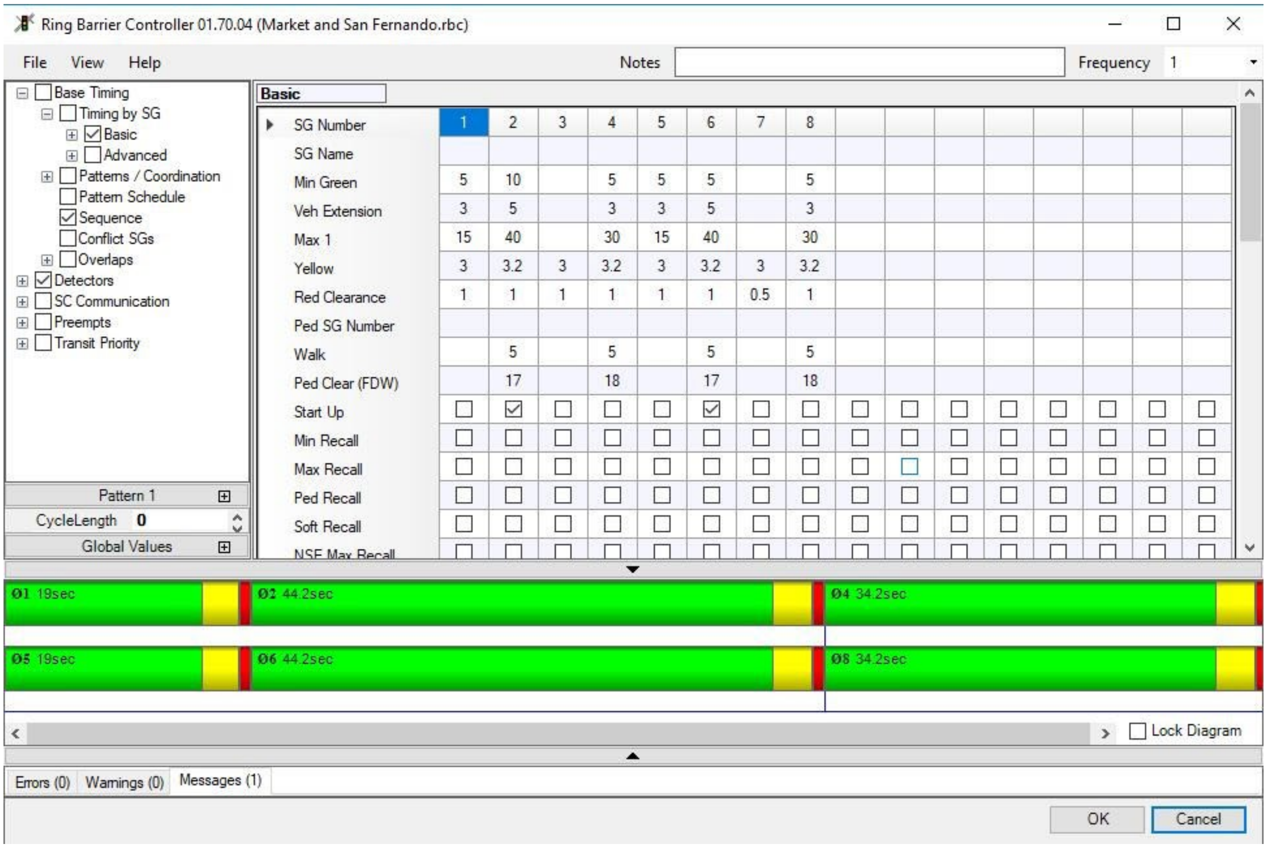

Figure 9. Ring Barrier Controller Timing Interface for PTV VISSIM

Vehicle Routes

With parking lots and on-ramps as origins and the same parking lots and off-ramps as destinations. Routes were chosen to minimize travel time from origin to destination using Google Maps for a Wednesday between 5:00–6:00 PM, the PM peak period. Google Maps would produce a minimum of one and maximum of three possible routes with every origin-destination pair and their travel time. The total input flow at the origins to destinations was divided into all routes based on travel time. Routes between O–D pairs that utilized a freeway mainline were not coded into the network since the network of interest did not have any freeways. All other routes provided by Google Maps were coded into the network. Figure 7 shows an example of a route decision generated by Google Maps and how it was coded into the network.

