16. Abstract In a joint effort, the FAA and The Boeing Company investigated the structural robustness and damage-resistance capabilities of adhesively bonded repair technology through the testing and analysis of metallic B727 fuselage panels at the FAA Full-Scale Aircraft Structural Test Evaluation and Research (FASTER) lab. The program objectives were to characterize the durability and fatigue performance of boron/epoxy (B/Ep) and aluminum-bonded repairs under simulated service load conditions over the typical design service goal of an airplane (60,000 cycles for B727), and to investigate tools for evaluating and monitoring the repair integrity over the life of the part. In this study, the effects of environment on the durability and fatigue performance of bonded repairs to fuselage panels under simulated service load conditions were investigated using the FAA's FASTER facility. For this study, modifications were made to the fixture to apply synchronous mechanical, temperature, and humidity loading profiles. A hot-wet environmental condition with a temperature of 165°F and humidity of 85%, and a cold-dry environmental condition with a temperature of -25°F were applied to both B/Ep and aluminum-bonded repair patches installed on a B727 fuselage panel subjected to mechanical fatigue loads to at least one design service goal. Bonded repair patches were intentionally made deficient and contained defects to encourage damage growth. During all test phases, damage formation and growth of cracks and disbonds were monitored and recorded using a prototype structural health monitoring system and several nondestructive inspection methods, including visual inspections, eddy current, flash thermography, and resonance ultrasonic. In addition, strains in the vicinity of the repair patches were continuously recording, using strain gauges and the digital image correlation method. In total, 100,000 fatigue cycles have been completed for which representative results are summarized herein. In general, the overall fatigue performances of the repairs were reduced as the quality and condition of the repairs were degraded. In addition, environmental effects were a contributing factor to fatigue crack growth measured in the B/Ep repair patches for which the rates were typically slower under hot-wet conditions compared to ambient conditions. Elevated temperatures of the hot-wet condition apparently reduced the residual strains induced during the original curing process of the B/Ep patch installation. The cold-dry condition marginally increased the residual strains at the crack tips of the B/Ep patches. However, multi-site-damage formed during the cold-dry fatigue cycling, resulting in a 20-inch-long crack after 97,000 cycles. Because of stress redistribution, data analysis was terminated at that point. Data from this program will be used to assess tools and methods for evaluating and monitoring the repair integrity over the life of the part.

EXECUTIVE SUMMARY

In a joint effort, the FAA and The Boeing Company investigated the structural robustness and damage-resistance capabilities of adhesively bonded repairs through the testing and analysis of metallic B727 fuselage panels at the FAA William J. Hughes Technical Center in Atlantic City, NJ. The program objectives were to characterize through testing the durability and fatigue performance of boron/epoxy (B/Ep) and aluminum-bonded repairs under simulated service load (SL) conditions over the typical design service goal of an airplane (60,000 cycles for the B727), and to investigate methods and tools used for analysis and predictive performance of the repairs and those used for evaluating and monitoring the repair integrity during the life of the part. The damage scenario for the bonded repairs was primarily a center-bay crack. Normally, a crack is completely removed from the structure prior to a repair application. However, for the purpose of this research, the crack was not removed. Therefore, active damage (a crack that has not been stop-drilled or removed) is left under the repair patch to provide data necessary to support all of the objectives of the research. This approach is not advocating active damage be left under a repair in nonresearch-related applications.

In this portion of the study, the effects of environment on the durability and fatigue performance of bonded repairs to fuselage panels under simulated SL conditions are being investigated using the FAA's FASTER facility. For this study, modifications were made to the fixture to apply synchronous mechanical, temperature, and humidity loading profiles. A hot-wet environmental condition with a temperature of 165°F and a humidity of 85%, and a cold-dry environmental condition with a temperature of -25°F were applied to both B/Ep and aluminum-bonded repair patches installed on a B727 fuselage panel subjected to mechanical fatigue loads to at least one design service goal. Bonded repair patches were intentionally made deficient and contained defects to encourage damage growth. During all test phases, damage formation and growth of cracks and disbonds were monitored and recorded using a prototype structural health monitoring system and several nondestructive inspection methods, including visual inspections, eddy current, flash thermography, and resonance ultrasonic. In addition, strains in the vicinity of the repair patches were continuously recorded using strain gauges and the digital image correlation method. In total, 100,000 fatigue cycles were completed for which representative results are summarized herein.

In general, the overall fatigue performance of the repairs were reduced as the quality and condition of the repairs were degraded. In addition, environmental effects were a contributing factor to fatigue crack growth measured in the B/Ep repair patches in which the rates were typically slower under hot-wet conditions compared to ambient conditions. Elevated temperatures of the hot-wet condition apparently reduced the residual strains induced during the original curing process of the B/Ep patch installation. The cold-dry condition marginally increased the residual strains at the crack tips of the B/Ep patches. However, multi-site-damage formed during the cold-dry fatigue cycling resulting in a crack linkup to a 20-inch-long crack after 97,000 cycles. Because of stress redistribution, data analysis was terminated at that point. Data from this program will be used to assess tools and methods for evaluating and monitoring the repair integrity over the life of the part.

1. INTRODUCTION

There has been an extensive amount of research and development efforts regarding bonded repairs over the past three decades. Adhesively bonded repairs of aircraft structures are frequently used in military applications, especially with the Royal Australian Air Force, which has instituted this technology to maintain their aging fleet. A noteworthy reference that provides an outstanding summary of the advances and real-world applications of bonded repairs is a two-volume book edited by Baker, Rose, and Jones [1]. As part of a USAF-led effort, The Boeing Company developed an initial design tool for bonded repairs called Composite Repair of Aircraft Structures (CRAS).

Bonded repair technology has matured considerably and has been demonstrated to be a viable alternative to metallic fastened repairs. Obvious advantages are the aerodynamic and structural efficiency of bonded repairs and the ability to significantly reduce stress concentrations. Despite these advantages, commercial application of bonded repairs is quite limited because of the lack of confidence in bonding. In the past, bonded repairs on transport airframe structures were not always successful, resulting in unexpected bond failures. It is difficult to reliably determine and assure bond integrity. As such, credit is typically not provided for inhibiting crack initiation, slowing crack growth, and restoring strength. Consequently, the FAA issued a Policy Statement (PS-AIR-100-14-130-001) regarding bonded repairs to critical structures: "All critical structures must have a repair size limit no larger than a size that maintains limit load residual strength capability with the repair completely failed, or failed within arresting design structures." To expand the size limits of a given bonded repair, repair designs must have structural substantiation based on tests or analyses supported by tests. Additional data are required to qualify bonded material and process compatibilities, to demonstrate the proof of structure, and to establish reliable inspection procedures.

In a joint effort, the FAA and The Boeing Company are investigating the structural robustness and damage-resistance capabilities of adhesively bonded repair technology through the testing and analysis of metallic B727 fuselage panels at the FAA Full-Scale Aircraft Structural Test Evaluation and Research (FASTER) lab. The program objectives are to characterize the durability and fatigue performance of boron/epoxy (B/Ep) and aluminum-bonded repairs under simulated service load (SL) conditions over the typical design service goal of an airplane (60,000 cycles for B727), and to investigate tools for evaluating and monitoring the repair integrity over the life of the part.

The damage scenario being addressed in this study primarily consisted of a center-bay crack in the fuselage skin. Center-bay cracks are not common; however, this approach simplified the analysis, repair installation, and inspection. Additionally, the accepted practice for repairing cracks is to cut out the crack before installing the repair. However, to achieve the objectives of the research, the simulated cracks in the fuselage skin were not removed prior to repair installation. This research required that the damage be left in place to gather the necessary data to show the ability of the repairs to slow damage growth, provide data for analysis tools correlation, and provide active damage that can be used to evaluate the ability of monitoring systems such as structural health monitoring (SHM) and nondestructive inspection (NDI) to detect any growth in damage size. It is emphasized that this research does not advocate leaving active damage (a crack that has not been stop-drilled or removed) under a repair in non-research related applications.

A phased approach was taken involving the testing and analysis of several panels containing B/Ep and aluminum-bonded patches. A variety of loading and environmental conditions, damage scenarios, and repair conditions were considered. The first panel tested provided baseline data and was completed in 2010 [1–4]. The results demonstrated that properly designed and installed bonded repairs can be durable under fatigue to at least one design service goal under SL conditions and to at least 20,000 cycles at elevated loads of 115% and 133% of the SL conditions. In addition, the repairs are capable of effectively containing significant damage (e.g., a 26-inch, two-bay notch in a lap joint with central stiffener severed) under severe static loads in excess of ultimate load requirements, 150% limit load.

The second follow-on test was completed in 2012, in which repair patches were intentionally made deficient and contained defects to permit damage growth [5–6]. In general, the capability to detect growing flaws under bonded patches and to monitor the effectiveness of the repairs was demonstrated using several NDI methods and a prototype piezoelectric-based SHM system. Model predictions were in good agreement with crack-growth test results for the majority of repair patch configurations. However, the test and analysis correlations revealed that further research is needed to better account for thermal residual stresses and thick patch configurations.

The two panels previously discussed were tested at laboratory temperature ambient conditions. In this current phase of the program, a third B727 panel is being used to assess the effects of environment on the durability and fatigue performance of B/Ep and aluminum-bonded repairs and to continue investigating tools to evaluate and monitor the repair bond integrity. Major modifications were made to fully integrate an environmental system with the FASTER fixture to apply synchronous mechanical, temperature, and humidity load profiles. With this new enhancement, fuselage panels can now be tested under a variety of operating environments, ranging from hot-wet (165°F and 85% to 95% humidity) to extremely cold (-25°F) conditions.

The primary focus of this study was to determine the effect of environment on the fatigue performance of adhesively bonded repairs to a metallic fuselage, including repairs made intentionally deficient to promote damage growth. This report summarizes the fixture modification for environmental fatigue testing, provides an overview of the test plan, and presents the results up to the 100,000 fatigue cycles for this third panel test. Repair configurations from the first two panel tests were generally retained for comparison purposes to assess the effects of hot-wet (165°F and 85% humidity) environmental conditions (80,000 cycles) and cold-dry (-15°F) environmental conditions (20,000 cycles) on repair performance. The effectiveness of an updated SHM system and several NDI methods, including visual inspections, eddy current (EC), flash thermography, and resonance ultrasonic, were studied throughout the test to monitor the growth of the cracks and disbonds.

In general, the overall fatigue performance of the repairs was correlated to the relative condition and quality of the repairs. Fatigue crack growth measured in the B/Ep composite repair patches was slower under hot-wet conditions than under ambient conditions. Mismatches in the thermal coefficient of expansion of the composite B/Ep patch and aluminum fuselage result in the development of residual stresses ahead of the notch during the initial patch-installation curing process. At elevated temperatures, tensile residual stresses are relaxed, contributing to slower crack growth. The cold-dry condition marginally increased the residual strains at the crack tips of the B/Ep patches. Results for the aluminum repair indicated limited effect of environment on the

fatigue crack growth because both the repair and the fuselage skin are made of aluminum. During fatigue testing multi-site-damage (MSD) developed along the lap joint of the B727 fuselage panel. At approximately 97,000 cycles, MSD crack linkup occurred, resulting in a 20-inch-long crack. Because of stress redistribution, data analysis was terminated at that point. This effort provides the data to calibrate and verify methodologies to assess the integrity of bonded repairs.

2. EXPERIMENTAL PROCEDURE

This section provides information on the experimental procedure used for the full-scale test. First, the test fixture and fixture modifications are discussed. Next, a description of the test panel, including aircraft history, panel dimensions, materials, and panel preparation for the test are provided. Then, the test phases and the applied loads is provided. Finally, an overview of the inspection and monitoring methods employed is provided.

2.1 FASTER FIXTURE DESCRIPTION AND MODIFICATIONS

The FASTER fixture was used in this study, which is capable of testing full-scale aircraft fuselage panels under the simulated flight service loading conditions, as shown in figure 1. The FASTER fixture is located at the FAA William J. Hughes Technical Center (WJHTC). To gain a better understanding of the durability and damage-tolerance aspects of bonded-repair technology under environmental loading conditions, enhancements and modifications made to the FASTER fixture are discussed in this section.

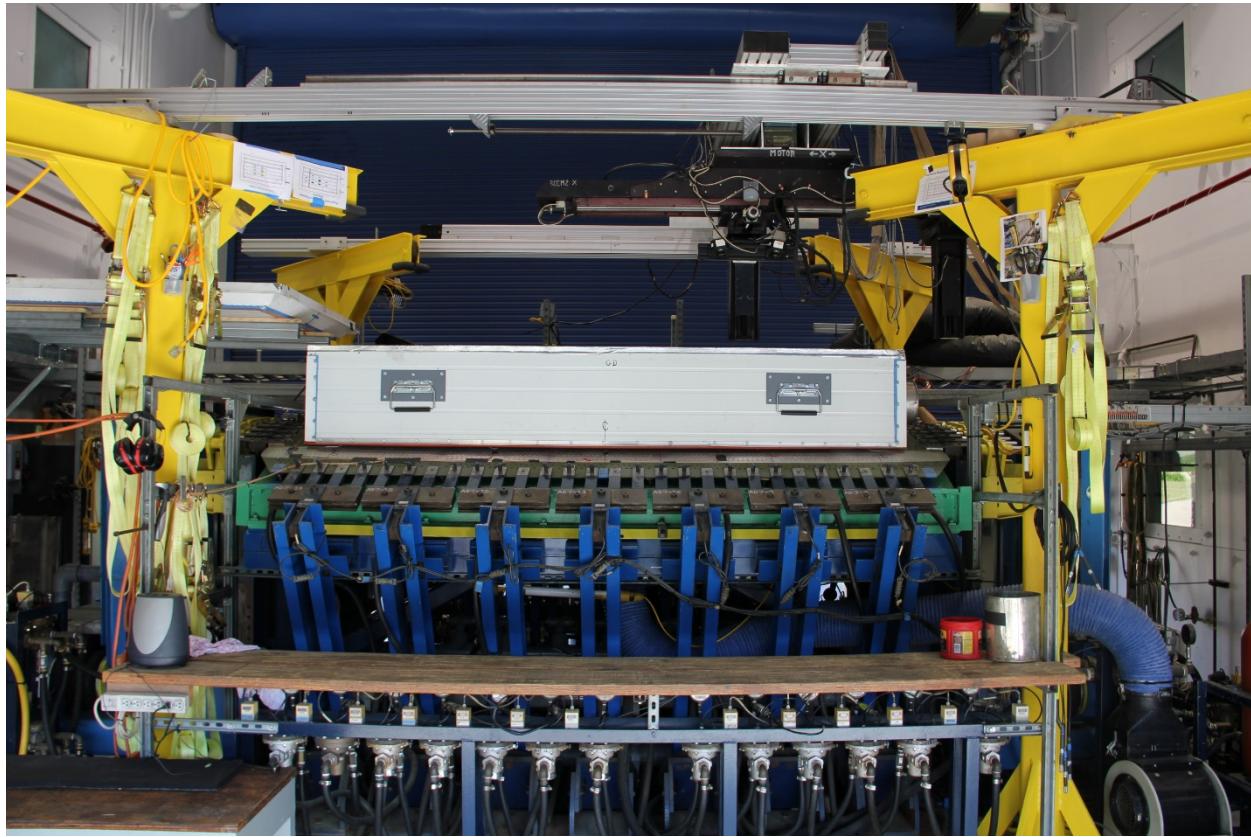

Figure 1. FASTER fixture configuration for environmental loading

The FASTER fixture was originally designed for accelerated fatigue studies of metallic fuselage structures. The fixture can apply combined internal pressure and axial load with appropriate hoop reactions to narrow-and-wide-body fuselage panels. Internal pressurization can be applied using water or air as the pressurization medium. The FASTER fixture uses two sets of four axial loaders at each end of the panel, two sets of seven hoop loaders along each straight edge of the panel, and two sets of six frame loaders connected directly to the frame ends. For the purpose of conducting the environmental test, a detailed description of the modification is provided below.

To apply synchronous mechanical and environmental loadings to the test panel, two components—an environmental chamber and a remote conditioner—were integrated with the existing mechanical loading fixture. Figure 2 shows the final configurations of the fixture modifications.

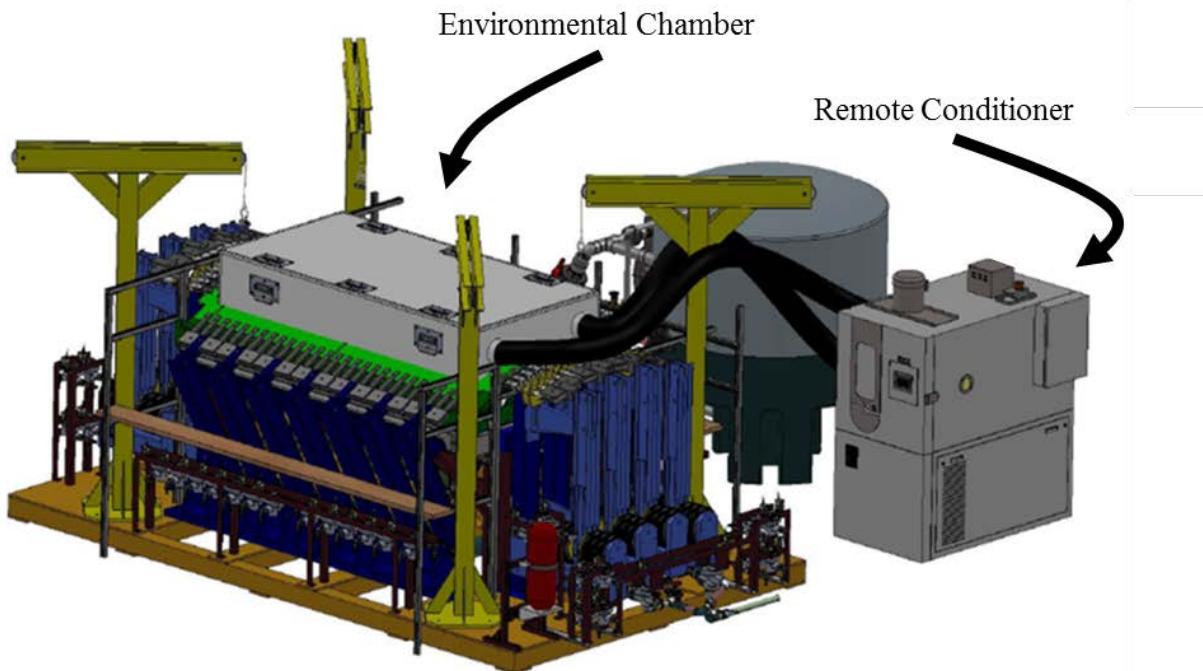

Figure 2. FASTER fixture integrated with environmental chamber and remote conditioner for synchronous mechanical, temperature, and humidity-loading profiles to fuselage panels

2.1.1 Environmental Chamber

An environmental chamber was designed to contain the temperature and humidity conditions outlined in table 1 to a 4-by-9-by-1-foot volume covering the outer surface of the fuselage panel, as shown in figure 3. The chamber was built using prefabricated insulated panels constructed with 4-inch-thick expanded polystyrene foam core insulation material having a thermal resistance rating of 4.17 per inch thickness, sandwiched between 26-gauge galvanized steel sheets. An airtight interface between the chamber and fuselage panel was accomplished using a double layer of rubber bulb seals and 1-inch-thick weather-resistant neoprene foam. The chamber was secured to the fuselage panel with mechanical straps.

Table 1. Temperature—humidity requirements

Condition	Temperature, °F	Relative Humidity, %
Operational Conditions:		
Hot-Dry	96	3–8
Hot-Wet	96	85–95
Cold	-25	Tending toward saturation
Test Capability:		
Hot-Dry	165	3–8
Hot-Wet	165	85–95
Cold	-50	Tending toward saturation

Figure 3. Environmental chamber with air-tight seal; insert shows the bottom seal consisting of rubber bulb seal and weather-resistant neoprene foam

2.1.2 Remote Conditioner

A remote conditioner was used to generate the temperature and humidity conditions in the environmental chamber to the specifications in table 1. For this, a commercially available unit was used, namely a Cincinnati Sub-Zero Z-plus remote conditioner (P/N Model ZPRCHS-816-6-6-SC/AC), which can be operated both locally and remotely. Locally, the unit has a built-in 30-inch³ volume chamber used to condition coupons and small components. Remotely, the unit is interfaced with the environmental chamber using a pair of 8-inch inside diameter insulated ducts, one inlet and one outlet, for a closed-loop environmental conditioned system. A control interface was added to the existing FASTER graphic user interface to allow for full operation of the remote conditioner,

including system startup, defining temperature and humidity profiles, adjusting set point values, and setting tolerances while running a fatigue test.