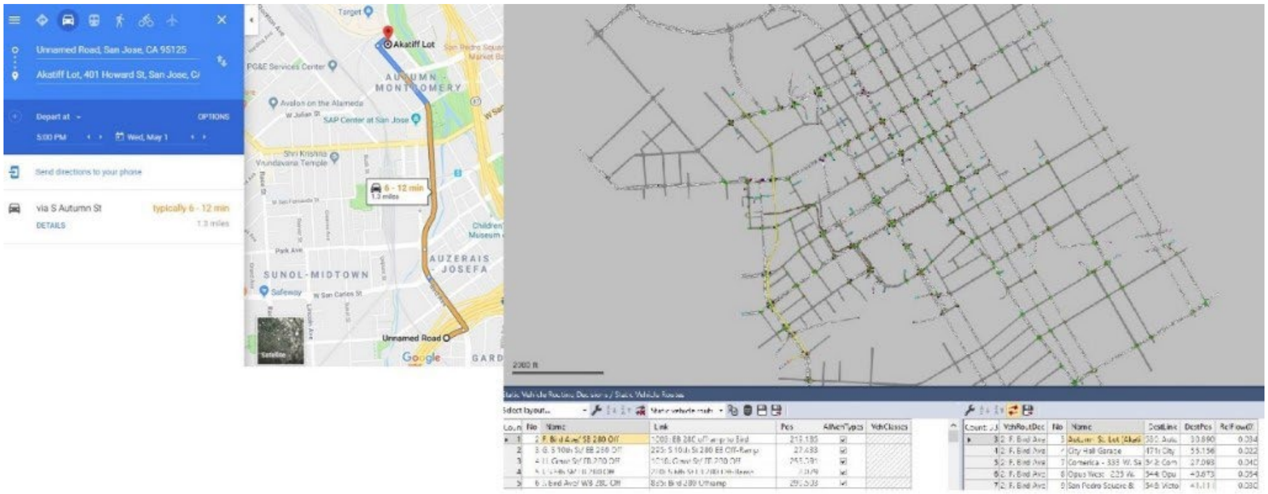

Figure 10. Route Decision from Google Maps and its coding in the Network

Transit

Public transport lines were incorporated into the model similarly to vehicle routes, where buses follow same fixed route every day. According to PTV VISSIM,[51] a PT (Public Transport) line consists of buses or trams serving a fixed sequence PT stops according to a timetable.

Cyclists

Cyclists were coded into the model as their own vehicle class and routed through corridors with Class 2 bike lanes. Based on the data provided by the city, an estimate of 30 cyclists per hour for each corridor was coded into the network. Cyclists' speeds ranged from 9.32 to 12.43 mph. Cyclists were coded in the corridors listed in Table 2. These corridors were identified as having bike lanes based on the data provided by the city.

Table 2. Cyclists Corridors

Streets with most significant bicycle traffic
San Fernando Street
3rd Street
4th Street
7th Street
Paseo de San Antonio

Pedestrians

Pedestrians were coded into the model using real-world data from pedestrian areas. Pedestrian signal heads and detectors were placed at each end of the footpath link crosswalk. An estimate of 100 pedestrians per hour per origin was coded into the network. Pedestrian input was assumed to comprise 50% males (1022: IMO-M 30–50) and 50% females (1023: IMO-F 30–50), with speeds ranging from 2.17–3.62 mph and 1.59–2.66 mph, respectively based on the program default values. Pedestrians were assigned to the intersections listed in Table 3 based on turning movement counts data obtained from the city.

ORIGIN-DESTINATION MATRIX AND ROUTES

An origin-destination (O–D) matrix O–D is a table displaying the number of trips going from each origin to each destination. This is how PTV VISSIM routes traffic in the network. The process involved identifying network locations as Origins and Destinations and providing VISSIM with the path between each O–D pair. The paths or routes between each O–D pair was identified using Google Maps. Parking lot exits and freeway off-ramp locations on the network were used as origins and the same parking lot entrances and on-ramp locations were used as destinations. The routes between each O–D pair were generated with Google Maps for a Wednesday afternoon peak period of 5:00–6:00 PM. These routes were then coded into VISSIM as static routing decisions made by each vehicle at each origin. The process for obtaining the volume counts for each O–D pair is described in the next section. Appendix B: Origin-Destination Matrices shows the final O–D matrix for the base network.

CALIBRATING THE NETWORK

As noted in the literature review section, calibration and validation are necessary steps to ensure the model's reliability and accuracy. Calibration efforts included comparing the model's traffic volumes to those of the City of San Jose's and/or Caltrans' count data, as well as comparing the model's estimated travel times to the distribution of the travel times observed in the real world. Behavior parameters were iteratively modified such that the model's data closely resembled the actual data.

Driving Behavior Parameters

The network consisted only of local streets that utilized one driving behavior parameter set. This set used the unaltered "Urban (motorized)" driving behavior default values in PTV VISSIM. Figure 8 below shows a screenshot of the final parameter set for the City of San Jose network. Note that each of the parameters shown in the screen shot below represents the central tendency or the average value for that parameter's distribution. Each vehicle in the simulation environment gets a value from the distribution assigned to it that in turn controls its behavior.

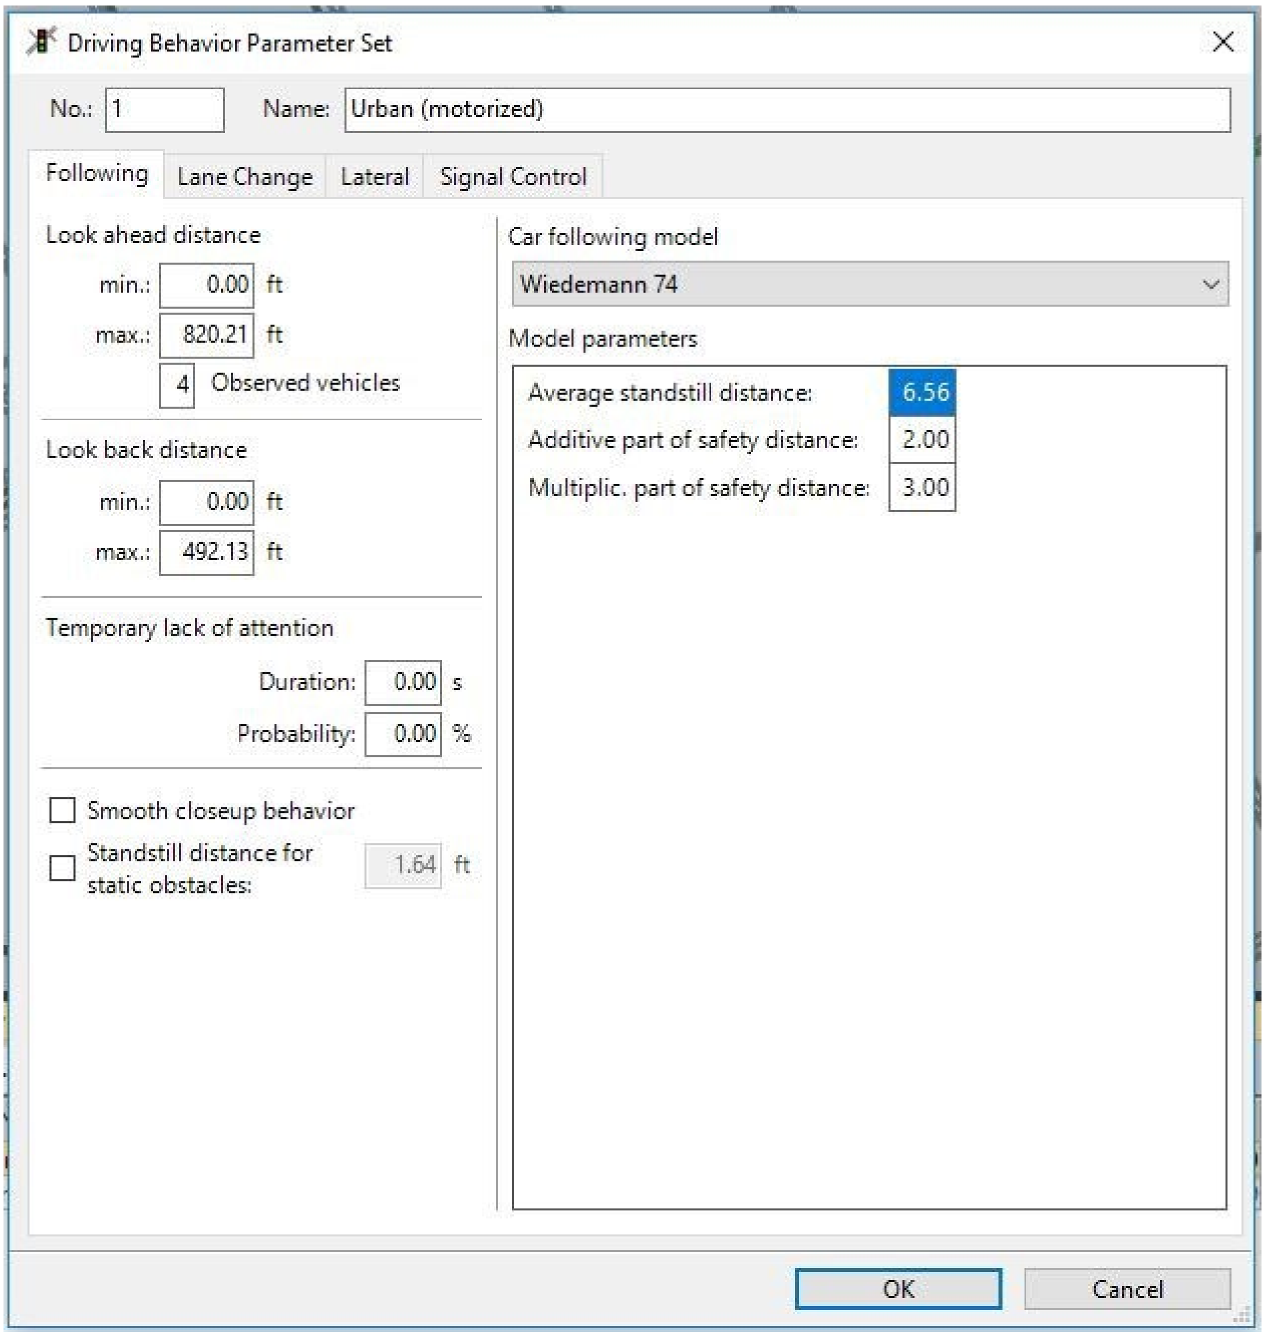

Figure 11. Driving Behavior Parameter for the Model

Vehicle Record Data

The validation of the PTV VISSIM model was based on the comparison of the real-world traffic data with the same data elements collected in the PTV VISSIM environment using features named "data collection points", "queue counters.", and "travel time measurements" These were placed at study area intersections and key corridor segments. Data collectors tallied every vehicle passing over the location where the data collection point is placed for the analysis period of 3,600 seconds. The analysis period did not involve the prior 1500 seconds of warm-up time and subsequent 900 seconds of clearing time. Data collectors also measured speed for each individual vehicle passing through their location and output the average spot speed (i.e., speed measured at a point in the network rather than over a segment). VHelper, a PTV VISSIM utility program, was used as a preliminary calibration and validation tool to catch coding mistakes and to estimate and visualize intersection turning volumes.[52] Queue counters provide average queue length, maximum queue length, and number of vehicle-stops within the queue as outputs. Queue size measured in vehicles is counted from the location of the queue counter on the link upstream to the final vehicle that is in queue condition. If the queue backed up from multiple different approaches, the total queue is the sum for all of queues at all approaches. Travel times were measured as the average travel time, including waiting or dwell times, for vehicles to cross the first (start) and second (destination) cross-sections specified for the travel time measurement (a built-in VISSIM feature) placed on the key corridors. Delay could be found for any selected segment where travel time was measured. A delay time measurement determined the mean time delay over free flow travel time calculated from all vehicles observed on a single or several link sections. Table 4 displays the locations of data collectors, queue counters, and the corridors for which travel time was measured.