An acceptance test was conducted to verify the functionality of the integrated system. An array of sensors was used throughout the environmental chamber to measure the temperature and humidity distribution. The fully integrated system was run to verify that all conditions in table 1 were met (i.e., at steady state) and that both temperature and humidity were evenly distributed throughout the environmental chamber within $\pm 3^{\circ}\text{F}$ and $\pm 5\%$ RH, respectively.

2.2 TEST PANEL DESCRIPTION

The fuselage panel used in this study was removed from a retired passenger service Boeing 727-225 aircraft with tail number N675MG and serial number 22553, as shown in figure 4. During service, the aircraft accumulated 48,579 flight hours and 29,821 flight cycles. A large section of the fuselage was removed from the crown of the aircraft from frame stations STA560 to STA660 and stringer stations S-3R to S-6L, intact with skin, frames, shear clips, stringers, a longitudinal skin splice joint, and a cutout and doubler pad up for an upper rotating beacon.

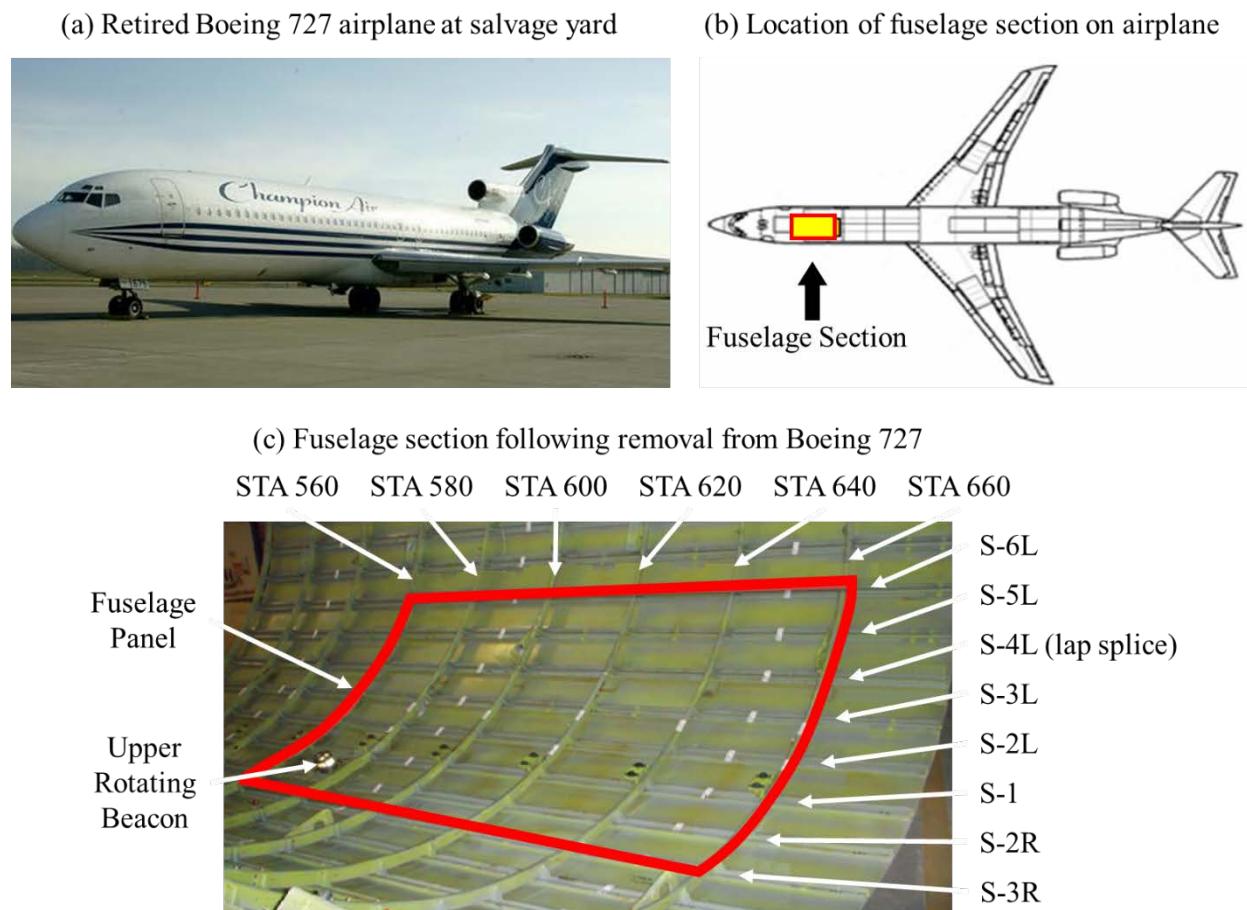

Figure 4. Highlights of B727 airplane and panel: (a) retired airplane in salvage yard, (b) location of panel section on airplane, and (c) internal view of removed panel section

After the panel was removed, detailed inspections were made to determine the condition of the panel test section and to repair the damaged structure. The panel was then cut to size to fit into the FASTER fixture. Reinforcing doublers were installed along the outer perimeter of the skin and to the frame ends for load attachment points of the fixture. Holes of 0.5-inch diameter were drilled along the reinforced doubler edge of the panel at a specific spacing for load introductions in the axial and hoop directions.

The final panel dimensions were 125 inches by 73 inches with a radius of 74 inches, as shown in figure 5. The skin thickness was 0.04 inch throughout the test section. The substructure included six stringers in the axial direction with 9.5-inch spacing and six frames in the hoop direction with 20-inch spacing. A longitudinal lap-joint was located along stringer S-4L. Appendix A of this document provides the fuselage panel engineering drawings.

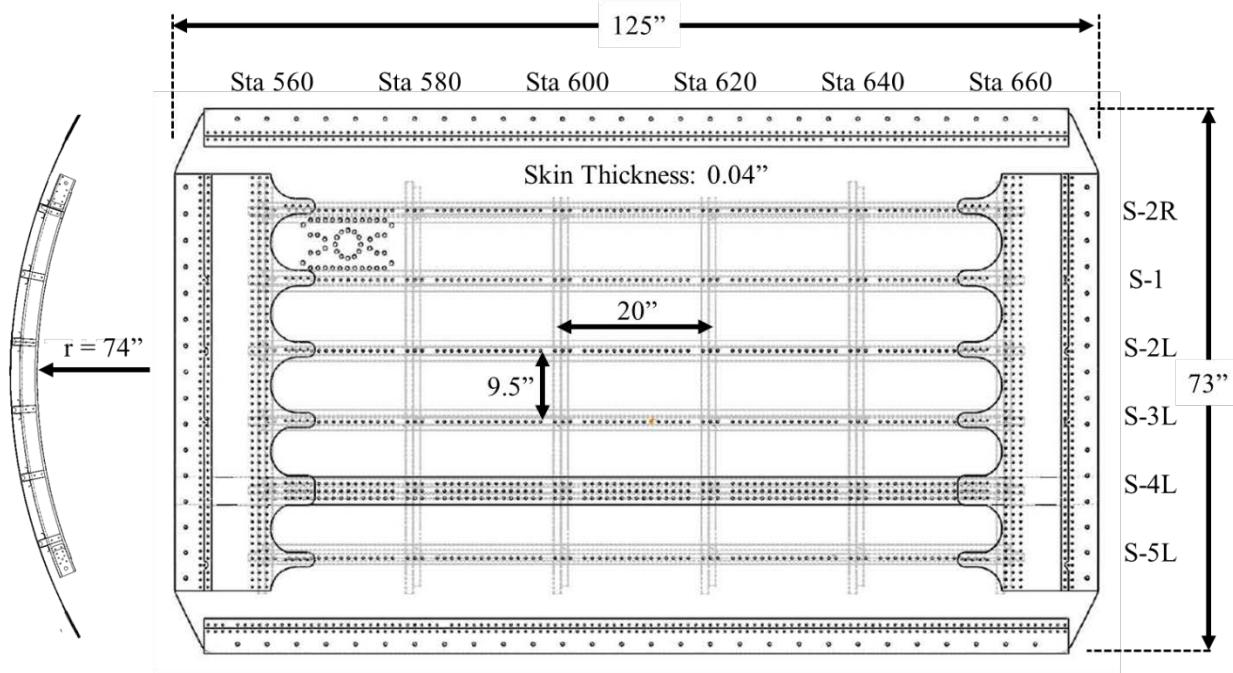

Figure 5. Panel configuration

2.3 PANEL LOAD HISTORY

The complete load history of the panel is shown in figure 6. During service, the aircraft accumulated 29,821 flight cycles. In this test program, two test phases were conducted for the extended fatigue test. In phase 1, the panel was tested at 100% simulated SL under the hot-wet (HW) environmental conditions for 80,000 cycles. In phase 2, the panel was tested at 100% SL under cold-dry (CD) environmental conditions for an additional 20,000 cycles. Accounting for the aircraft operational history the total number of SL cycles accumulated in the test panel was 129,831 cycles. During the fatigue cycling, MSD formed, resulting in a 20-inch-long crack after 97,000 cycles. Because of stress redistribution, data analysis and results are presented up to 90,000 cycles in this report. The details of the MSD are provided in section 4.

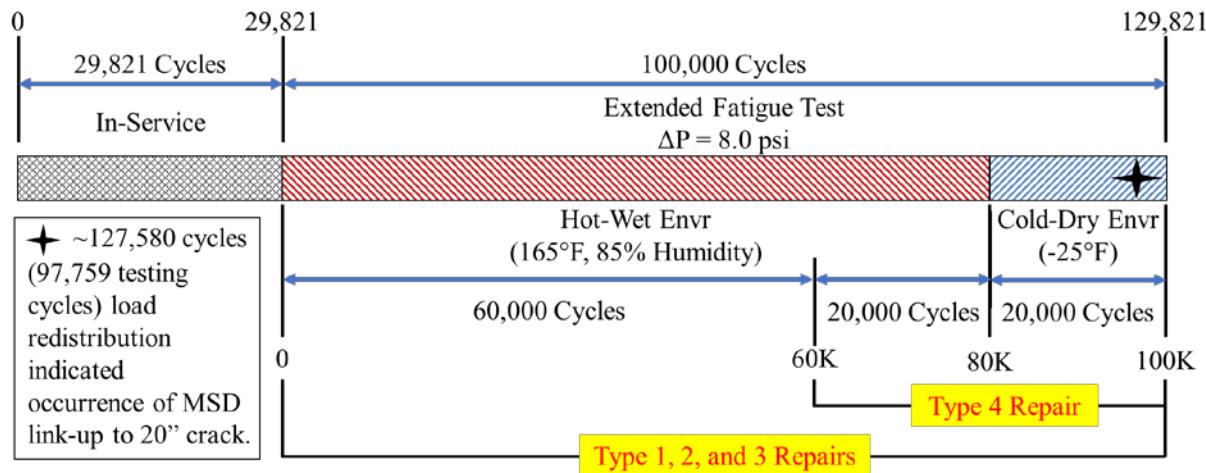

Figure 6. Entire loading history of panel 3

2.4 APPLIED LOADS

A summary of applied loads is shown in table 2. The loads used for the fatigue test simulated the SL conditions, including cabin pressurization (8.9 psi) and fuselage vertical bending, and were represented by an equivalent constant-amplitude spectrum. The magnitude of the applied loads used in the strain survey and fatigue pre-cracking to insert the initial damage was 75% of the SL conditions used for the fatigue test. For the baseline strain survey tests, quasi-static loadings were applied in 10 increments up to the maximum loads. For the pre-cracking and fatigue test, constant-amplitude loading was applied at a frequency of 0.033 Hz (resulting in two pressurization cycles per minute) with an *R* ratio (minimum to maximum load) of 0.1.

Table 2. Applied loads

Description	Maximum Mechanical Load					Constant Environmental Load
	Load Phase	Pressure (lb.)	Hoop (lb.)	Axial (lb.)	Frame (lb.)	
Strain Survey, 75% of SL	Quasi-static	6.7	7140	6675	1133	Ambient Hot-wet Cold-dry
Fatigue pre-cracking, 75% of SL	Cyclic, <i>R</i> = 0.1	6.7	7140	6675	1133	Ambient
Fatigue, 100% of SL	Cyclic, <i>R</i> = 0.1	8.9	9520	8900	1510	Hot-wet (80,000 cycles) Cold-dry (20,000 cycles)

2.5 INITIAL DAMAGE SCENARIO

The initial damage scenario for each repair consisted of 3-inch mid-bay through thickness cracks, as shown in figure 7. Damage was introduced in the form of a crack starter notch using a grind wheel and jeweler's saw, having a length of 2.8 inches and notch-tip width of 0.008 inch. Fatigue pre-cracking was conducted at an applied load of 75% of the SL conditions to generate natural cracks with sharp crack tips. As shown in figure 7, symmetric and colinear crack extension was obtained from the notch tips. The pre-cracking was continued until the natural cracks generated extended from the notches for a total length of 3 inches. Details of the damage scenarios and repair patches are provided in appendix B.

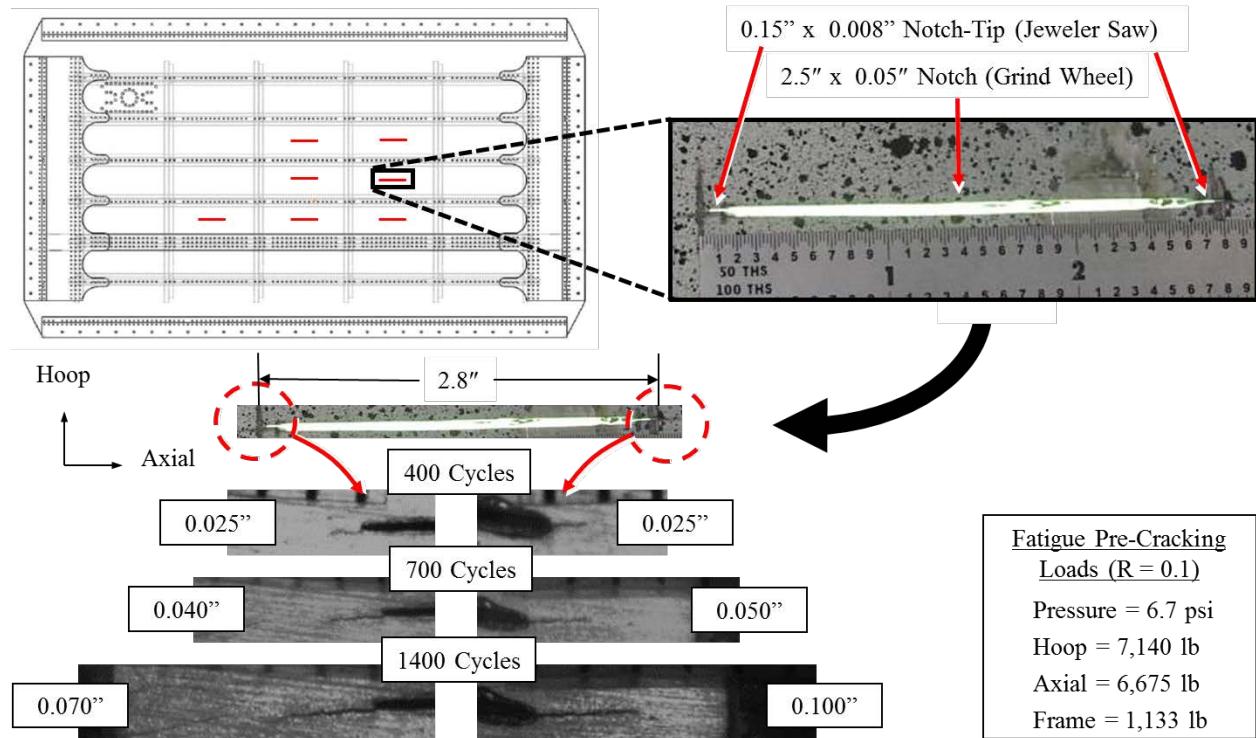

Figure 7. Photographs of crack growth from mid-bay notch during fatigue pre-cracking

2.6 TEST MATRIX AND REPAIR TYPES

Five repair types were considered in this program, as shown in table 3 and figure 8. Repairs were installed after the mid-bay crack length was approximately 3 inches, as shown in figure 7. A brief description of each repair type is included in this section and the details are provided in appendix B.

Table 3. Test matrix and repair types

Repair Type	Description	Designation
Type 1: Reference repairs	Introduced at the beginning of the test. Fatigue at SL under hot-wet conditions for 80,000 cycles and then under cold-dry conditions for additional 20,000 cycles.	RA, RB
Type 2: Under-designed repairs	Introduced at the beginning of the test. Fatigue at SL under HW conditions for 80,000 cycles and then under CD conditions for additional 20,000 cycles.	UA, UB
Type 3: Under-designed & partial disbond repairs	Introduced at the beginning of the test. Fatigue at SL under hot-wet conditions for 80,000 cycles and then under CD conditions for addition 20,000 cycles.	UDA, UDB
Type 4: Hand sanded	Introduced at 60,000 cycles. Fatigue at SL under HW conditions for 20,000 cycles and then under CD conditions for 20,000 cycles.	HS

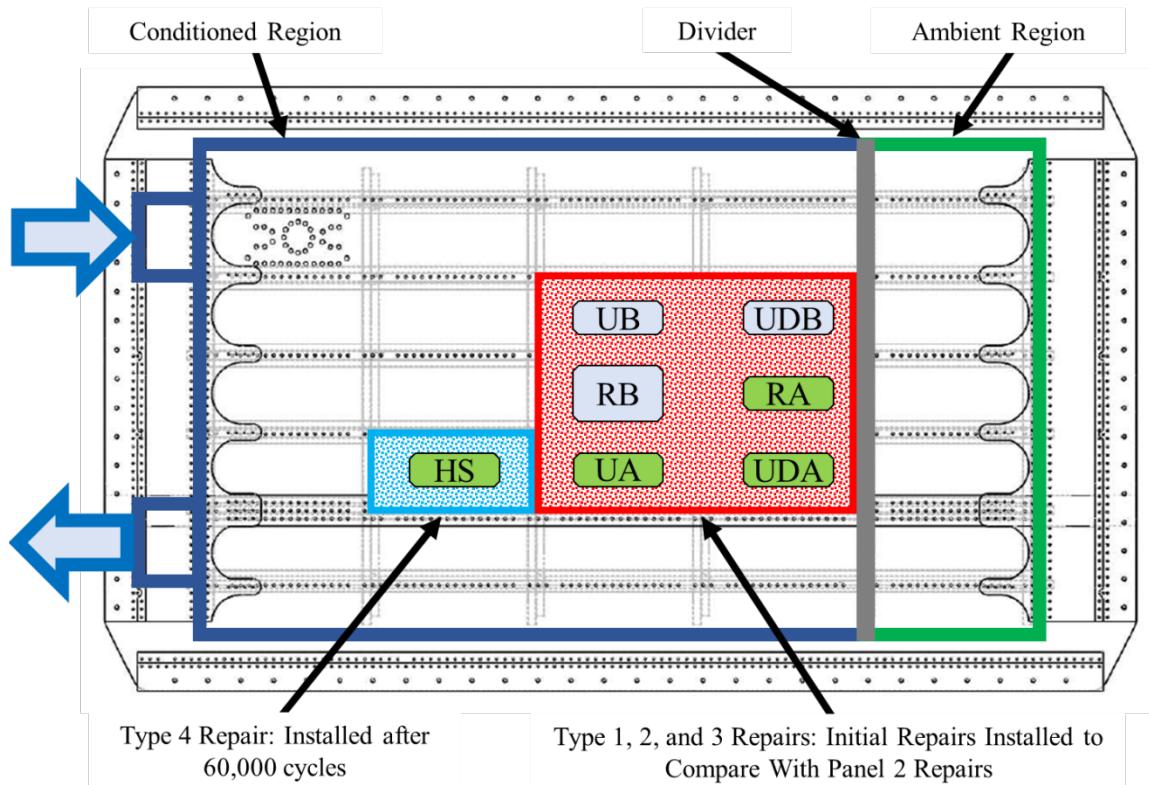

Figure 8. Locations of all four types of repair patches tested in this program

Type 1: Reference Repairs

The reference repair patches included a nine-ply B/Ep patch and a three-layer aluminum patch over a 3-inch mid-bay crack (see figure 9). The reference B/Ep repair was tested in panel 2 and provided a baseline performance for all the other bonded repairs, and were designed to contain damage and withstand one design service goal (60,000 cycles). The reference B/Ep repair patch had an octagon shape footprint approximately 8 inches in the axial direction by 5 inches in the hoop direction and consisted of nine plies ($20^\circ/-20^\circ/20^\circ/-20^\circ/0/-20^\circ/20^\circ/-20^\circ/20^\circ$) with a taper ratio of 20:1 in which the 0° fiber direction was perpendicular to the crack (see figure 9a). The reference aluminum patch also had an octagon shape footprint approximately 8 inches in the axial direction by 3 inches in the hoop, consisting of three 0.02-inch-thick aluminum doublers with a taper ratio of 20:1 (see figure 9b).