VALIDATING THE BASE NETWORK

The validation process compared output data from multiple runs of the well-calibrated network to the volume and travel time data from the real world. This process required estimation of the Geoffrey E. Havers (GEH) statistic, which will be described presently.[53] A validated network justifies the simulation's usage in different future scenarios. Estimated GEH statistics for the base model (i.e., the model for 2015 network traffic conditions) indicated that the network was representing real-world conditions reasonably well.

Seed Numbers

Validation requires multiple runs of the simulation model using different seed numbers. Random seed numbers in PTV VISSIM affect the values of the driver behavior and input traffic volume generators used in the model. Note that driver behavior parameters selected at the calibration stage represented the average values or the central tendency for the parameters. For each run with a different seed number the model picks a value from that distribution and produces different output. In other words, seed values influence the arrival times of vehicles in the networks and stochastic variability of the driving behaviors, allowing for the accounting of random variations in traffic patterns at the same location.[54] Running the simulation with the same seed number would produce the same exact data for volumes, speeds, queue lengths, and travel times at any given network location. Changing the seed number would output differing results based on the actual values of the driving behavior parameters derived from the specified distribution for these parameters. For this project, validation of the base network was based on 10 simulation runs.

GEH Statistics Validation for Turning Movement Counts

The GEH Statistic is a formula commonly used in transportation analysis to compare two sets of traffic volumes. The empirically measured GEH Statistic was used to compare field counts by the City of San Jose to simulation turning volumes. The formula is defined by Equation 2.

$$GEH = \sqrt{\frac{2\,(M-C)^2}{M+C}} \qquad (2)$$

where

M: Traffic volume from the simulation model

C: Traffic volume observed in the real world

The GEH statistic is useful for comparing traffic volumes because the formula does not follow a linear pattern and a single acceptance threshold based on GEH can be used over a fairly wide range of traffic volumes, avoiding common pitfalls witnessed in using simple percentage comparisons.[55] For traffic modeling work in the existing base scenario, a GEH of less than 5.0 is considered a good match between the model and observed volumes. The measurements with GEHs in the 5.0–10.0 range have a medium chance of error and those with GEHs greater than 10.0 have a high probability of error.[56] Data collected from model runs using 10 different seed numbers were averaged and used to calculate the GEH statistic for each output measurement.

With 74.71% of GEH statistics lower than 5.0 and only 5.75% of GEH statistics higher than 10.0 for the turning movement counts at key intersections, these values meet the following validation criteria, defined based on the Washington State Department of Transportation (WSDOT) guidelines:[57]

1. A minimum of two-thirds of GEH statistics for turning movements less than 5.0

2. A minimum of ninety percent of GEH statistics for turning movements less than 10.0

Complete statistics detailing average vehicle counts for turning movements from 10 different seed number runs, the field data values, and the corresponding calculated GEH statistic can be found in Appendix B.

Speed Validation

The City of San Jose provided average speed data for peak hours on key corridors. This information was compared and matched with spot speed (speed measured at a point in the network) data from PTV VISSIM to ensure the replication of the drivers' behavior. As a calibration target, the average speed of straight-through movements at intersections in the corridor was required to fall in the range of speeds provided by the City. Table 5 summarizes average speed data from 10 runs compared to corridor speed data from the City. Speed data provided by the City can be found in Appendix E.

Table 5. Existing Baseline Speed (mph) Summary

	Average from Model (mph)	Range from City Data (mph)
Market Street	11.8	7–18
Almaden Boulevard	12.0	10–16
3rd Street	12.4	12–25
4th Street	8.9	6–16
San Carlos Street	13.9	5–11
St. James Street	10.2	8–20
Santa Clara Street	11.7	11–23

Travel Time Validation

In addition to the GEH statistic for traffic counts and speed validation, travel times were recorded for key corridors. Since no real travel time data was available, estimates for 'actual' travel times were obtained from Google Maps during a Wednesday PM peak. Approximately, 80% of travel times along the key corridors were within Google Maps' estimated travel time range. Table 6 summarizes travel times in the model and from Google Maps.

Table 6. Existing Baseline Travel Time Summary

Travel Time Corridors	Vehicles	Existing Baseline (min)	Google Range (min)
EB Santa Clara Street	134	6.9	4–12
WB Santa Clara Street	141	5.9	2–8
NB Market Street	2	6.1	3–9
SB Market Street	69	8.7	4–12
NB 3rd Street	83	6.2	2–7
SB 4th Street	288	12.3	3–8
EB San Fernando Street	52	13.7	5
WB San Fernando Street	15	7.1	3–6
NB Almaden	57	5.0	2–6
SB Almaden	235	8.7	2–8

RESULTS FROM NETWORK MODELING

Based on the validation data, the base model was well-calibrated based on the guidelines specified by WSDOT. In certain locations, however, there were some specific movements that did not calibrate quite as well, including:

- EB movements at 4th Street/San Fernando Street. Modeled travel times were much longer than observed travel times, possibly due to queues on San Fernando Street resulting from modeled vehicles waiting to change lanes to turn right.

- SB movements on 4th Street. Modeled travel times were much longer than observed travel times, possibly due to queues on 4th Street resulting from vehicle slowdown in conflict areas despite having priority.

The travel times that did not calibrate have a lower, yet, acceptable volume. There were only two corridors out of the ten shown in Table 6 for which the travel time was found to be significantly outside the range reported by Google Maps. As such, these discrepancies are not anticipated to have a significant impact on the analysis for future scenarios discussed in forthcoming chapters.

Analysis and Network Measures of Effectiveness

Table 7 shows the network measures of effectiveness (MOEs), including vehicles, travel time, speed, delay, and stops, derived from the Existing Condition Baseline PTV VISSIM model.

Table 7. Existing Baseline Network Measures of Effectiveness

Network	
Number of Vehicles	15,250
Total Travel Time (h)	9,325,456
Total Distance (mi)	16,647
Total Delay (h)	5,171,654
Per Vehicle	
Average Speed (mph)	6
Average Delay (s)	286
Average Number of Stops	6
Average Stop Delay (s)	157

The numbers in Table 7 are compared to the scenarios discussed in the next chapter to assess the network-wide impacts of the complete street strategies evaluated in the next section.

IV. ALTERNATIVE SCENARIOS

After calibrating and validating the existing condition baseline model, referred to as Scenario 0 in the remainder of this report, complete street conversion scenarios were discussed with the city and implemented in PTV VISSIM in order to analyze changes in the overall MOEs listed in Table 7. The impact of complete street conversions on the overall network is a major contribution of the study.

2040 TRAFFIC VOLUMES

The initial plan was to test each of the conversion scenarios and report detailed output metrics for both 2015 and 2040 volumes. The city provided the 2040 volumes from the travel demand forecasting models. These traffic volumes were in the form of zonal O–D matrices. The zones for the City of San Jose are shown in the figure below.

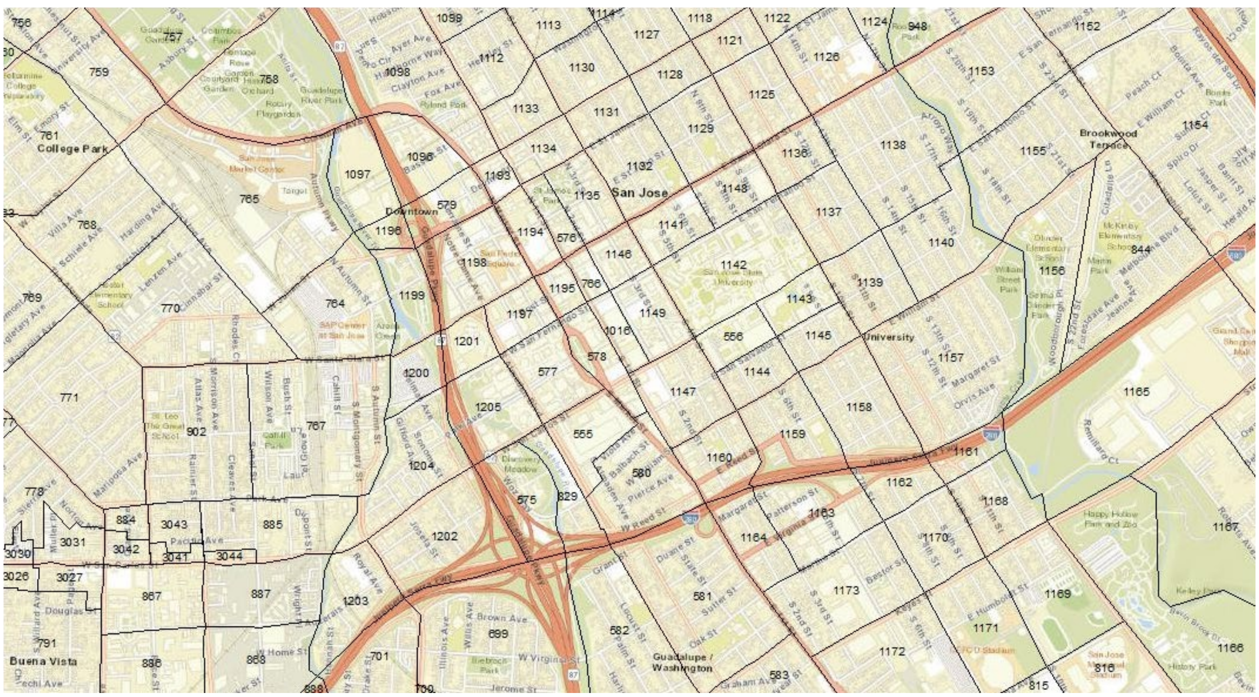

Figure 12. Zones for the O–D Matrices (Year 2015 and 2040)

Note that the region shown in Figure 4 is larger than the downtown core modeled in PTV VISSIM. In comparing the O–D matrices for the year 2015 (Scenario 0) and for 2040 it was apparent that the city's travel demand model is forecasting a large increase in automobile traffic. Several zones according to the model are expected to have the automobile volume increase by a factor of as much as 20. Clearly, the projected increase in automobile travel demand is not sustainable with the current network; inputting anywhere close to that traffic volume in the PTV VISSIM O–D led to complete gridlock in the scenario network.