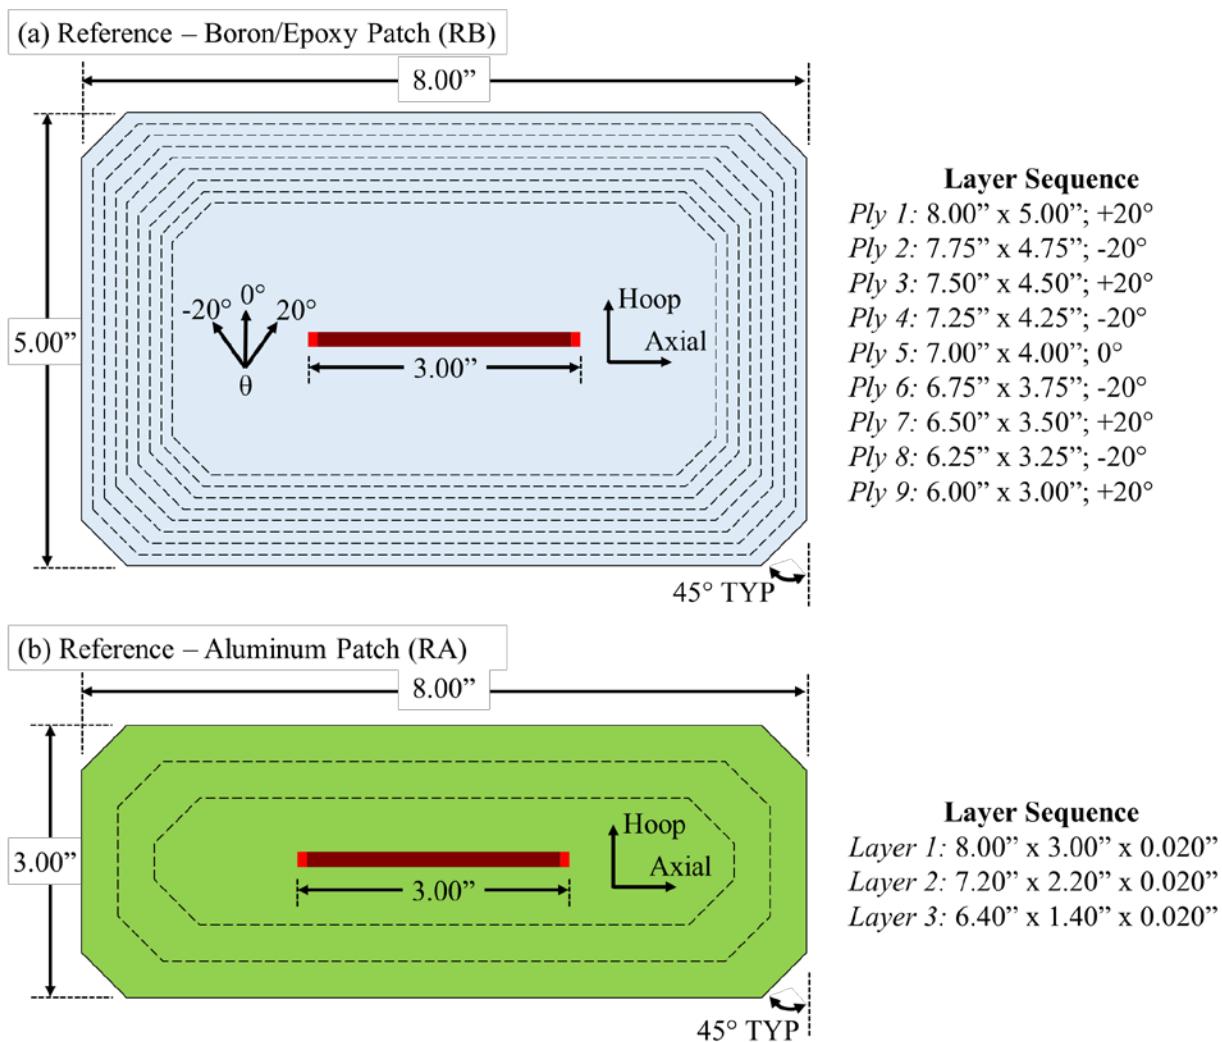

Figure 9. Reference repair configuration: (a) B/Ep patch, RB; (b) aluminum patch, RA

Type 2: Under-Designed Repairs

Type-2 repair patches included a B/Ep patch and a two-layer aluminum patch over a 3-inch mid-bay crack (see figure 10). These repairs were intentionally under-designed by reducing the number of reinforcing B/Ep plies and aluminum doublers and reducing the patch footprint in the hoop direction of the B/Ep repair only. The under-designed B/Ep repair had an octagon shape footprint approximately 8 inches in the axial direction by 3 inches in the hoop direction and consisted of five plies ($20^\circ/-20^\circ/0/-20^\circ/20^\circ$) with a taper ratio of 20:1. The approximate thickness of each B/Ep ply was 0.0057 inch in which the 0° fiber direction was perpendicular to the crack (see figure 10a). The under-designed aluminum patch had the same footprint (8-by-3 inch) consisting of two 0.02-inch-thick aluminum doublers with a taper ratio of 20:1 (see figure 10b).

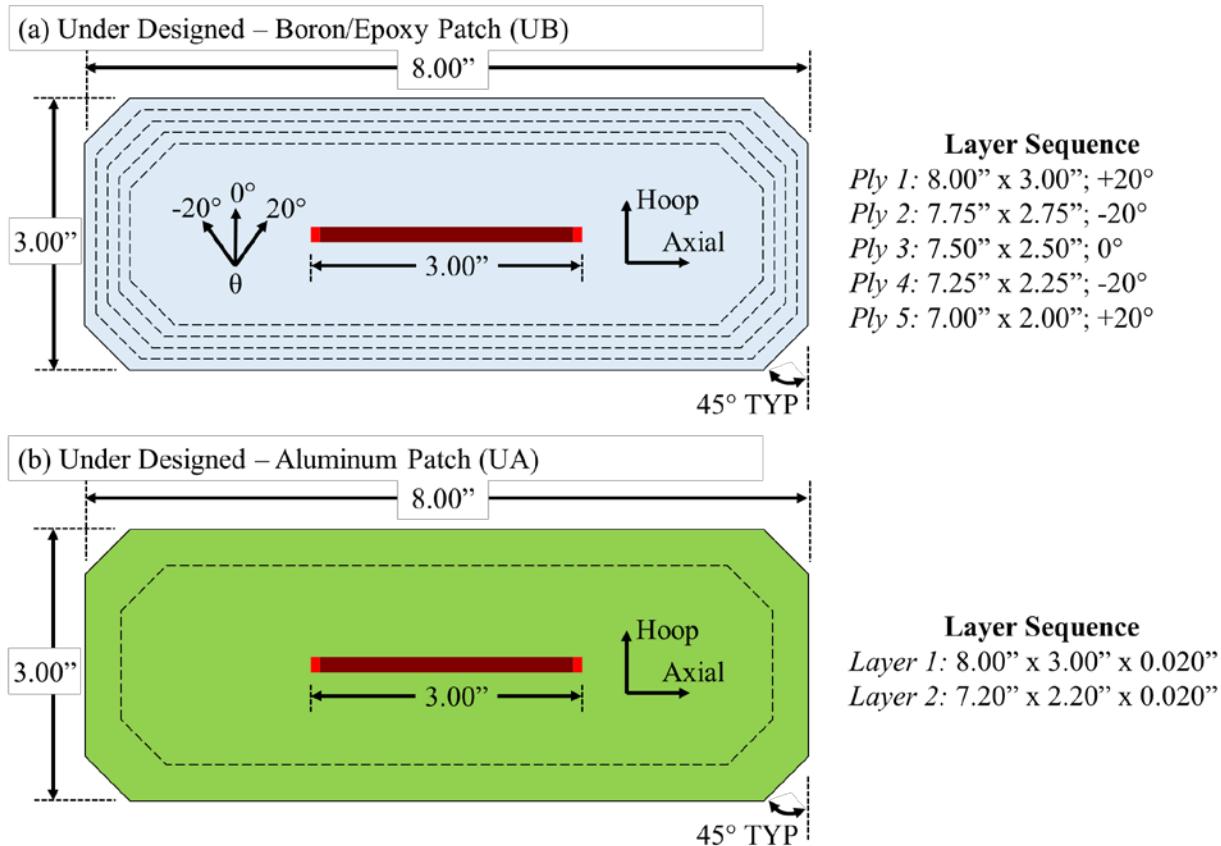

Figure 10. Type-2 repair configuration: (a) B/Ep composite repair, UB; (b) aluminum patch repair, UA

Type 3: Partial Disbond Repairs

Type-3 repair patches included a B/Ep patch and a two-layer aluminum patch over a 3-inch mid-bay crack (see figure 11). The repairs included engineered disbonds, which were introduced using fluorinated ethylene propylene (FEP) inserts and aluminum shims (coated with mold release agent). During the curing process, FEP inserts were installed around the crack region between the fuselage skin and adhesive, and the aluminum shims were located at the edge of the patch. After curing, the aluminum shims were removed. The patch dimensions and designs for both the B/Ep

and aluminum patches were identical to the type-2 repair configurations. Figure 11 shows the disbond size, shapes, and locations in the repair patches.

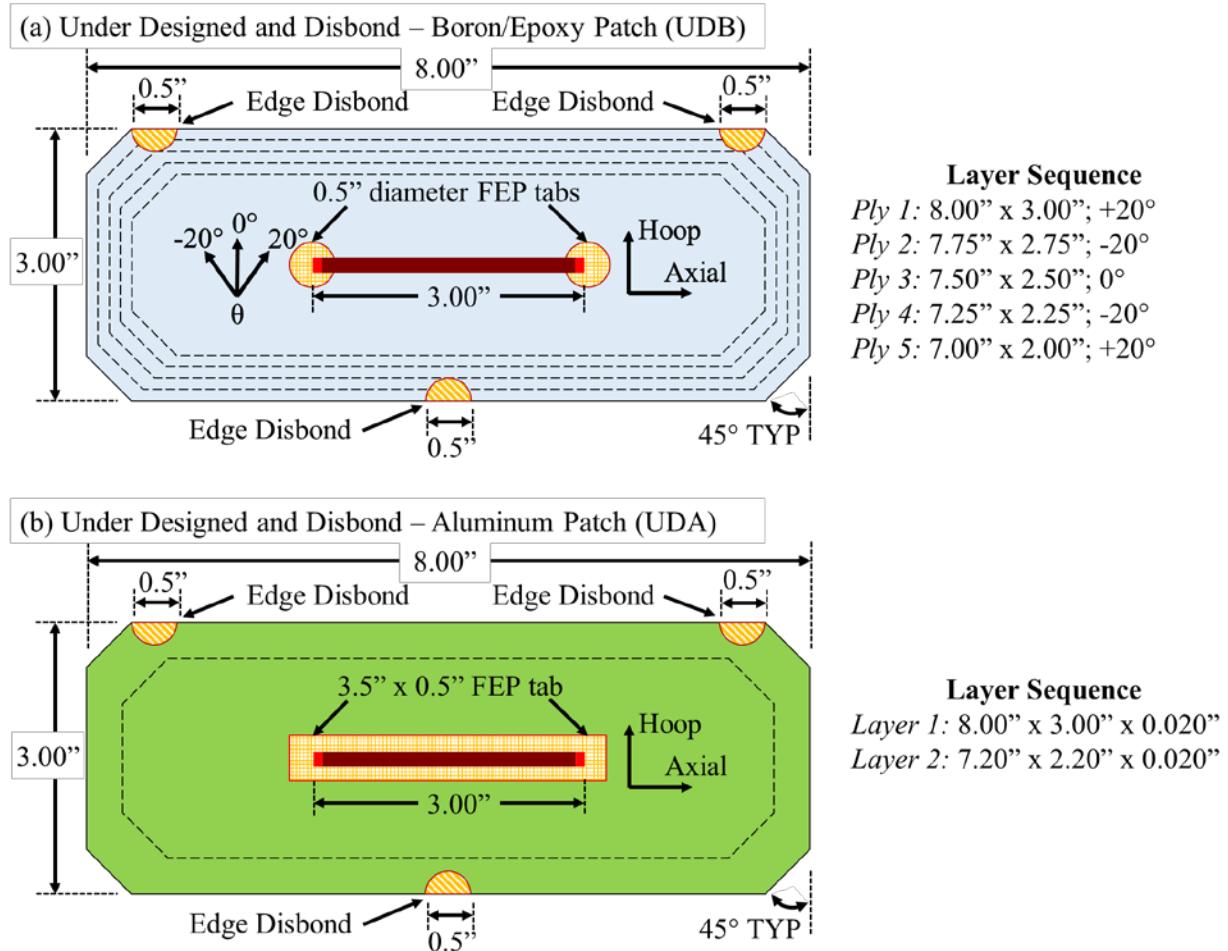

Figure 11. Type-3 repair configuration: (a) B/Ep composite repair, UDB; (b) aluminum patch repair, UDA

Type 4: Hand-Sand Repairs

Similarly, the patch dimensions and design for the type-4 aluminum patch were identical to the type-2 aluminum repair configuration. Normally, the outer skin of the panel was deoxidized using grit blast before repairs were bonded. However, instead of using grit blast to deoxidize the surface of the panel, the skin of the panel was hand sanded (HS). The repair designated HS was bonded normally using film adhesive.

2.7 INSPECTION METHODS

Periodic inspections were made every 10,000 cycles. Several NDI methods were used to monitor and record damage formation, crack propagations, and patch disbonds. Two methods were used for disbond and delamination detection—flash thermography and resonance ultrasonics. For crack detection, visual inspections and EC techniques were used. Visual inspections were made on the

inner and outer surfaces of the skin using high-magnification cameras, which could be remotely controlled during the test. Low-frequency eddy current (LFEC) was used on the outer surface to inspect for cracks in the skin underneath the B/Ep composite repair patches. High-frequency eddy current (HFEC) was used on the inner surface of the skin. Thermography, resonance-ultrasonic, and EC were conducted in a laboratory environment under no load conditions. Digital image correlation (DIC) data were collected in a laboratory environment under strain survey loads, and strain gauges data were collected under three environmental conditions (i.e., ambient, hot-wet, and cold-dry). A brief description of each inspection method is provided in table 4. Details of these inspection techniques can be found in the DOT/FAA/AR-11/4 [4].

Table 4. Inspection methods

Method	Inspection	Interval	Conditions
High-magnification visual from interior surface	Crack growth monitored at inner surface under all patches	Continuous	No load/ambient
HFEC from internal surface	Crack growth monitored at inner surface under all patches	10,000 cycles	No load/ambient
LFEC from external surface of patch	Crack growth monitored from outer surface of B/Ep patches	10,000 cycles	No load/ambient
Flash thermography from exterior surface of patch	Disbonding of all patches	10,000 cycles	No load/ambient
Resonance ultrasonic from exterior surface of patch	Disbonding of all patches	10,000 cycles	No load/ambient
DIC from external surface of the panel	Full-file strain variation and displacement	10,000 cycles	Strain survey load/ambient

Flash Thermography

The flash thermography system was used for disbond detections. The system sends a pulse of light to heat the structure and measures the surface temperature as the sample cools. Defects such as disbonds trap the heat flow, resulting in a temperature gradient on the surface, which outlines the disbond region.

Resonance Ultrasonic

The resonance ultrasonic technique using the Olympus BondMaster® was used to detect disbonds. The methodology relies on deviation of the resonance frequency response curve measured on a specimen with a crack/defect and on an identical non-cracked specimen. The detection criteria include: 1) shift of the peak position, 2) increase of the bandwidth, and 3) reduction of the amplitude.

EC

EC was used to detect cracks. EC is an electromagnetic testing method to detect and characterize surface and sub-surface flaws in conductive materials. ECs flow in closed loops within conductors, and they can be induced within nearby stationary conductors by a time-varying magnetic field created by an AC electromagnet. When the probe approaches to a defect, the EC changes in phase and amplitude.

2.8 STRAIN MEASUREMENTS

With these inspection methods, the strain gauges and DIC method were used to monitor strains throughout the tests.

2.8.1 Strain Gauge Monitoring

The panel was instrumented with approximately 200 strain gauges to monitor strains throughout the test. Strains were monitored at various locations, including the inner and outer surface of the skin, frames, and stringers (see figure 12). For each repair patch, strain gauges were placed along the boundaries on the inner and outer skin surfaces, at the patch outer surface, and along the notch-tip. Typically, each repair patch included eight strain gauges (see figure 13). For the selected patches, the local notch-tip strain field was measured using the strain gauge chain to capture a higher resolution of the strain distribution at 80,000 cycles (see figure 14).