The alternative approach adopted for this work then was to model the scenario provided with varying traffic volume to provide the city with an estimate on what the network might look like with either a modest increase (in the range of 5 to 10%) in automobile demand or an aggressive decrease in automobile travel demand (i.e., decrease of 20%). A total of five scenarios are analyzed in this report (including scenario 0 which is the base case). Each scenario is described along with the network metrics collected in the subsequent sections of this chapter. Also, note that the base network may be used to model any traffic/street redesign including tactical urbanism. However, based on the conversation with the stakeholders, at this point, the street redesign scenario only includes the conversion of existing one-way streets to two-way operations.

SCENARIO 1: ALMADEN BOULEVARD CONVERSION WITH 2015 DEMAND LEVEL

Assumptions

In the existing condition baseline model (Scenario 0), Almaden Boulevard between St. John Street and Santa Clara Street is a one-way southbound street. This scenario converted this section of Almaden Boulevard to a two-way street, allowing left and right turns from Santa Clara Street onto Almaden Boulevard. Additional turns added included right turns onto Carlysle Street and left turns onto St. John Street from Almaden Blvd. Previous research has shown that converting one-way street pairs to two-way operations has a positive impact on the livability of communities.[58]

Vehicle Routes

Converting Almaden Blvd. to two-way operation meant that, for some of the O–D pairs, there were additional ways for vehicles to more effectively traverse to their destinations. A total of 56 vehicle routes were adjusted to utilize a newly added northbound Almaden Boulevard segment between St. John Street and Santa Clara Street. Appendix G lists routes adjusted for the Almaden Boulevard Conversion scenario. Modifications to the routes allowed us to examine the impact of the conversion on the overall network beyond just the street corridor being converted.

Analysis and Network Measures of Effectiveness (MOEs)

Table 8 below shows the network measures of effectiveness for Scenario 1, and compares it to the base case (Scenario 0). It may be observed that the conversion of Almaden St to the two-way operation did not result in a noticeable reduction on the average speeds at key data collection locations, and in fact, some of the peak hour speeds marginally increased (e.g., at St. James Street), potentially due to smoother flow of traffic.

Table 8. Scenario 1 (Almaden Conversion) Speed (mph) Summary

	Scenario 1 (Almaden Conversion)	Scenario 0 (Existing Baseline)
Market Street	12.3	11.8
Almaden Boulevard	12.0	12.0
3rd Street	12.3	12.4
4th Street	8.9	8.9
San Carlos Street	14.2	13.9
St. James Street	12.8	10.2
Santa Clara Street	11.7	11.7

Table 9. Almaden Conversion Travel Time Summary

Travel Time Corridors	Scenario 1 (Almaden Conversion)	Scenario 0 (Existing Baseline)
EB Santa Clara Street	6.6	6.9
WB Santa Clara Street	5.8	5.9
NB Market Street	6.1	6.1
SB Market Street	8.5	8.7
NB 3rd Street	6.1	6.2
SB 4th Street	12.2	12.3
EB San Fernando Street	13.4	13.7
WB San Fernando Street	7.1	7.1
NB Almaden	4.7	5.0
SB Almaden	9.3	8.7

Table 9 shows the travel-time comparisons; it may be observed that travel time average for Scenario 1 and Scenario 0 on all major corridors of the downtown core were essentially unchanged.

Table 10. Almaden Conversion Network Measures of Effectiveness

	Network	
	Scenario 1 (Almaden Conversion)	**Scenario 0 (Existing Baseline)**
Number of Vehicles	15,177	15,250
Total Travel Time (h)	9,264,036	9,325,456
Total Distance (mi)	16,531	16,647
Total Delay (h)	5,137,334	5,171,654
	Per Vehicle	
	Almaden	**Existing Baseline**
Average Speed (mph)	6	6
Average Delay (s)	285	286
Average Number of Stops	6	6
Average Stop Delay (s)	156	157

Table 10 shows the average delays for automobile traffic, which on average was not adversely affected by the conversion.

SCENARIO 2: ALMADEN BOULEVARD CONVERSION AND INCREASE AUTOMOBILE DEMAND 5%

Assumptions

Scenario 2 considered the same Almaden Boulevard conversion as Scenario 1, but with input volume increased by 5% throughout the network.

Analysis and Network Measures of Effectiveness (MOEs)

Table 11 below shows the network measures of effectiveness for Scenario 2. It is apparent that while the speed at some of the locations was reduced by a small amount, the overall level of service (LOS) of the network did not noticeably worsen by 5% increase in automobile demand. The travel times on the corridor also increased only slightly. The highest percentage increase in travel time, compared to Scenario 1, is on EB Santa Clara and NB 3rd Street, with 12% and 13%, respectively.

Table 11. Almaden Conversion plus 5% Demand Speed (mph) Summary

	Almaden plus 5% Demand (Scenario 2)	Almaden Conversion (Scenario 1)	Existing Baseline (Scenario 0)
Market Street	12.2	12.3	11.8
Almaden Boulevard	12.0	12.0	12.0
3rd Street	12.3	12.3	12.4
4th Street	8.7	8.9	8.9
San Carlos Street	14.1	14.2	13.9
St. James Street	12.8	12.8	10.2
Santa Clara Street	11.4	11.7	11.7

Table 12. Almaden Conversion plus 5% Demand Travel Time Summary

Travel Time Corridors	Almaden Conversion plus 5% Demand (min)	Almaden Conversion (min)	Existing Baseline (min)
EB Santa Clara Street	7.4	6.6	6.9
WB Santa Clara Street	5.8	5.8	5.9
NB Market Street	6.5	6.1	6.1
SB Market Street	8.7	8.5	8.7
NB 3rd Street	6.9	6.1	6.2
SB 4th Street	13.1	12.2	12.3
EB San Fernando Street	14.5	13.4	13.7
WB San Fernando Street	7.0	7.1	7.1
NB Almaden	4.6	4.7	5.0
SB Almaden	9.4	9.3	8.7

Table 13. Almaden Conversion plus 5% Demand Network Measures of Effectiveness

Network			
	Almaden plus 5% Demand	**Almaden**	**Existing Baseline**
Number of Vehicles	15,527	15,177	15,250
Total Travel Time (h)	10,031,002	9,264,036	9,325,456
Total Distance (mi)	16,937	16,531	16,647
Total Delay (h)	5,799,015	5,137,334	5,171,654
Per Vehicle			
	Almaden plus 5% Demand	**Almaden**	**Existing Baseline**
Average Speed (mph)	6	6	6
Average Delay (s)	310	285	286
Average Number of Stops	6	6	6
Average Stop Delay (s)	174	156	157

The network-level indicators worsened due to increased automobile demand, with average delay per vehicle increasing from 285 s to 310 seconds, an almost 9% increase.

SCENARIO 3: ALMADEN BOULEVARD CONVERSION AND INCREASE DEMAND 10%

Assumptions

Scenario 3 considered the same Almaden Boulevard conversion as Scenario 1, but with automobile demand increased by 10%.

Analysis and Network Measures of Effectiveness (MOEs)

Table 14 below shows the network measures of effectiveness for Scenario 3. It is apparent that the average speed at key network locations was reduced by a small amount.

Table 14. Almaden Conversion plus 10% Demand Speed (mph) Summary

	Almaden plus 10 % Demand	Almaden plus 5% Demand	Almaden Conversion	Existing Baseline

Table 15. Almaden Conversion plus 10% Demand Travel Time Summary

Travel Time Corridors	Almaden Conversion plus 10% Demand (min)	Almaden Conversion plus 5% Demand (min)	Almaden Conversion (min)	Existing Baseline (min)
EB Santa Clara Street	7.6	7.4	6.6	6.9
WB Santa Clara Street	6.1	5.8	5.8	5.9
NB Market Street	5.7	6.5	6.1	6.1
SB Market Street	8.7	8.7	8.5	8.7
NB 3rd Street	6.1	6.9	6.1	6.2
SB 4th Street	13.5	13.1	12.2	12.3
EB San Fernando Street	16.5	14.5	13.4	13.7
WB San Fernando Street	7.2	7.0	7.1	7.1
NB Almaden	4.5	4.6	4.7	5.0
SB Almaden	9.4	9.4	9.3	8.7

Travel time increased by 20.4% on Fernando St compared to the base case. The network-wide metrics in Table 16 show that the average delay for this scenario increased by 14.2% compared to the base case.

Table 16. Almaden Conversion plus 10% Demand Network Measures of Effectiveness

Network				
	Almaden plus 10% Demand	**Almaden plus 5% Demand**	**Almaden**	**Existing Baseline**
Number of Vehicles	14,801	15,527	15,177	15,250

SCENARIO VISUALS AND PUBLIC OUTREACH

It is clear from the scenarios and the analysis of the data from 2040 Envision San Jose[59] that the conversion scenarios' success may depend on the TDM measures the city is able to adopt. These measures include congestion pricing, transit oriented development etc. In this case, public outreach is even more critical to the success of realizing a multimodal downtown core. The Safe, Accountable, Flexible, Efficient, Transportation Equity Act: A Legacy for Users (SAFETEA-LU) mandated the use of visualization techniques for describing plans to the public within transportation planning process.[60, 61] Even though the legislation expired in 2009, it remains a good guideline. Accordingly, the agencies (e.g., cities and Metropolitan Planning Organizations (MPOs)) generally need to organize public meetings to publicize plans and get feedback from the public prior to the implementation of street redesign projects. For each of the scenarios tested in the report, a 3D video was developed that may be used in public meetings prior to real-world implementation. Differences between scenarios with varying demands may be used to help stakeholders decide between various plans to redesign the streets. Previous studies[62, 63] indicated that visualization techniques are useful for the public, and most of the participants at the public meetings want transportation agencies to spend more time and budget on video simulation and public involvement. Visualization helps audiences to picture transportation plans and associated impacts, using composite images, video overlay, and animations.

There is some evidence in the literature for a lower participation rate of female residents and young residents in public meetings; however, conducting outreach activities at schools, youth centers, shopping malls, etc. could increase the rate of female and young resident participation. The internet could be an effective medium for keeping the younger participants involved.[64]

To increase the public involvement, the City of San Jose may leverage the credibility of individual(s) who play the role of a bridge between residents and other project partners,[65] such as superintendents of schools and/or San Jose State University faculty. Also, articles or advertisements in a neighborhood newspaper, and social media, could be used to increase public engagement.