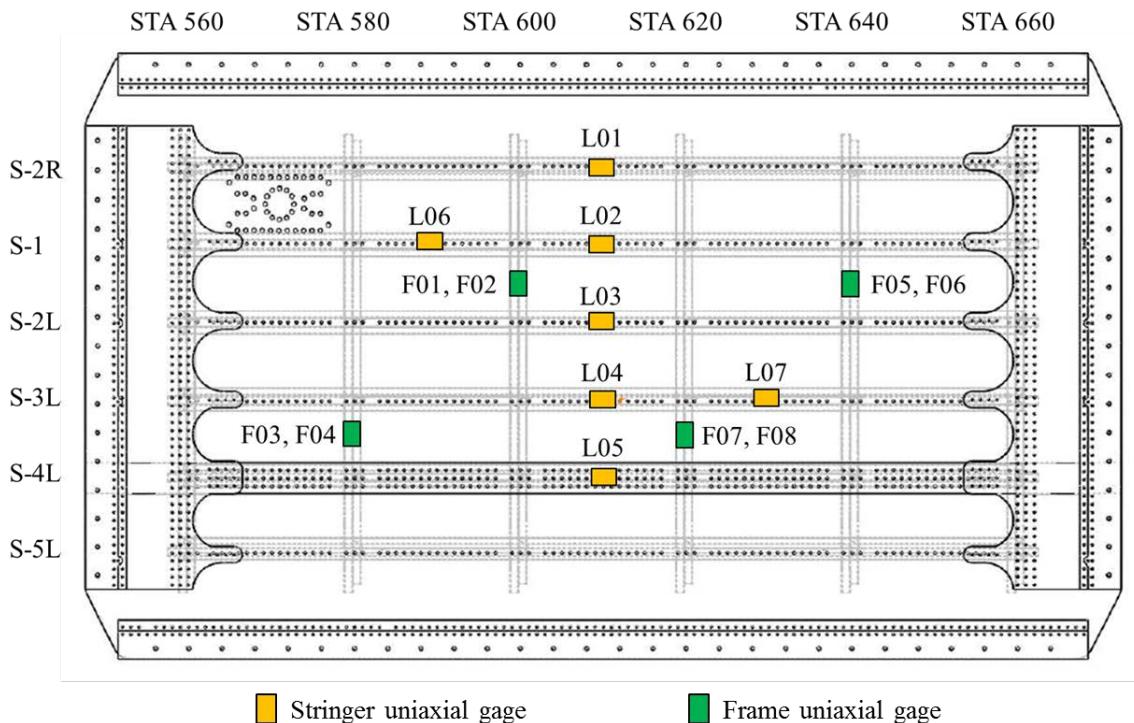

Figure 12. Strain gauge locations for substructures

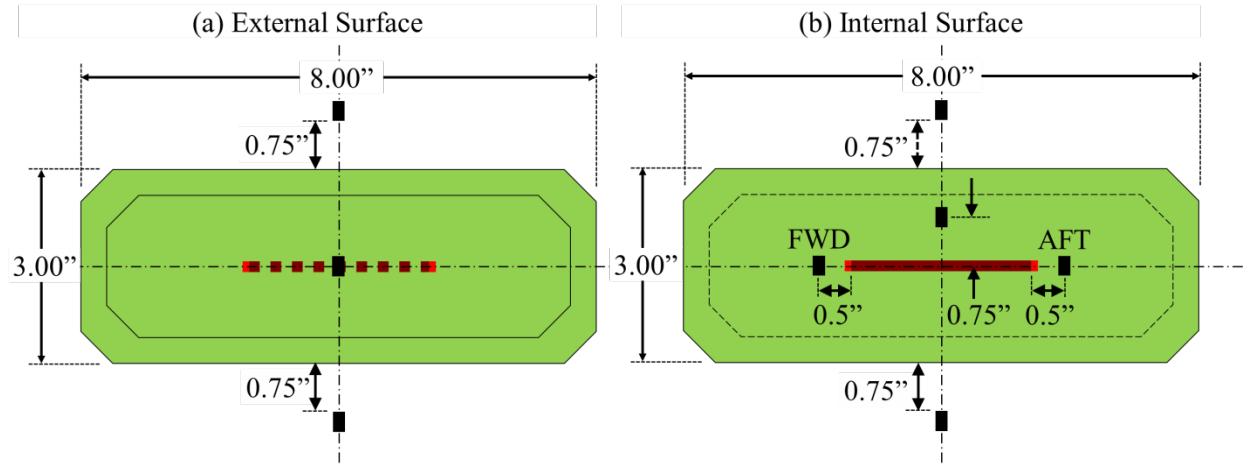

Figure 13. The typical strain gauge layout on the panel: (a) external surface, and (b) internal surface

In this supplementary study, the objective of using a strain gauge chain was to examine whether a single gauge is sufficient to accurately determine the stress intensity factor (SIF) for a curved panel with bonded repairs. The strain gauge chain was installed right in front of the crack tip (see figure 14). Details of the strain gauge layout and strain gauge chains are provided in appendix C.

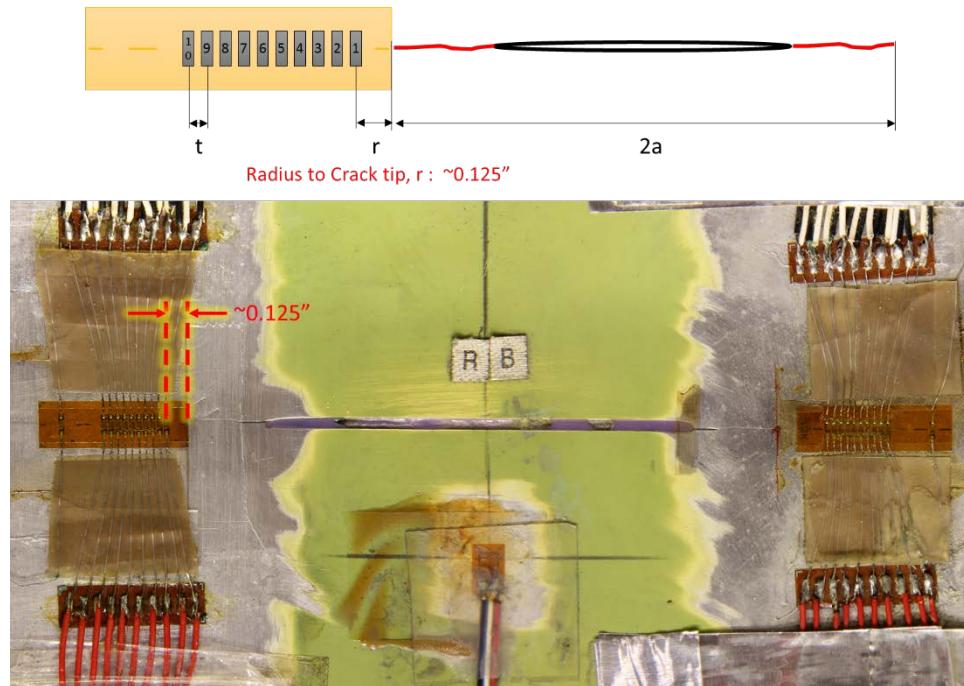

Figure 14. Typical setup of the strain gauge chain

2.8.2 DIC Monitoring

DIC was used to measure displacement and strain fields. The DIC is an optical method that tracks changes in images. The system consists of two digital cameras triangulating on top of the

specimen. The specimen is painted with a speckle pattern. By measuring the relative displacements of the speckle pattern, the DIC method resolved full field measurements of the strain and displacement.

It should be noted that the DIC data can be collected only in a laboratory environment under strain survey loads. It was limited by the size of the environmental chamber. The details of the inspection methods and strain monitoring methods are provided in references [7].

2.9 DESCRIPTION OF SHM SYSTEM

2.9.1 Approach

The SHM system in this study consisted of a network of surface-mounted piezoelectric actuators and sensors at two repair locations and the associated hardware for collecting data. The two patches monitored included the underdesigned boron patch and the underdesigned boron patch with disbonds.

The SHM actuators were excited by a short hanning windowed voltage signal, which in turn propagated ultrasonic waves throughout the structure via the electromechanical coupling intrinsic in piezoelectric transducers (PZT) material. The surrounding sensors responded mechanically and outputted a voltage signal that is collected by a data acquisition unit. A variety of signal characteristics that correspond to each wave path were used to train a linear regression model to understand crack length. The trained model was then used to predict crack length and compared to truth data provided by NDI and visual inspection to validate the SHM system.

The baseline plan for this test was to determine the survivability of the SHM sensors by assessing the ability to provide acceptable signal quality under the environmental conditions for the first 20,000 cycles. The goal was to develop and implement an SHM system that can withstand the environmental conditions outlined in this test plan, and then identify damage locations and sizing for the subsequent cycles of the test.

The network of piezoelectric ultrasonic transducers was used to assess the integrity of each bonded repair via wave propagation signals that correlate to crack and disbond growth. The locations of the transducers relative to the bonded repair were the same locations as for the previously tested panel 2 and are described in figures 15–16. Two types of transducers were used for this test:

1. Acellent SMART Layer (SML-SP-1/4-0) PZT Transducers on the inner surface of the panel
 - 0.25-inch diameter by 0.010-inch-thick PZT
 - Size = 0.45-by-1.5-by-0.030 inch
 - Flexible circuit: copper transmission lines sandwiched in polyimide layers
 - Removable wiring via standard Molex connector
2. Boeing Prototype SHM Environmental PZT Transducers on the outer surface of the panel, inside the environmental chamber
 - 0.25-inch diameter by 0.010-inch-thick PZT

- Size = 0.50-by-1-by-0.030 inch
- Flexible circuit: copper transmission lines etched in polyimide layer
- Potted for hermetic seal on all edges and wiring terminations with BMS 5-37, electrical potting compound

Transducers were bonded to both surfaces of the panel. Data cabling for the Acellent transducers was removable, but were installed with the intent to keep them connected at the transducer throughout the test. Data cabling for the Boeing transducers was permanent. Transducer locations and cables were routed as to not interfere with strain gauges or NDI inspection areas. Transducers were connected to a data acquisition unit and data were recorded during the periodic inspections of the test article.

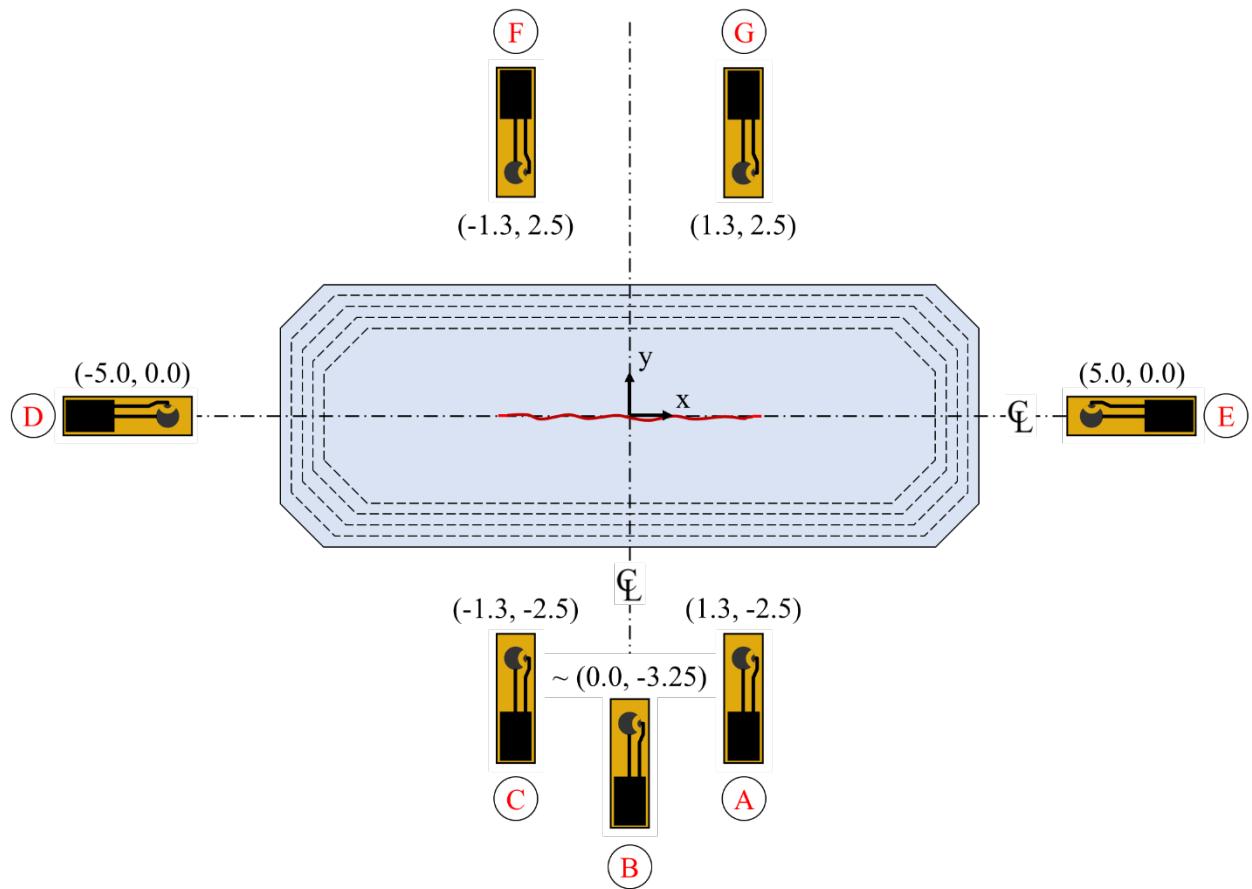

Figure 15. Piezoelectric transducer locations for the IML side at both UB and UDB patches

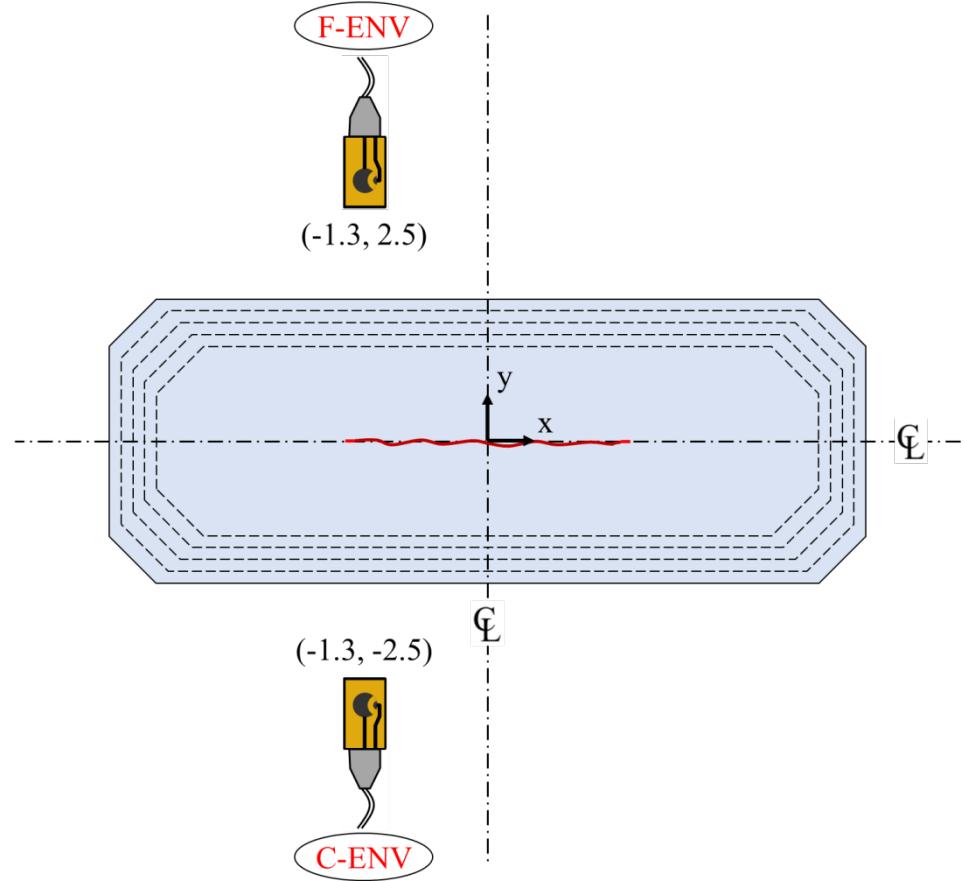

Figure 16. Piezoelectric transducer locations for the OML side exposed to the environmental test conditions at both UB and UDB patches

2.9.2 SHM System Requirements

2.9.2.1 Stay-out Zones

Regions of the test article must remain clear for NDI and ARAMIS strain mapping. An integrated instrumentation map was created to ensure all measurement techniques do not interfere. Additionally, piezoelectric transducers can experience significant performance degradation when exposed to strains over 1500 microstrain. Preliminary strains were used to determine areas unsuitable to bond transducers and ARAMIS strain survey data were checked before SHM instrumentation was bonded to the structure.

2.9.2.2 Data Collection

Boeing traveled to the site to install and set up the SHM systems. When the testing was stopped periodically for inspection, in accordance with the test procedures, SHM data were collected by FAA WJHTC personnel. Boeing trained FAA personnel on how to collect the data and transmit that data back to Boeing using the Boeing-approved encrypted data transfer system. An electronic copy of all recorded signal data, including transducer excitations and responses, was provided to all SHM team members. File format was CSV or MATLAB binary. Fixed length headers were

affixed to the files. Sample rate information was provided in the header or by other documentation. Each excitation and response was identified with a run number that corresponds with cycle number and the optically measured crack length. SHM data collection was performed using a Metis Design Intelli-Connector MD7 system. The data-collection equipment consists of a standalone hub with a power supply and a high-speed digital sensor node with a breakout board. Figure 17 shows a notional wiring diagram of this system.

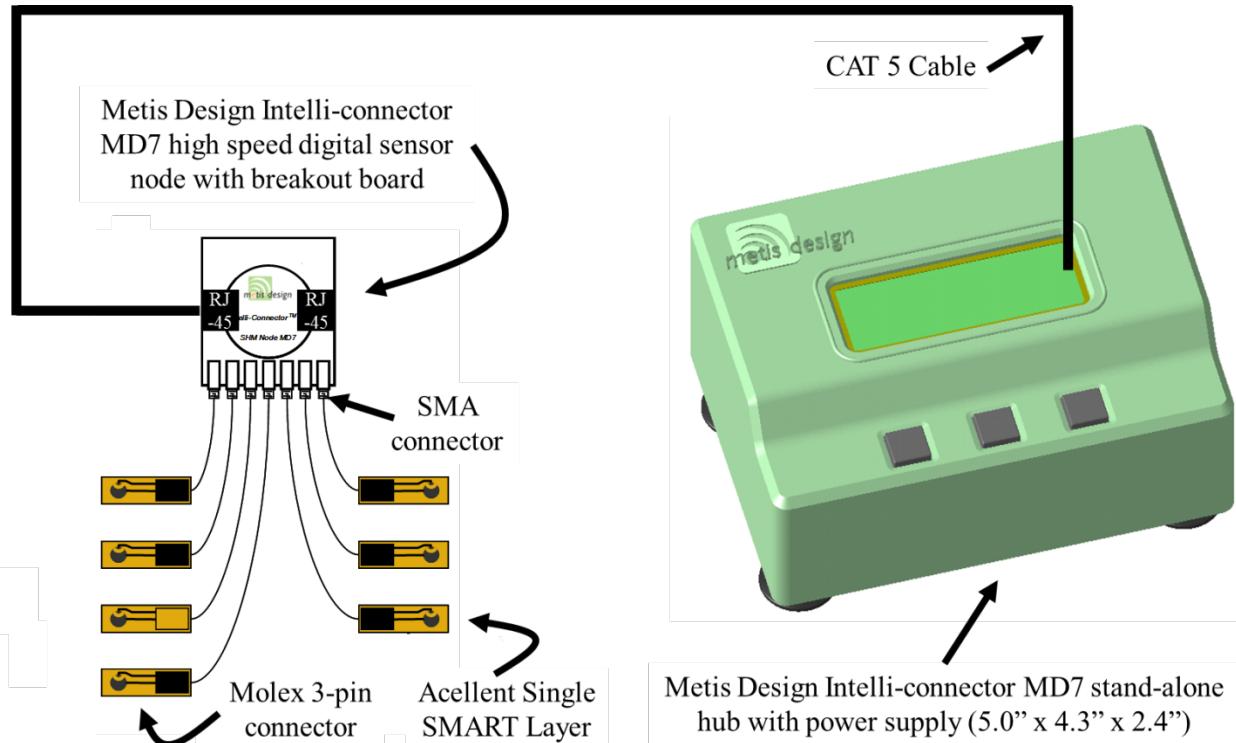

Figure 17. SHM data-collection system wiring diagram

2.9.2.3 Transducer Installation

Installing SHM transducers is similar to bonding a strain gauge in terms of surface preparation and time required. Note that SHM sensors were bonded to the structure after the successful application of the bonded repair. Boeing provided detailed transducer installation instructions.

2.9.2.4 Data to be Collected

The SHM system collected data as required to meet damage evaluation requirements. Boeing provided detailed data-acquisition instructions. To ensure that usable data were collected, the following safeguarding steps were followed:

1. The sensor system designs minimized noise and cross talk. Design features that performed this function were shielding for wiring on the sensor layer and separate ultrasonic actuation and sensing circuits.
2. After sensor installation, preliminary assessments were made to validate proper operation of the systems. Baseline data were collected after specimen installation in the test fixture but before fatigue cycling began. The data were analyzed to ensure proper bonding and to verify that the system was operating as expected.
3. Multiple datasets were collected for each data-collection cycle.

2.9.2.5 Time to Collect Data

SHM data collection required approximately 30 minutes.

2.9.2.6 Damage Detection and Evaluation Goals

The damage-evaluation systems determined the presence, location, extent, and type of damage in the specimen, as defined in table 5.

Table 5. Damage-detection goals

Category	Goal/Requirement
Presence	The damage-evaluation system must detect crack growth that is at least 0.2 inch from the initial cut or a disbond size of 1 inch ² .
Type	The damage-evaluation system must distinguish damage as either crack growth or patch disbond. The type of damage must be reported in a descriptive sense, such as “crack growth detected.”
Location	The system must report the location of damage in the specimen. The location of detected damage must be reported by the damage-evaluation system in a quantitative manner using engineering units (mm, cm, in.). Coordinate systems may be defined and used for reporting damage location. Alternatively, graphics may be used to show damage location.
Extent	The system must report the extent of the damage in the specimen. At a minimum, the system should report the length of a crack or the area of a disbond in a quantitative manner using engineering units. Coordinate systems may be defined and used for reporting the extent of damage. Alternatively, graphics may be used to show damage location.