Finally, it is not only public opinion that matters prior to project implementation; in addition, deliberation on the course of action, through partnership and communication, could gather multidisciplinary organizations with diverse interests to provide a robust strategy and practical action plan.[66] Communicating with planners, designers, and developers at early conceptual stages maximizes the benefits of the project, since both planners and designers are likely to be more open to modifying plans before having started than to making considerable design changes after the fact. The City is welcome to use the videos provided by the investigators of this project for any of its outreach plans. Moreover, since the modeled networks for each scenario have been provided to the city, they can create appropriate scenarios and create customized videos to use for public outreach.

V. CONCLUSION

SUMMARY AND EVALUATION OF RESULTS

This proposal addresses the needs identified by the City of San Jose, and the PIs have been in direct contact with the City. The City can use the results from the model to a) evaluate the strategies specifically evaluated and tested as part of this effort; b) demonstrate the transportation network operations before and after implementation of the strategies to stakeholders, including the community and businesses, via 3D animation; and c) run and evaluate future scenarios through the simulation model provided to the City by the investigators. To the broader research community, the proposed effort will provide a framework for evaluating combinations of strategies aimed at improved multimodal mobility and public life. The research will help communities around North America that have been reluctant to develop scenarios due to the lack of resources, capacity, or expertise, by offering a more effective method for illustrating the impact of policy/planning changes.

RELIABILITY OF DATA

For the 2015 base case model, the speeds from the PTV VISSIM model was within the range of the data provided by the city (Table 5). Travel time through major corridors in the city were also well-validated. GEH statistics for turning movement counts at intersections were also within the acceptable range and within the guidance provided by organizations such as WSDOT. Hence, we are confident the model is accurately capturing the real-world O–D patterns as well as road user behavior in the base case. The evaluation for the 2040 data was based on the city's output from the regional travel demand model. It accounts for the Envision San Jose 2040 general plan. However, the automobile demand estimate using the regional model is projected to overwhelm the network. The city, therefore, needs to reduce automobile demand through extensive TDM measures such as congestion pricing and transit oriented developments in addition to the redesign of streets.

RECOMMENDATION FOR IMPROVEMENT AND FURTHER RESEARCH

This research provided a framework for examining the network-wide impacts of complete street conversions. Most previous research on complete streets focused only on the impact on the streets being converted. For the broader research community, this research shows the way to move towards evaluation of complete networks and not just complete streets. The abrupt ending of sidewalks and lack of integration of pedestrian routes is often cited[67] as a reason for low pedestrian travel mode share and only complete networks can help address this issue. For the key stakeholders, the City of San Jose, the added value of this work is in the results documented in this report and the PTV VISSIM models provided to the city. The city staff can use the downtown core network provided by the research team and can address future scenarios as they are proposed. This will be especially critical for future tactical urbanism strategies that the city develops for using city streets for public interactions during events such as a street fair or farmer's markets.

ABOUT THE AUTHORS

BERNICE LIU

Bernice Liu is a Master’s degree candidate in Civil and Environmental Engineering at California Polytechnic State University, San Luis Obispo. She has a certified engineer-in-training (EIT) and has interned with W-Trans (June 2017–September 2017) and WSP Global, Inc. (September 2018–December 2018).

ALIREZA SHAMS, PHD

Dr. Alireza Shams is a Lecturer in the Civil Environmental Engineering department at Cal Poly San Luis Obispo. He received his Ph.D. from Clemson University in 2018. His research interests include Civil Integrated Management (CIM), Application of new sensing technologies in Transportation, Transportation Safety, and Geographic Information System (GIS).

JONATHAN HOWARD

Jonathan Howard is a Master’s degree candidate in Civil and Environmental Engineering at California Polytechnic State University, San Luis Obispo. He received in BS degree from Cal Poly and is working full-time with Caltrans District 5.

SERENA ALEXANDER, PH.D.

Serena Alexander is an Assistant Professor with the Department of Urban and Regional Planning at San José State University. Her primary research interests are in the areas of environmental planning, climate action, land-use and transportation planning, community economic development, and sustainable urban design. Before joining the SJSU faculty, Dr. Alexander conducted community economic development and environmental policy research at the Center for Economic Development and the Great Lakes Environmental Finance Center at Cleveland State University, where she also received her doctorate in Urban Studies. She holds master’s degrees in Urban and Regional Planning from California State Polytechnic University, Pomona, and Architecture from Azad University of Tehran.

ALEX HUGHES

Alex Hughes is a Master of Urban and Regional Planning student at San Jose State University with research interests in policy and transportation. He holds a Bachelor’s degree in Anthropology from the University of California Riverside with a dual emphasis in Cultural Anthropology and Archaeology. Currently, he works for the City of San Jose as a Planner I in the Planning, Building, and Code Enforcement Department.

ANURAG PANDE, PH.D.

Anurag Pande, Ph.D., is Professor of Civil Engineering at California Polytechnic State

University, San Luis Obispo. He also serves as the Faculty Liaison for Service-Learning and as such manages Cal Poly’s outreach efforts to local and regional government and non-profit agencies.

PEER REVIEW

San José State University, of the California State University system, and the Mineta Transportation Institute (MTI) Board of Trustees have agreed upon a peer review process required for all research published by MTI. The purpose of the review process is to ensure that the results presented are based upon a professionally acceptable research protocol.

MINETA TRANSPORTATION INSTITUTE