Results reported from the damage evaluation systems were compared to the crack lengths and disbond information recorded by visual inspection and NDI.

3. ANALYTICAL PROCEDURE TO VERIFY TEST SETUP

3.1 INTRODUCTION

The pristine global finite element (FE) model was built and analyzed prior to panel testing to verify the test setup and applied loads. The global FE analysis provided predictions of the stress/strain full-field measurements. Stress and strain distributions obtained from the global FE model of the curved panel were compared with strain gauge data and digital image correlation results.

3.2 MODEL DETAILS

The global FE structural analysis of the Boeing 727 panel 3 was conducted using the commercial code ABAQUS. The model contained the major geometric details and dimensions of the panel, including detailed dimensions of the skin, the substructures (frames, stringers, and shear clips), and the reinforced doublers. The pristine panel was modeled using quadratic shell elements with six degrees of freedom (S8R). Multi-point-constraint tie constraints were used between substructures to replicate the behavior of rivets in the structure. The mesh was defined predominantly with quadrilateral elements with a size of approximately 1 inch on the skin, and 0.5 inch on the substructures.

To save computation time and deliver results more efficiently, certain degrees of simplification were made. It was assumed that the reinforced doublers were perfectly bonded to the panel and disbonding or structural failure was not expected. Following this assumption, five layers of reinforced doublers were merged to be represented by a single shell. By assigning various cross section properties (i.e., section thickness) to the shell, the essential features of the reinforced doublers were still taken into consideration. Moreover, approximately 20,000 elements could be reduced by merging five layers of reinforced doublers into a single shell. Similarly, the lap joint and tear straps could be simplified using the same approach while keeping the essential characteristics of the detailed structure. Finally, the entire model includes 39,129 S8R elements. Figure 18a shows the full assembly of the panel with the frame and stringer substructure and the skin. Figure 18b shows the shell section thickness in color code. The dark blue color shows the thinnest area (0.04 inch) in all mid-bay locations; the red color shows the thickest area (0.292 inch) in the regions of the attached reinforced doublers. The material properties used in the analysis are listed in table 6 for various structural components of a curved panel, stringers, frames, and clips.

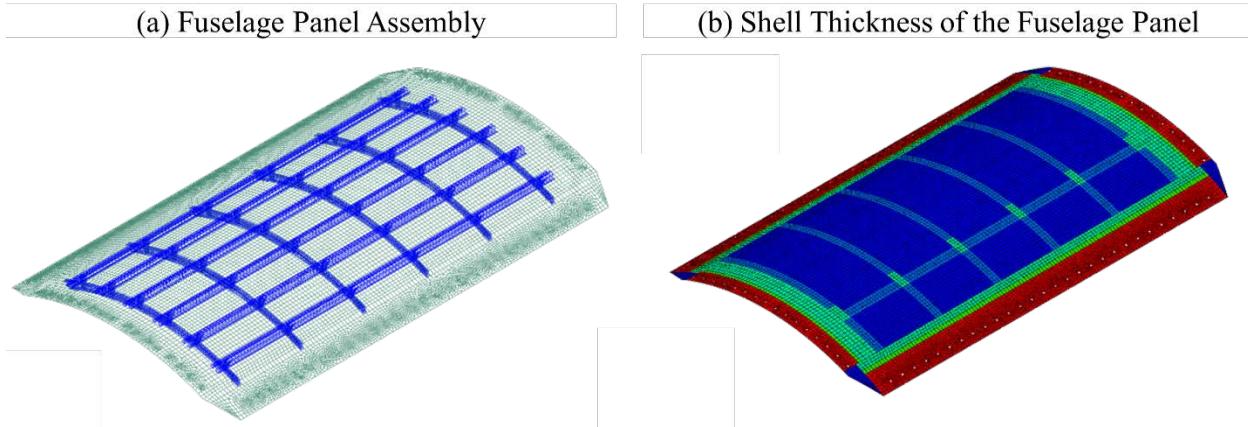

Figure 18. (a) Panel assembly; (b) shell section thickness of the panel

Table 6. Material properties of various structural components of the panel

Skin	
Material Type	2024-T3 Clad sheet, LT

Coefficient of Thermal Expansion	1.25E-05 in/ $^{\circ}$ F

3.3 LOADING CONDITIONS AND BOUNDARY CONDITIONS

Table 7 shows a load case representing 75% of the simulated service load. The mechanical loading conditions include internal cabin pressurization, longitudinal load, hoop load, and frame load. Figure 19 shows the final loading conditions, including the 14 simulated hoop loaders, eight simulated axial loaders, 12 simulated frame loaders, and the internal pressurization of the panel. Each loader consists of a whiffletree with four load-attached points. Because the whiffletree distributes load uniformly between all load-attached points, concentrated force will be applied directly to the panel, and the force value is equivalent to $\frac{1}{4}$ of each load transducer reading at the FASTER facility. Therefore, there is a total of 28 load-attached points along the hoop reinforced doublers and 16 load-attached points along the hoop reinforced doublers. This technique allows the model to simulate realistic applied loading conditions without modeling the whiffletree.

structure of the loaders. The same methodology was used to apply the longitudinal and frame loads. Note that the radial links of the frame loaders were modeled to provide extra flexibility when the panel deformed. A single beam element was used to model each radial link, with the bottom of the links pinned to constrain the radial and the hoop displacements. Finally, the midpoint of each edge was constrained to prevent rigid body motion.

Table 7. Strain survey loading conditions

Description	Maximum Mechanical Load					Constant Environmental Load	
	Load Phase	Pressure (lb)	Hoop (lb)	Axial (lb)	Frame (lb)	Temperature (°F)	Humidity (%)
Strain Survey, 75% of SL	Quasi-static	6.7	7140	6675	1133	Ambient	Ambient

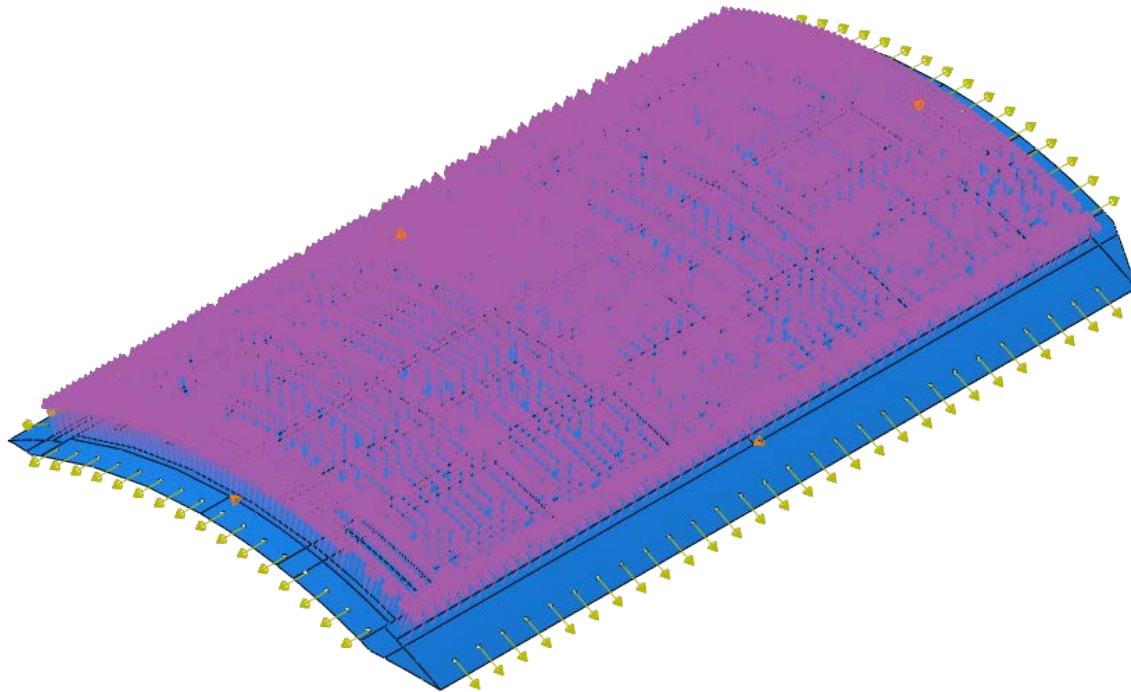

Figure 19. Final configurations of the simulated loaders (yellow) and internal pressurization (purple)

3.4 RESULTS AND COMPARISONS

Results predicted by the FE model of the pristine panel were compared to those measured during strain surveys. Figure 20 shows the strain gauge location on the external and internal skin of the panel. The test and simulation was conducted under 75% simulated service load at an ambient

environmental condition. The strain results were compared at various locations at the maximum strain survey loads.

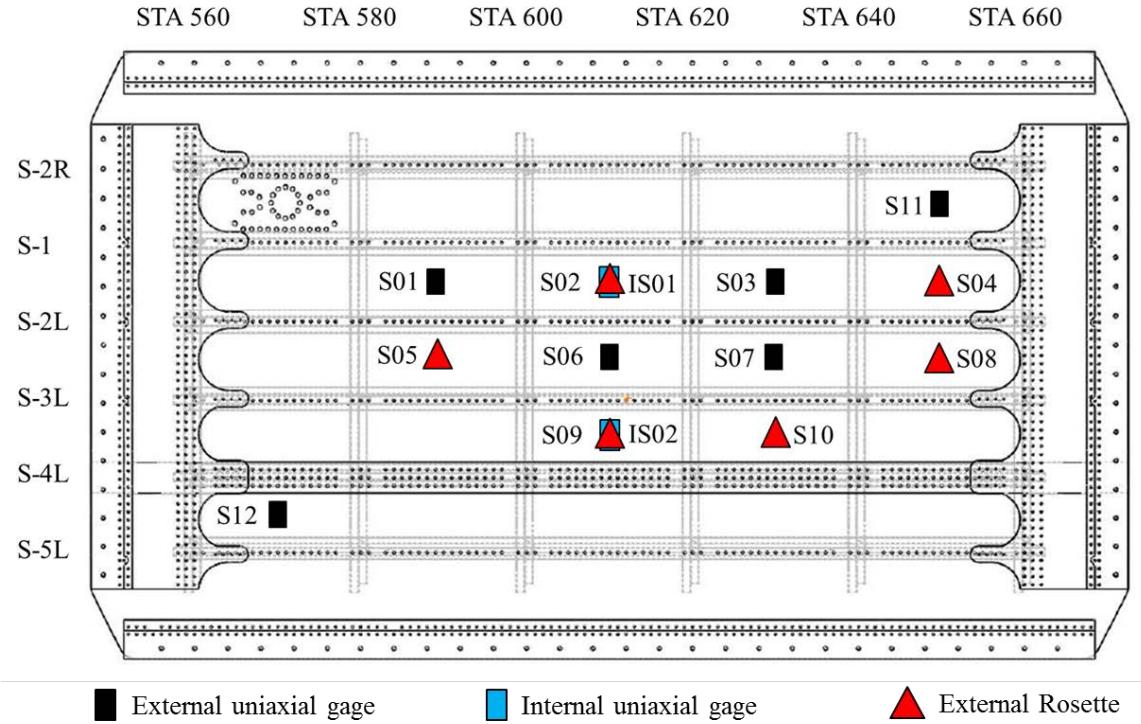

Figure 20. Strain gauge locations on the panel

Figure 21 shows the comparison between FE analysis prediction and the strain survey results of the pristine panel. Results indicated that both hoop and axial strain predictions from the FE model agreed very well with the strain survey results. The accuracy of the FE model ranged between 91% and 99% at all measured locations.

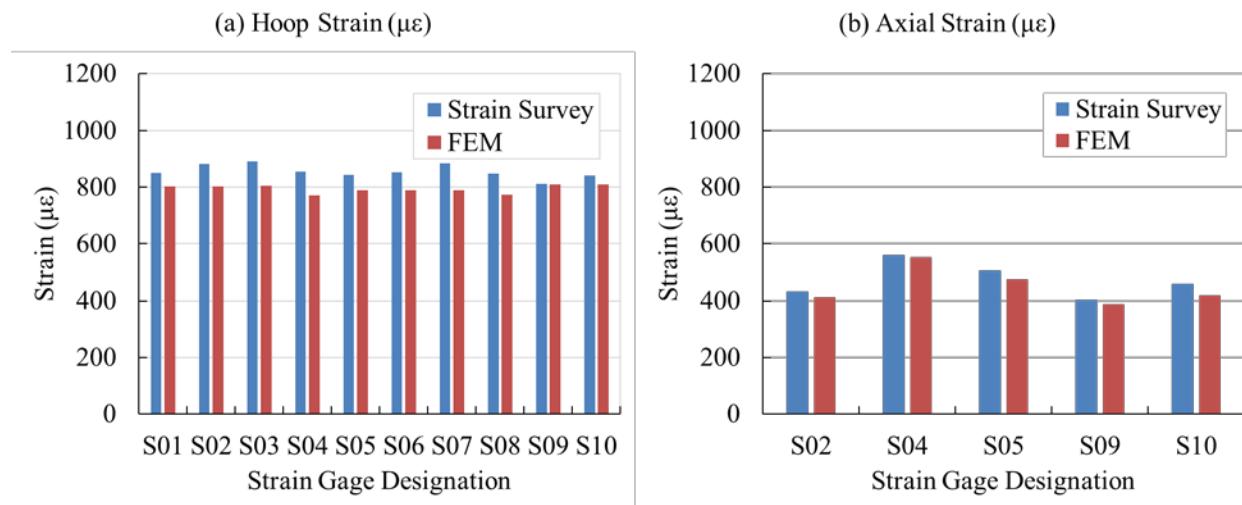

Figure 21. Comparison between fem and strain survey: (a) hoop strain, (b) axial strain

Further comparisons have been made showing the strain history as a function of internal pressure at the midbays next to the lap joint. Both hoop and axial strain were compared to three different strain surveys. Figure 22 shows the representative results of the comparisons compared with strain gauge S05, S09, and S10. Strain gauge S05 was installed on the external surface of the panel as shown in the green box. Strain gauges S09 and S10 were installed on the external surface and next to the lap joint, and are shown in the red and blue boxes. With panel pressurization, secondary bending occurred and introduced additional tension to the external surface of the lower side of the panel adjacent to the lap-joint because of local skin bulging. Therefore, a concave down tensile strain was observed at S09 and S10 locations. Overall the comparison of FE results and strain gauge results showed good agreement, verifying the test setup and applied loads.

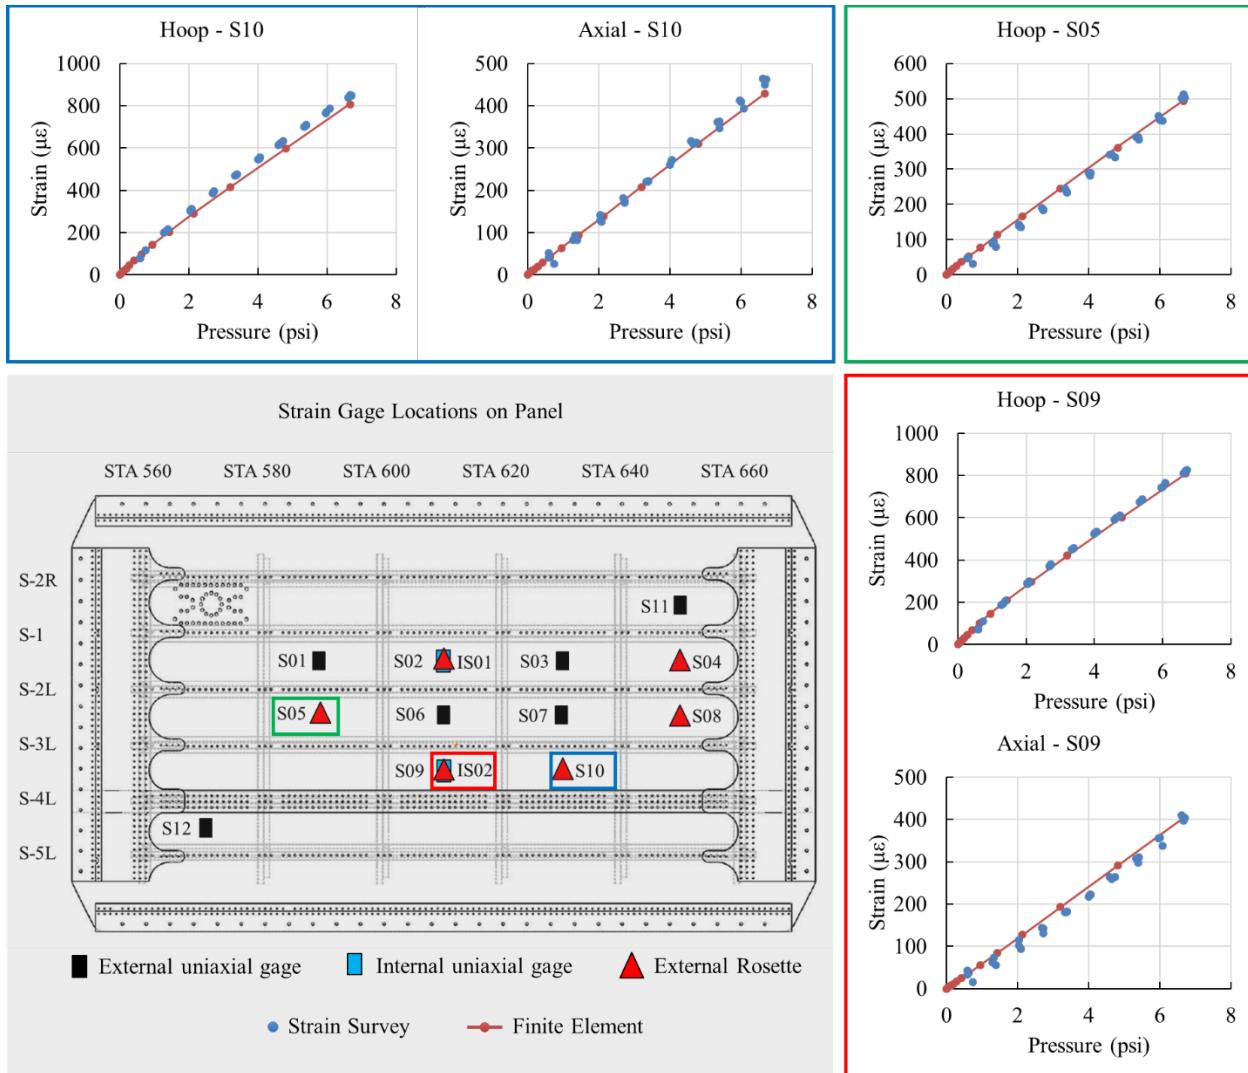

Figure 22. Strain ($\mu\epsilon$) as a function of internal pressure at S05, S09, and S10 locations

4. RESULTS AND DISCUSSION

Tests were performed to study fatigue performance of bonded repairs subjected to environmental conditions. The overall loading profile included mechanical fatigue loading simulated service

loads synchronized with temperature and humidity profiles. Representative results of strain survey, fatigue crack growth, and NDI are described in the subsequent sections.

4.1 UNEXPECTED MSD FORMATION

MSD unexpectedly formed during fatigue cycling, which evolved into a 20-inch-long crack (see figure 23). This was discovered during the 100,000-cycle inspection. As shown in the figure, MSD linkup is evident from the saw-tooth cracking pattern observed visually.

The MSD linkup was also manifested by the sudden change in strain distribution in all patches (see figure 24). The greatest change occurred in the hoop strain gauge data in the patch nearest to the MSD (the type 2 aluminum patch, UA), showing a sudden decrease in hoop strain ahead of both crack tips, as shown in figure 24d. The crack-tip strain dropped by approximately $500 \mu\epsilon$. The sudden drop in strain indicates that the MSD was linked up at approximately 97,800 cycles. Hoop-strain redistribution in the remote repair patches was also observed, as shown in all patches in figure 24. Unlike the UA patch, which is located right above the MSD region, other repair patches showed only a slight increase in the hoop strain. Because of the large strain redistribution near the repairs, results can be compared only up to the last inspection, which occurred prior to MSD linkup (i.e., 90,000 cycles).

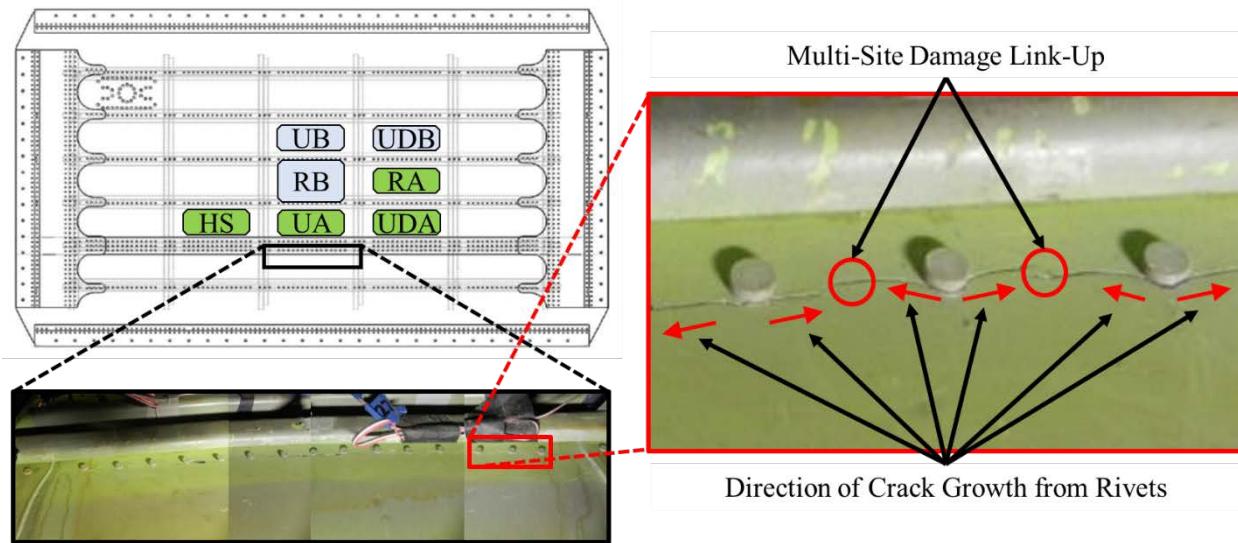

Figure 23. MSD on the internal surface of the skin

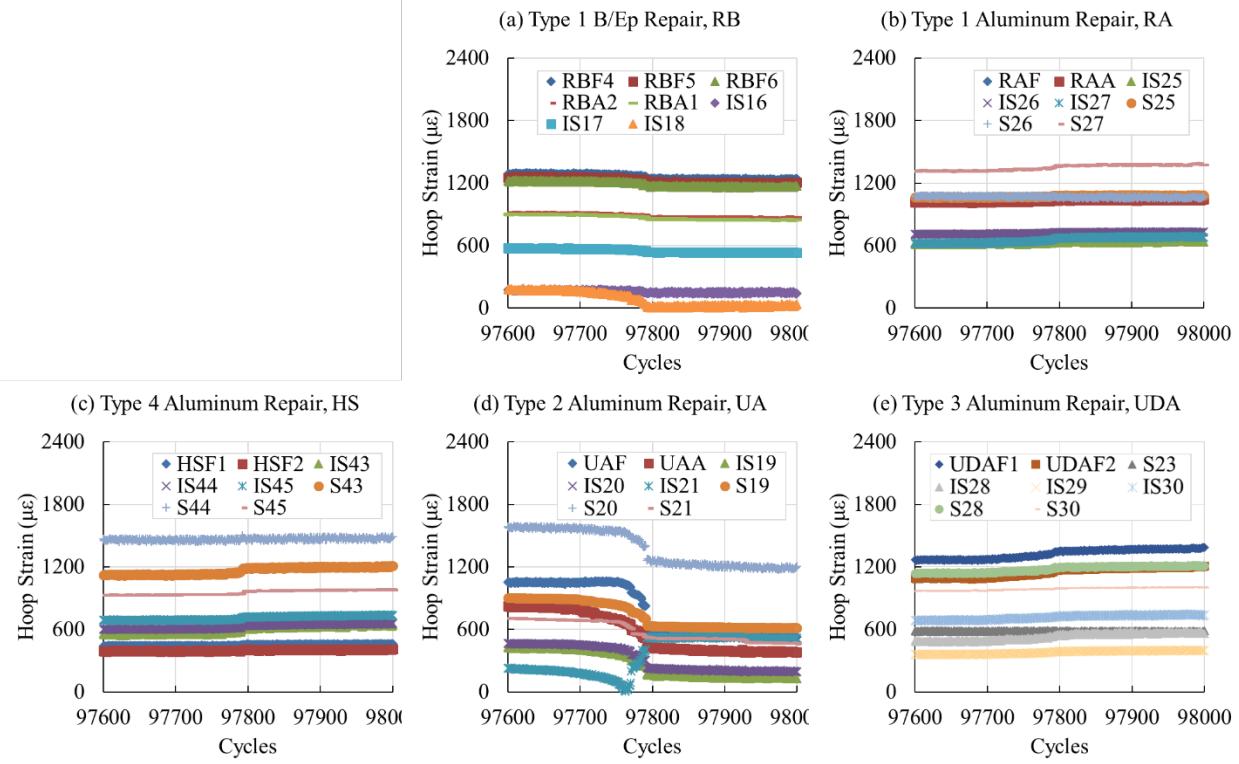

Figure 24. Hoop-strain monitoring during fatigue cycling. Hoop-strain redistribution observed at approximately 97,800 cycles: (a) RB, (b) RA, (c) HS, (d) UA, (e) UDA

4.2 THERMAL RESIDUAL STRAIN DURING CURING CYCLE

During the curing process of the repair installation, the strain near the crack tip and the temperature of the external surface were monitored. All measurements during the curing process are provided in appendix D. Representative results are provided in this section.

The typical strain gauge layout for each repair is shown in figure 25. The strain gauges installed 0.5 inch from the crack tip monitored the strain variations near the crack tip during the curing process. Back-to-back strain gauges installed 0.75 inch from the patch boundary monitored the occurrence of bending that happened during the curing process

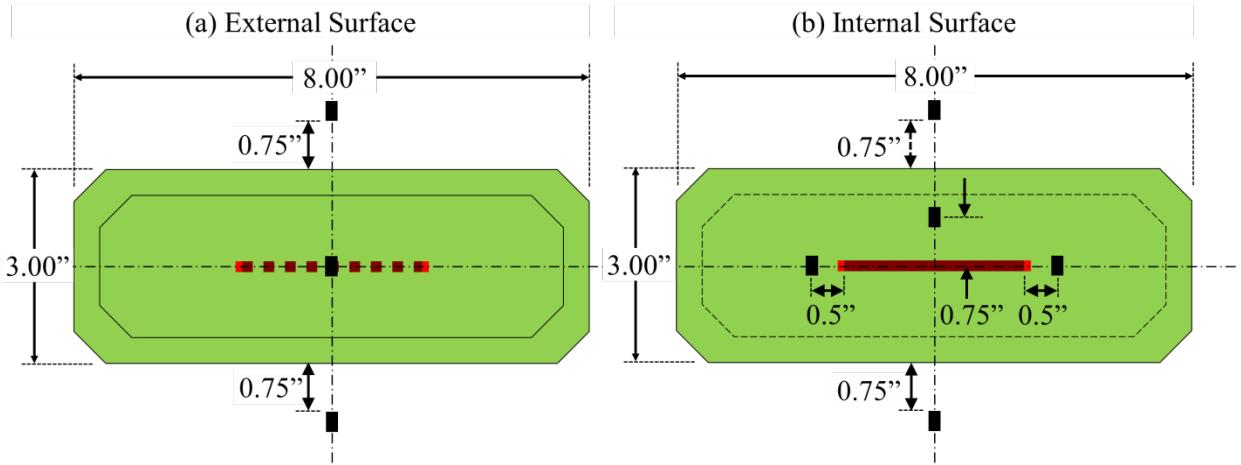

Figure 25. The typical strain gauge layout in the vicinity of each repair: (a) external surface and (b) internal surface

Representative results of the strain histories for reference B/Ep repairs are shown in figure 26. In the first 50 minutes of the curing process, the temperature was ramped up from room temperature to 250°F. The temperature was then held constant at 250°F for 90 minutes. In this stage, strain remained relative constant. After the temperature decreased to room temperature, thermal residual strains existed in all the repairs at the end of the cure cycle. The thermal residual strain in the vicinity or the crack-tip location for this repair was approximately 500 $\mu\epsilon$. All raw strain gauge data collected during the curing process are shown in appendix D.

Thermal residual strains, measured along the patch boundary of each repair at the end of the curing process, are shown in figure 27. In general, for both B/Ep and aluminum patches, the thermal residual strains on the internal skin surface along the patch boundary are in tension, whereas the corresponding strains on the external skin surface are in compression. The thermal residual strains at the boundary of the B/Ep patches were much higher than those in the aluminum patches because of the lower coefficient of thermal expansion of B/Ep.

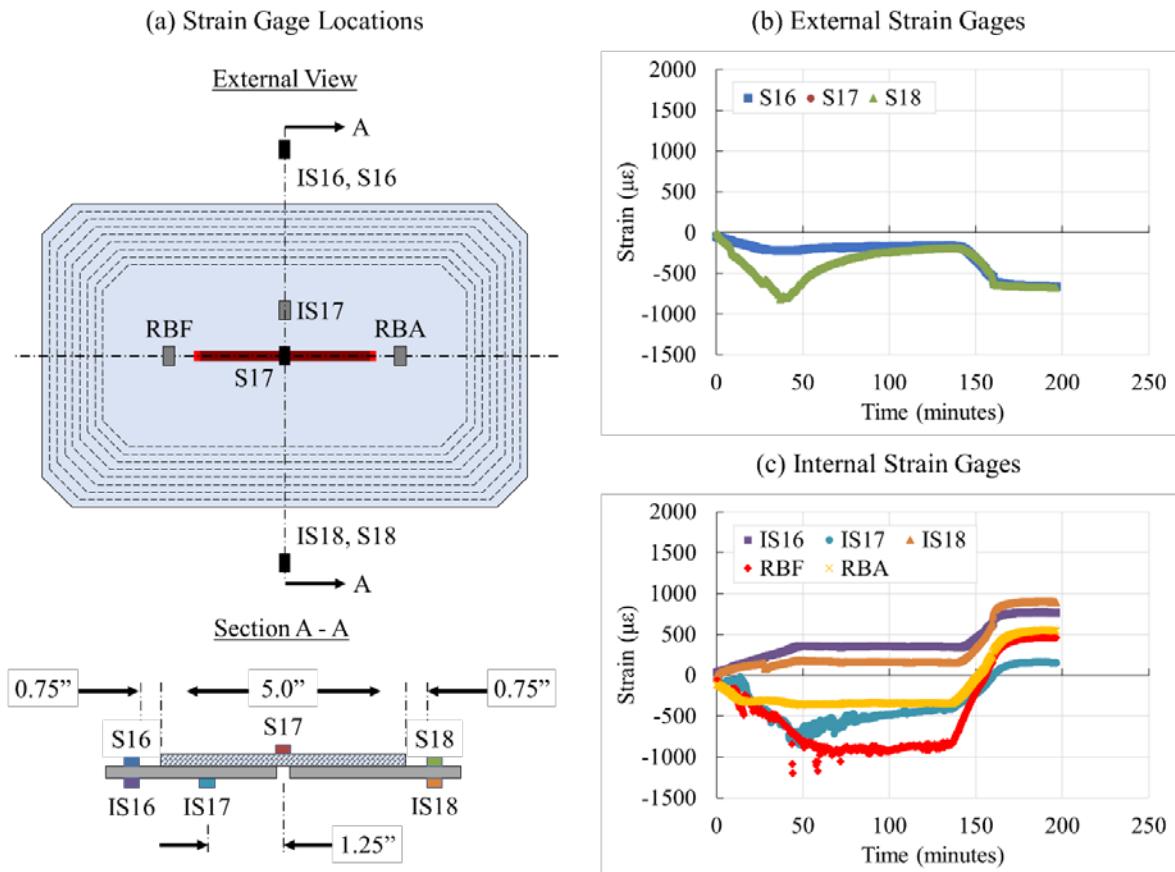

Figure 26. Strain history measurement during curing cycle of RB repair

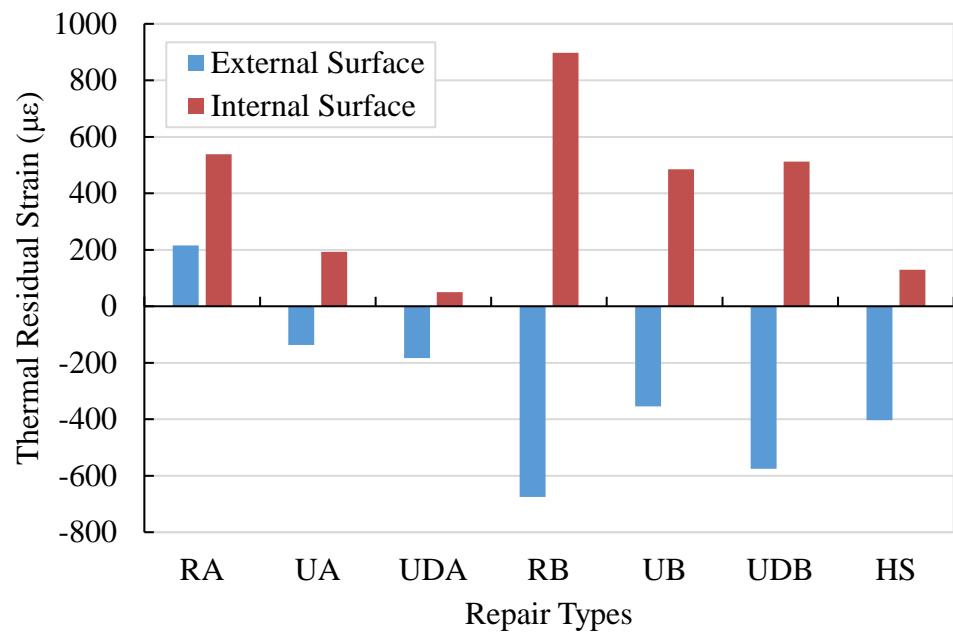

Figure 27. Thermal residual strain along the patch boundary of all repairs

4.3 STRAIN MONITORING

Strain surveys were taken at 75% of the simulated service load conditions under ambient conditions, at every 20,000 cycles, throughout the fatigue test. Representative results of the type-2 under-designed repairs are provided in the section. The strain history of all other repairs can be found in appendix E.

Type 2: Under-Designed Aluminum Repair

Figure 28a shows the typical strain gauge pattern and locations instrumenting each repair patch. For this example, a type-2 aluminum patch designated UA is considered. Along cross section A, gauges S19 and S21 were located on the outer surface of the skin, 0.75 inches away from the patch boundary. Gauges IS19 and IS21 were corresponding back-to-back gauges installed on the same location on the interior surface. Gauge S20 was located at the center of the patch on the outer surface.

Representative results for the UA patch are shown in figure 28b. The results indicate bending along the patch boundary where the outer skin surface is in higher tension than the inner skin surface. In addition, high compressive strains were measured in the center of the patch above the notch. The strain measurements history during fatigue is shown in figure 28c. The results of strain gauge S20 show that the compressive strain slightly decreased with fatigue cycles. However, these results are inconsistent because strain gauge S20 repeatedly disbonded because of compressive strains, and its replacement in a high-strain gradient region resulted in scatter. In general, strains remained relatively constant throughout the fatigue test.

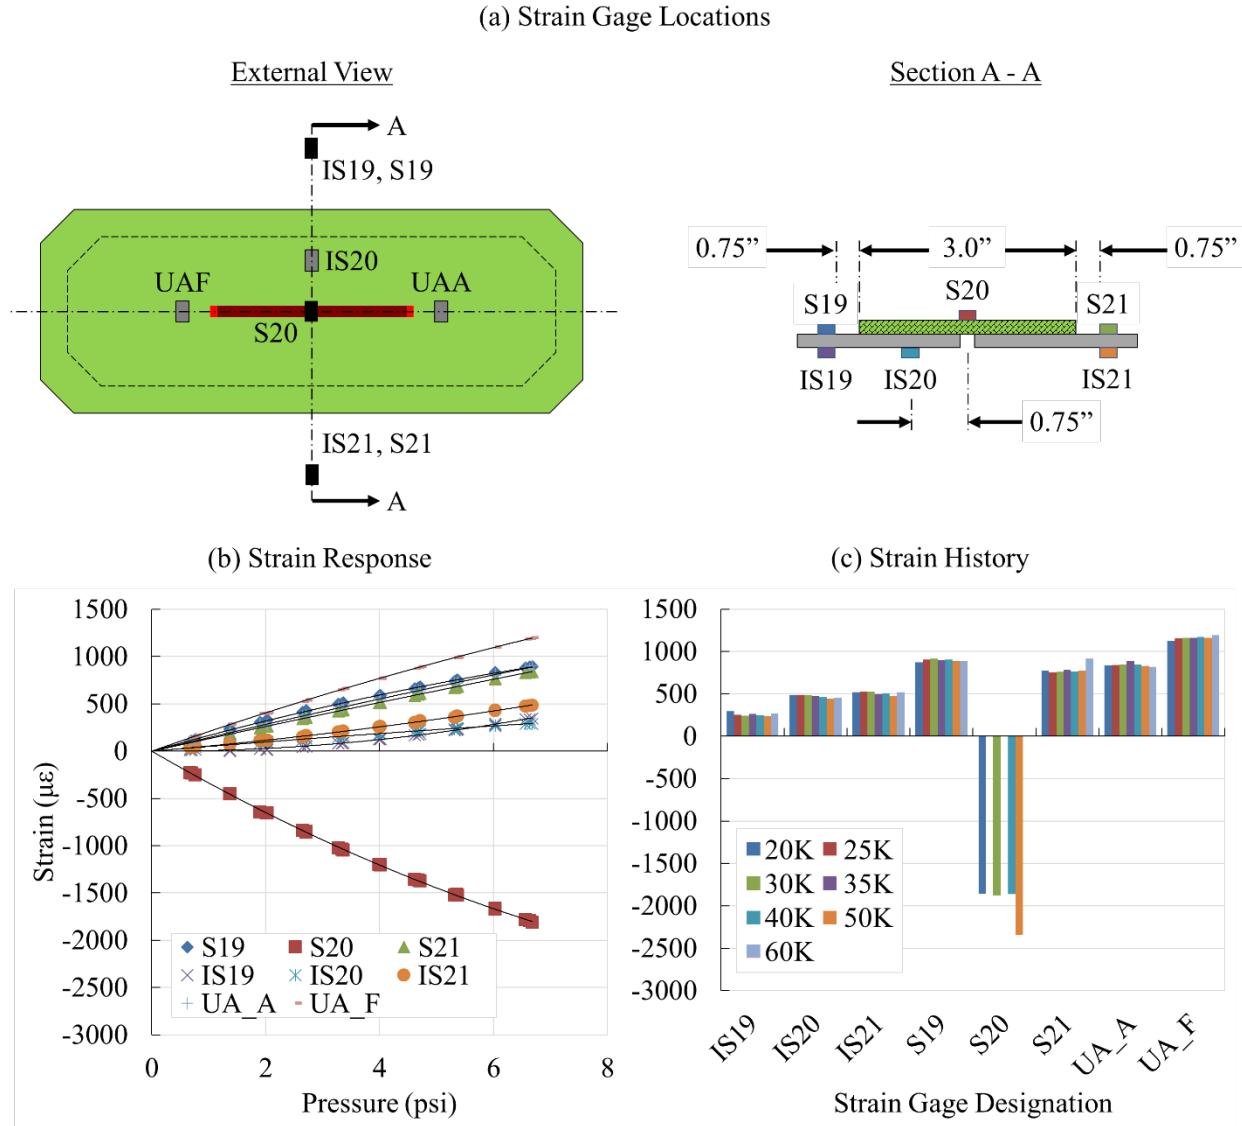

Figure 28. Strain-gauge measurements at strain survey loads in ambient environmental conditions during fatigue, type-2 aluminum repair, UA: (a) strain gauge locations, (b) strain survey as function of pressure, and (c) strain history

Type 2: Under-Designed B/Ep Repair

Similar results for a type-2 B/Ep patch, designated UB, are shown in figure 29. The strain gauges instrumenting the patch are indicated in figure 29a. Along the cross section A, gauges S13 and S15 were located on the outer surface of the skin, 0.75 inch away from the patch boundary. Gauges IS13 and IS15 were corresponding back-to-back gauges installed on the same location on the interior surface. Gauge S14 was located at the center of the patch on the outer surface.

Figure 29b shows a large amount of bending along the patch boundary where the outer skin surface is in tension, whereas the inner skin surface is slightly in compression. High compressive strains were measured on the outer surface of the repair patch over the notch centerline. The variation of

strain during fatigue is shown in figure 29c indicating a slight reduction in strains in the early stages of fatigue, resulting from the relaxation of residual strains induced during the curing process of the initial patch installation. After 10,000 cycles, the results appeared to be relatively constant throughout the fatigue test up to 90,000 cycles. The detailed raw strain gauge data for all the repair patches are provided in appendix E, and the procedure of the data reduction is provided in appendix F.

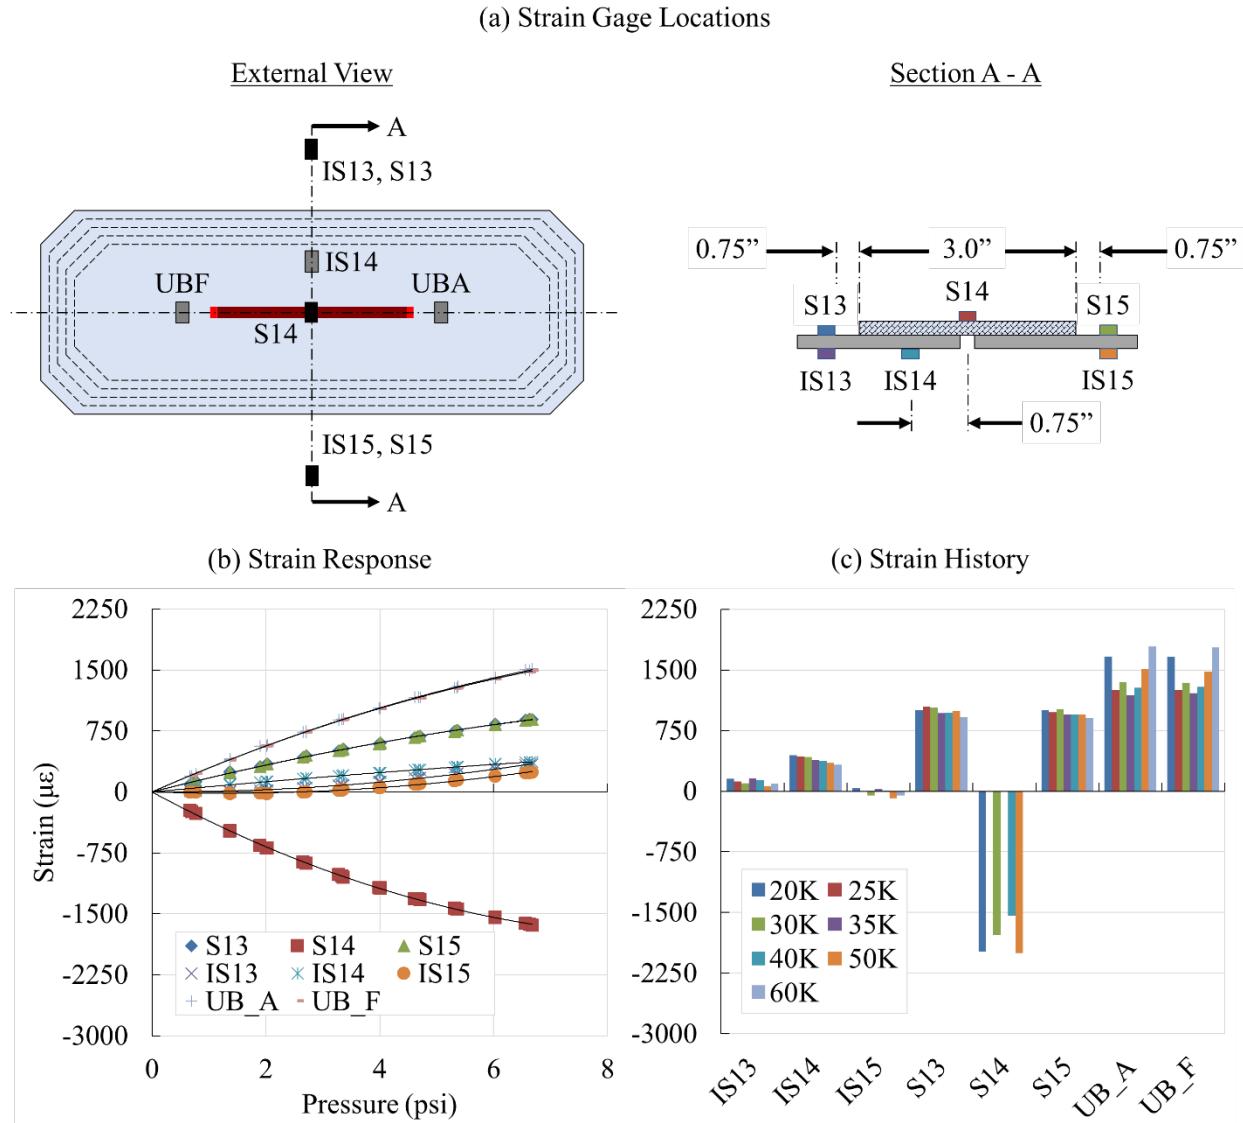

Figure 29. Strain-gauge measurements at strain survey loads in ambient environmental conditions during fatigue, type-2 B/Ep composite repair, UB: (a) strain gauge locations, (b) strain survey as function of pressure, and (c) strain history

Comparison of Type-2, Type-3, and Type-4 Aluminum Repairs

Representative results of type-2 (under designed), type-3 (under designed with disbonds), and type-4 (hand sanded) aluminum repairs are provided in this section. It should be noted that the

patch configurations (geometry and dimensions) of the type-4 repair were identical to that of the type-2 repair. Ideally, if the patches were perfectly bonded, strain field of all these patches should be similar. This is not the case, however, as surface preparation procedures and bonded surface areas were not the same for all of these repairs. In terms of surface preparation, the fuselage panel surface areas to which repair patches UA and UDA were installed were prepared using a grit blast deoxidization process, whereas the fuselage panel surface area to which repair patch HS was installed was prepared using a hand sanding process. In terms of bonded surface area, repair patches UA and HS featured identical patch geometry and dimensions and, therefore, identical bonded surface areas, whereas repair patch UDA included several areas of disbond that significantly reduced its bonded surface area.

Representative results are shown in figures 30 and 31 for strains measured along the patch boundary and in the center of the patch, respectively. In general, as shown in the figures, the measured strains of each repair remained relatively constant throughout the fatigue test. The back-to-back strain measurements along the patch boundary were compared between the type-2 aluminum (UA) repair, type-3 aluminum (UDA) repair, and the type-4 aluminum (HS) repair (see figure 30). In general, the bending hoop strains along the patch boundary were similar for the three types of aluminum repairs. The hoop strains at the center of the patch were compared between the UA, UDA, and HS repairs (see figure 31). Strains measured for UA and HS, repair patches with identical configurations, were approximately equal on the internal and external surfaces, whereas strains measured for UDA were significantly reduced. This difference in strain response can be attributed to the presence of disbonds that are prevalent in UDA and not the other two aluminum repairs.

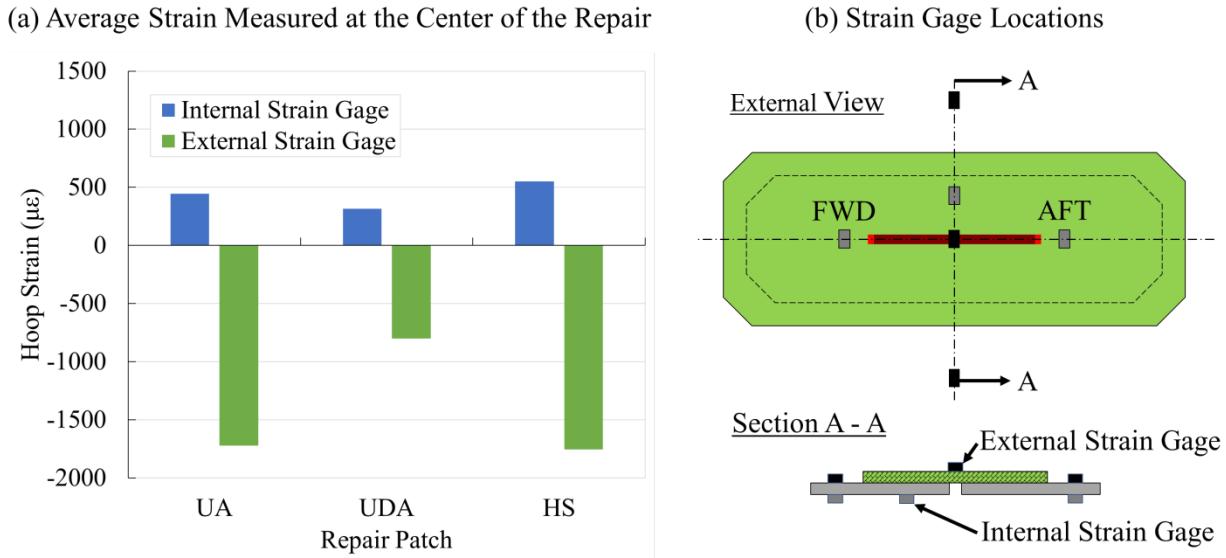

Figure 31. (a) Comparison of the average strain measured at the centers of repair patches and (b) the location of strain gauges with respect to the repair patches

Strain Surveys at Different Environmental Conditions

During the test, strain surveys were conducted at every 10,000 cycles. This strain survey data were collected at ambient and hot-wet (165°F and 85% RH) environmental conditions during 20,000 to 80,000 fatigue cycles and at ambient, hot-wet (165°F and 85% RH) and cold-dry (-25°F) environmental conditions during 80,000–90,000 fatigue cycles. All results are provided in appendix G.

Representative strain survey results for B/Ep repairs are shown in figure 33 for three environmental conditions at 80,000 cycles. The location of these gauges with respect to the repair patch are shown in figure 32. Shown in figures 33a, 33b, and 33c are the strain measurements as a function of increasing pressure at cold-dry environmental conditions, ambient environmental conditions, and hot-wet environmental conditions, respectively, for the external and internal gauges in the vicinity of the patch. The comparison of the strains at maximum strain survey loads is shown in figure 33d. Shown in figure 34 are strain measurements at three environmental conditions at maximum strain survey loads for the crack-tip strain gauges.

Assessing the results, strain values measured at cold-dry environmental conditions were higher than those measured at ambient environmental conditions, and strains measured at ambient environmental conditions were higher than those measured at hot-wet environmental conditions. Similarly, both forward and aft side crack-tip gauges showed that the strains at cold-dry conditions were highest, and the strains at hot-wet conditions were lowest. Furthermore, as the gauge distance from the crack tip increases, the magnitude of strains reduced.

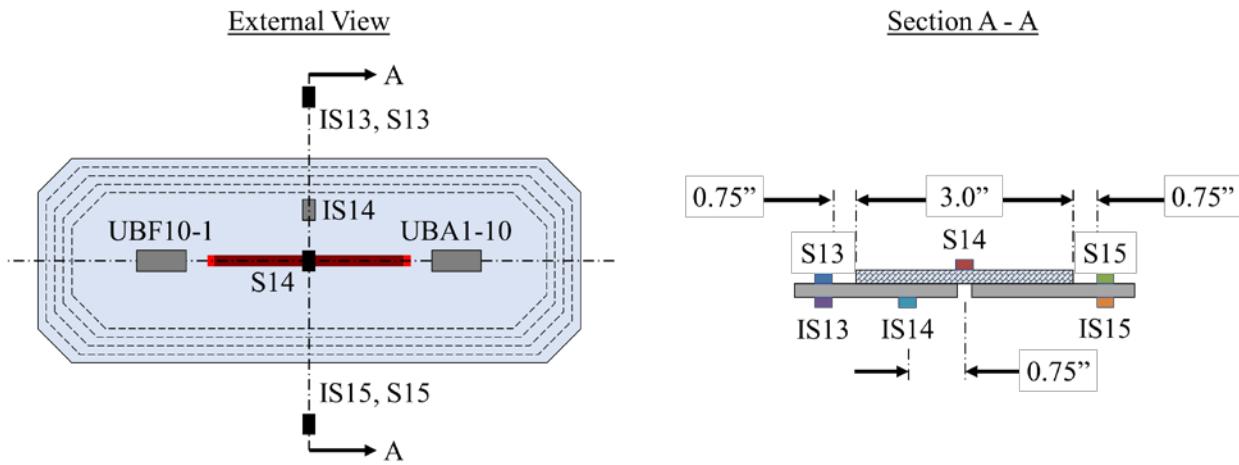

Figure 32. Location of strain gauges in the vicinity of the type-2 B/Ep repair patch, UB

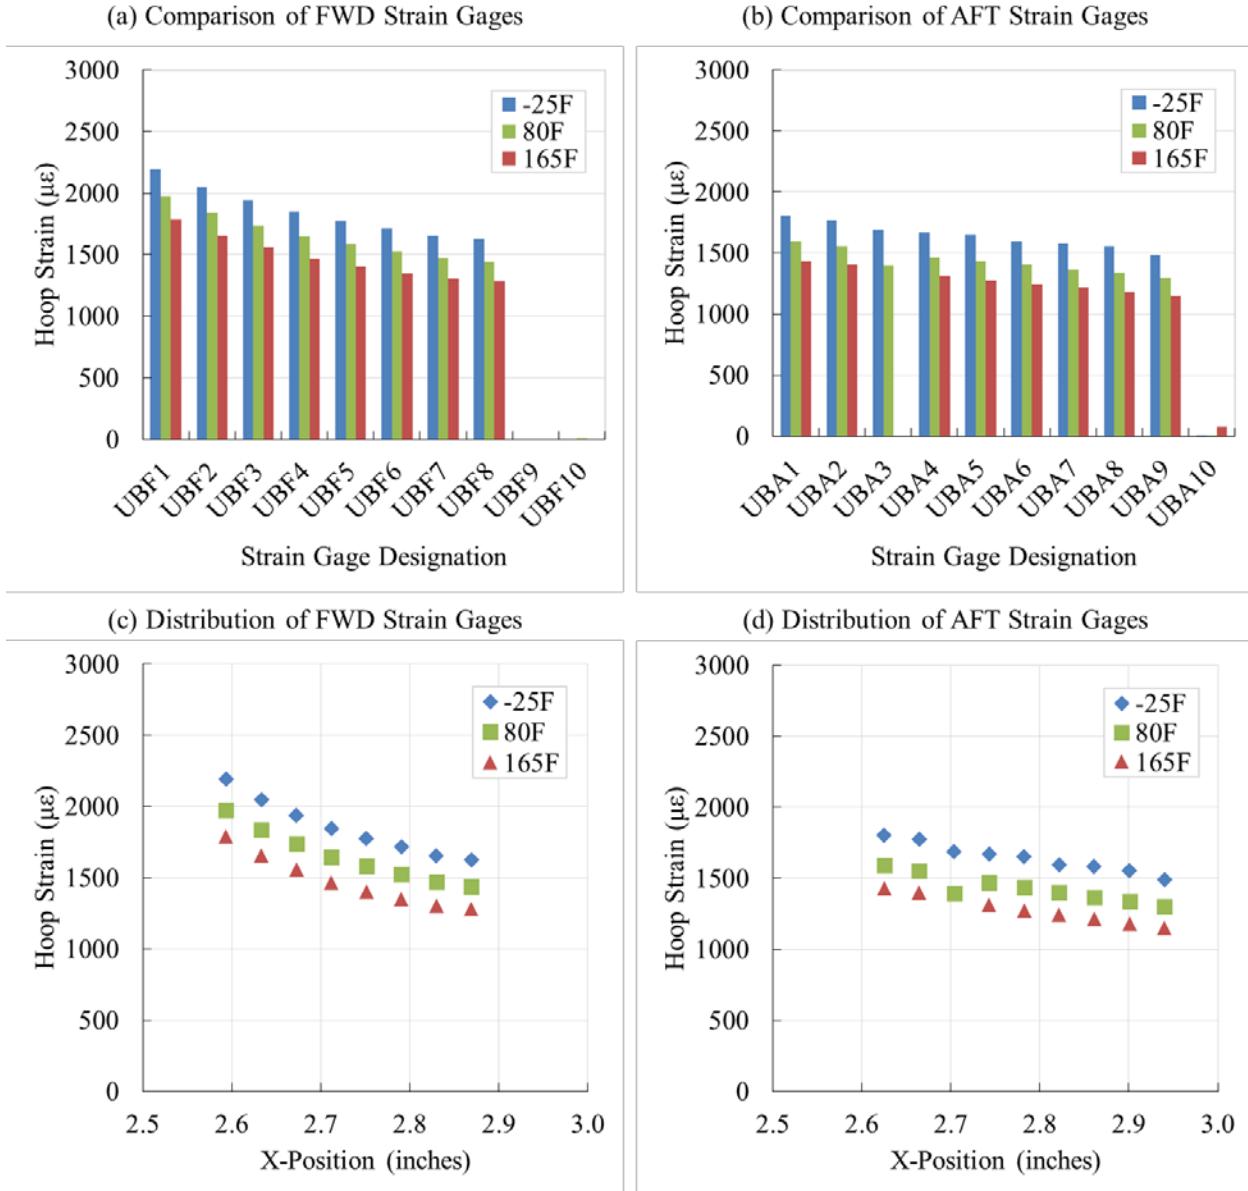

Figure 34. Notch-tip strain comparisons at maximum strain survey loading conditions under three different environmental conditions: (a) forward strain gauge chain and (b) aft strain gauge chain and strain distribution ahead of the (c) forward crack tip and (d) aft crack tip

Representative strain survey results for aluminum repairs are shown in figure 36 for three environmental conditions at 80,000 cycles. The location of these strain gauges with respect to the repair patch are shown in figure 35. Shown in figures 36a, 36b, and 36c are the strain measurements as a function of increasing pressure at cold-dry environmental conditions, ambient environmental conditions, and hot-wet environmental conditions, respectively, for the external surface, internal surface, and crack-tip gauges. The comparison of the strains at maximum strain survey loads is shown in figure 36d.

Assessing the results, strain survey measurements for the aluminum repairs showed that environmental conditions have a negligible effect on the strain at all locations within the vicinity of the repair. This difference in behavior can be attributed to the material properties of the fuselage panel and the repair patches. For the B/Ep repair, the difference between the coefficient of thermal expansion of the panel and the repair patch facilitated the development of thermal residual strain during the patch-curing process. The aluminum repair, however, exhibited the same material properties as the fuselage panel; therefore, the coefficients of thermal expansion were equal, and negligible thermal residual strain was developed during the patch-curing process.

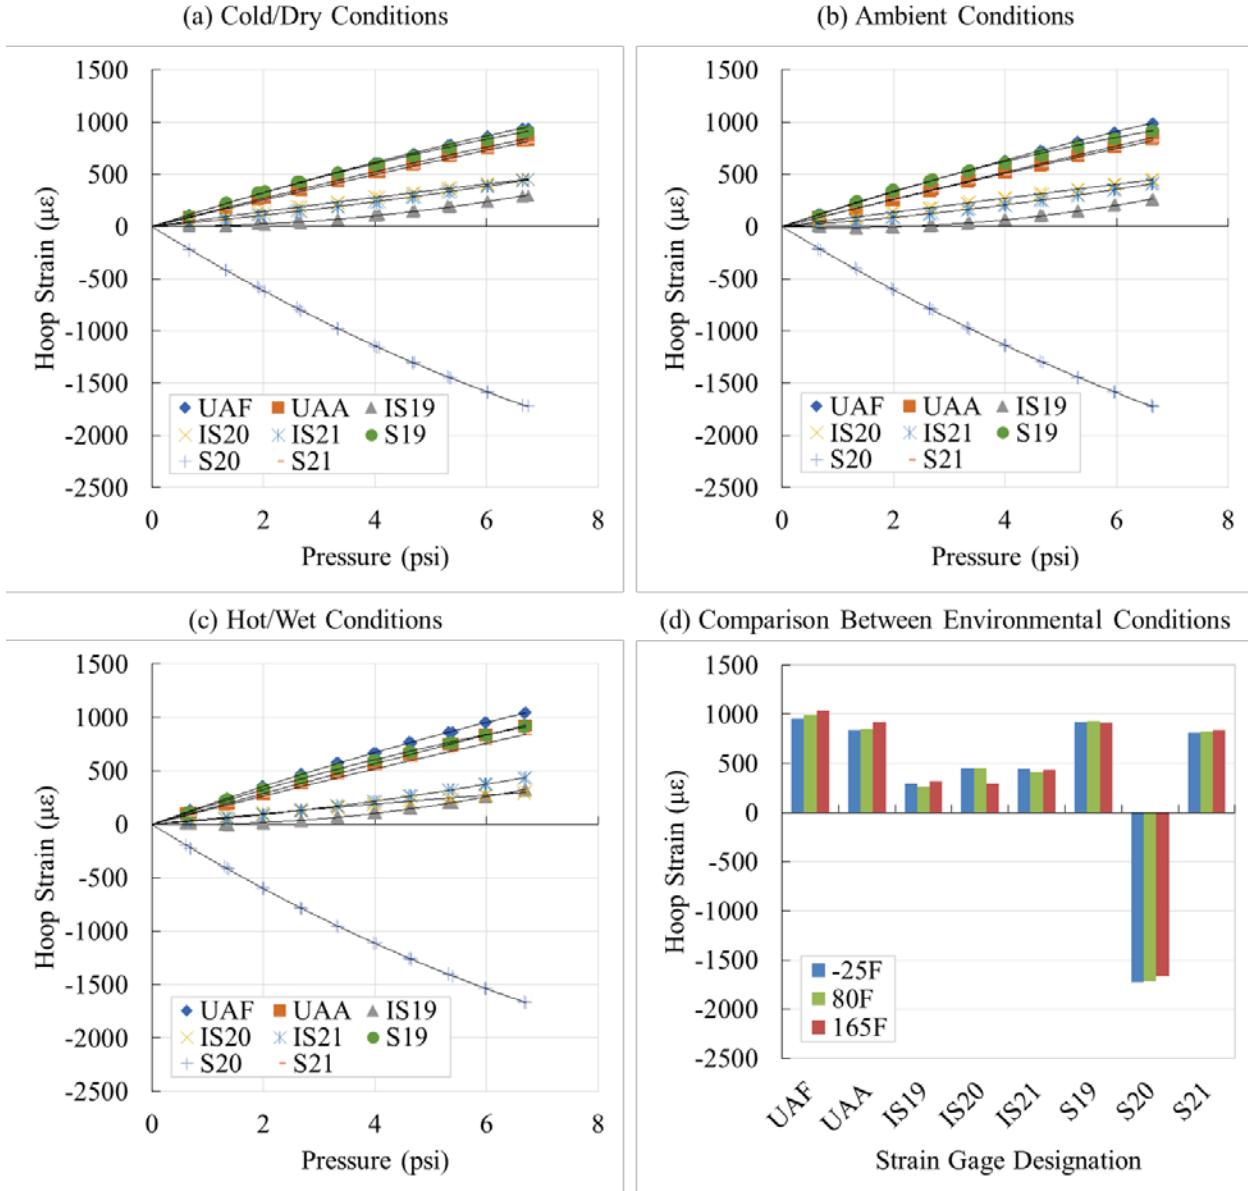

Figure 36. Results of strain survey conducted at 80,000 cycles at three environmental conditions for the type-2 aluminum repair, UA: (a) cold-dry conditions, (b) ambient conditions, (c) hot-wet conditions, and (d) a comparison between environmental conditions

Full-Field Strain Distributions

Wide-field-of-view (WFOV) images of the repair patch and surrounding area were taken using the DIC method to monitor for strain redistribution and load transfer. Full-field images of strain were taken periodically under laboratory ambient conditions at 75% service load conditions. Representative results of the full-field hoop strain are shown in figure 37 for type-2 aluminum repair, UA, at several fatigue cycles. As shown, tensile strains were measured in the vicinity of the patch boundary in the skin, whereas compressive strains were measured in the center region of the patch along the notch centerline. Similar trends in the results were observed from strain gauge

measurements shown in figure 36. In general, the global strains on the external surface remained relatively constant throughout the fatigue test up to 90,000 cycles.

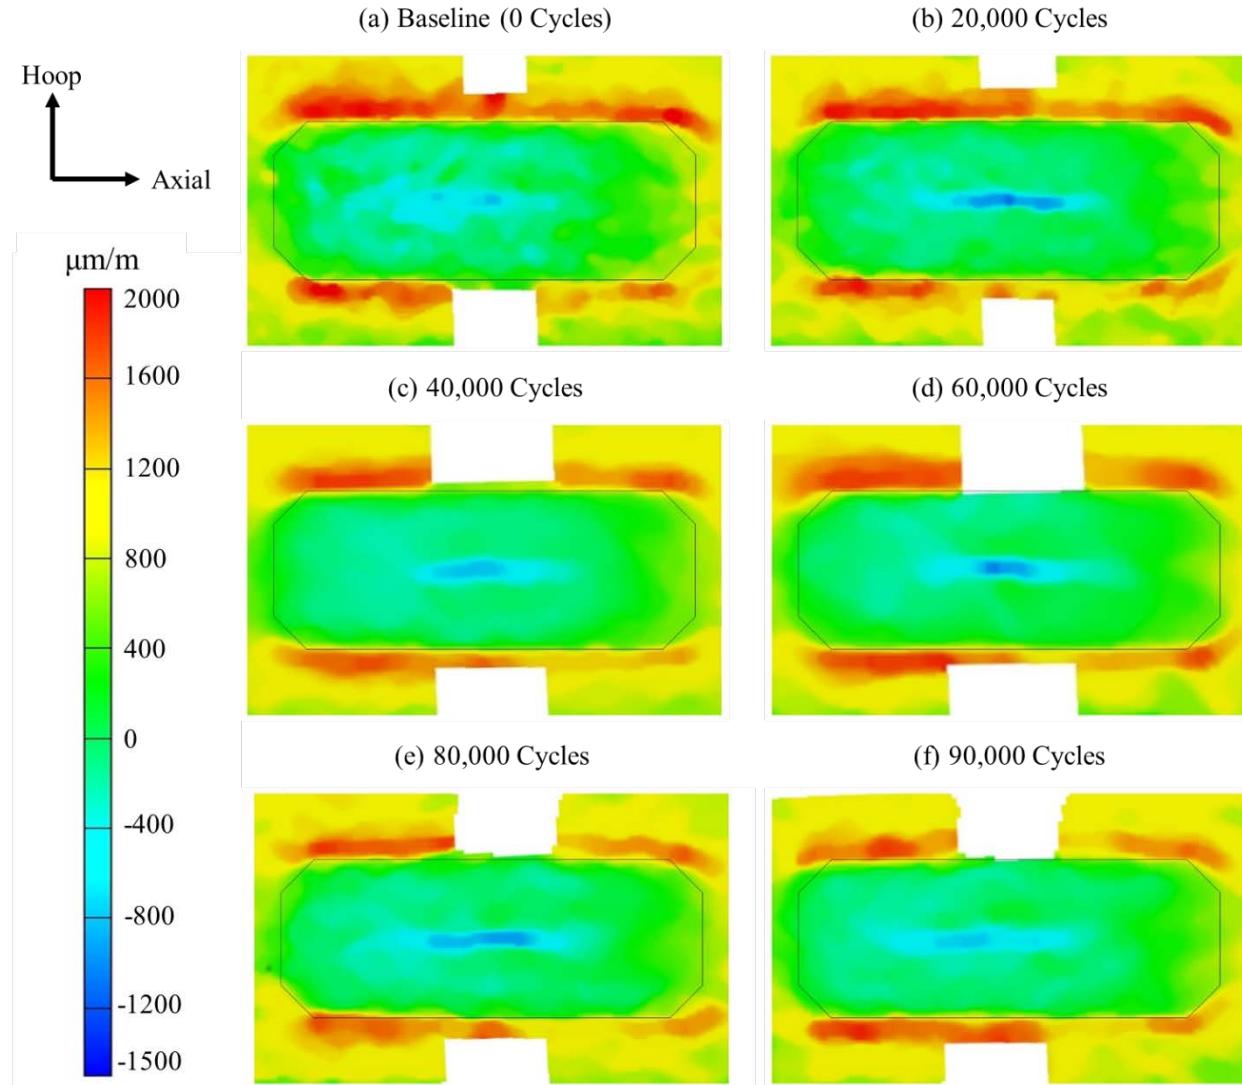

Figure 37. WFOV full-field hoop strain for UA repair at strain survey loads in ambient environmental conditions during hot-wet phases: (a) baseline, (b) 20,000 cycles, (c) 40,000 cycles, (d) 60,000 cycles; and during cold-dry phases: (e) 80,000 cycles and (f) 90,000 cycles

Further details from higher resolution, full-field strain measurements near the notch region are provided in the narrow-field-of-view (NFOV) images using the DIC method, which is shown in figure 38. The figure shows strain measurements made at three stages of the fatigue test: baseline (zero cycles), the middle of the fatigue test at 40,000 cycles, and the end of the fatigue test at 80,000 cycles. Local strain redistribution is evident by the expansion of the compression zone at the center of the repair patch, which is a result of crack extension.

In addition, the hoop-strain variation across the patch, shown in figure 38, is provided along three vertical sections equally spaced at 1.5 inches apart: section 1, located along the centerline of the

patch; section 2, located within the original crack-tip region; and section 3, located in the intact region ahead of the original crack tip. Overlaid in the section plots are strains measured using strain gauges. In general, the hoop strain varied most along the patch boundaries and toward the center of the patch where the notches were located. Strain redistribution occurred with crack extension, as seen by the growth of the compressive region in the center of the patch. In addition, there was good correlation between strain measured by strain gauges and that which was measured using DIC.

Along section 1, the hoop-strain values ranged from approximately 2000 $\mu\epsilon$ in the skin outside the patch to approximately -2500 $\mu\epsilon$ in the center of the patch for the baseline measurement (see figure 38a). High-strain gradients were evident over short distances at the patch boundary and the notch region. Across the patch boundary, the strain was reduced from 2000 $\mu\epsilon$ to zero over a distance of approximately 0.2 inch. The strain gradient was also quite high in a narrow band of approximately ± 0.5 inch around the notch. Over this short distance, the strain ranged from 0 to -2500 $\mu\epsilon$. The magnitude of the compressive strain in the center of the patch was reduced to approximately -2000 $\mu\epsilon$ as the number of cycles increased, as shown in figures 38b and 38c for 40,000 and 80,000 cycles, respectively. As shown in the strain-variation plots, data from the DIC were in good agreement with data measured using strain gauges that were also located along section 1.

Similar trends in strain distributions were displayed along section 2, where high-strain gradients occurred over short distances at the patch boundary and the notch region. The values ranged from approximately 2000 $\mu\epsilon$ in the skin outside the patch to approximately -1500 $\mu\epsilon$ in the center throughout the fatigue test.

Along section 3, high-strain gradients were initially measured over short distances only at the patch boundary. Hoop-strain values ranged from approximately 2,000 $\mu\epsilon$ in the skin outside the patch to approximately -500 $\mu\epsilon$ in the center, as shown in figures 38a and 38b, at the baseline (zero cycles) and 40,000 cycles, respectively. As shown in figure 38c, the compressive region crosses section 3, resulting in an increase in the compressive hoop strain to -1500 $\mu\epsilon$ in the center of the patch. Similar results obtained from all other repair patches are shown in appendix H (DIC data).

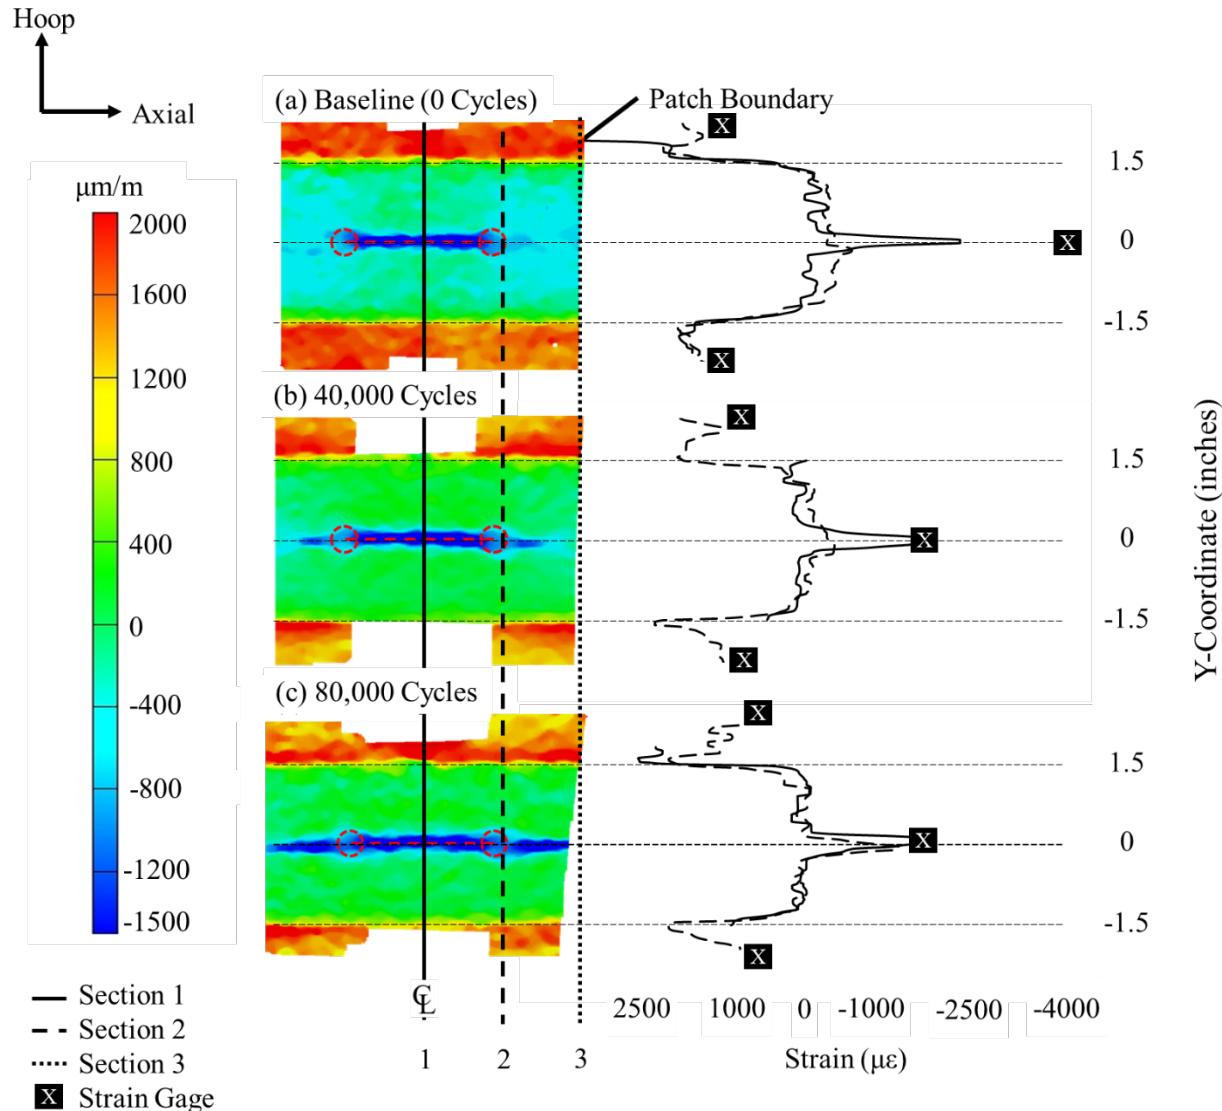

Figure 38. NFOV hoop-strain variation in the type-3 B/Ep repair, UDB; and comparison between DIC and strain gauge measurements at different cycles: (a) baseline (0 cycles), (b) 40,000 cycles, and (c) 80,000 cycles

4.4 FATIGUE CRACK GROWTH

Fatigue crack growth in the fuselage skin under each repair was continuously monitored visually using high-magnification cameras. Both low- and high-frequency EC inspections were made in 10,000 cycle intervals. In general, limited crack growth was observed in the type-2 aluminum repair, UA, as shown in figure 39. Apparently, the underdesigned configuration was conservative for this aluminum patch repair.

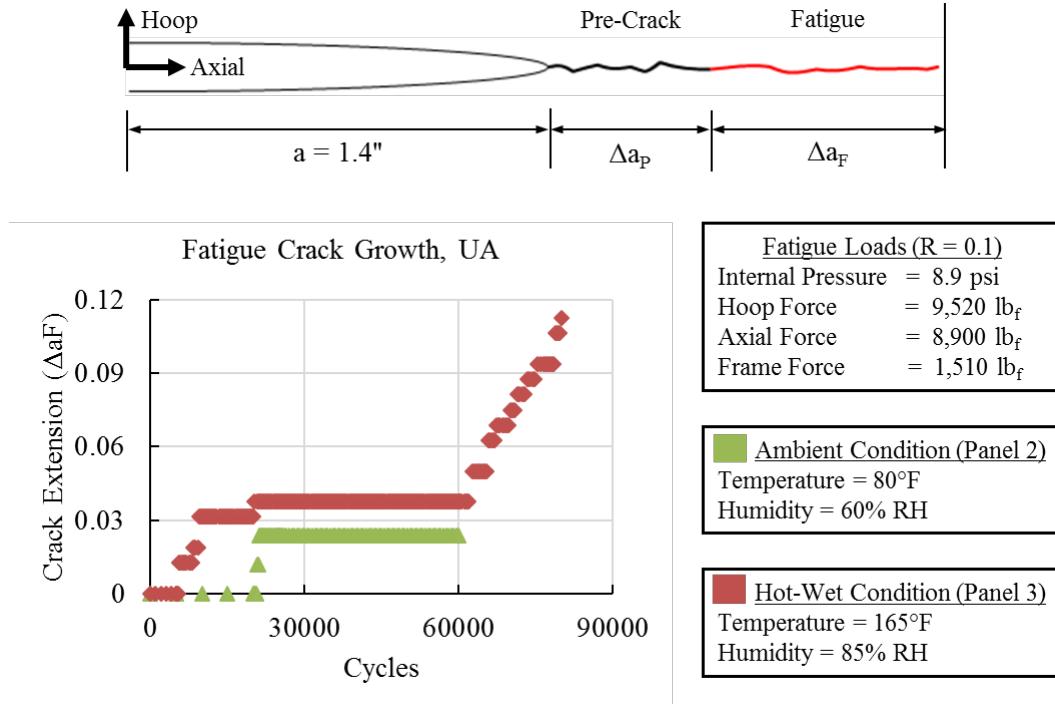

Figure 39. Fatigue crack-growth measurements of the underdesigned aluminum repair, UA

For the remaining repairs, namely the type-2 B/Ep repair (UB) and type-3 repairs (UDB and UDA), considerable fatigue crack growth was observed. Representative results are shown in figure 40 for the UDB and UDA repairs. As shown, slow and stable crack growth was observed in both repair patches. In addition, the crack growth was symmetric and co-linear, and the measured rate was nearly constant after the initial 5000 fatigue cycles. Results from visual and HFEC inspections were in good agreement. The complete crack-growth data in tabular form are provided in appendix I (Crack Growth Data).

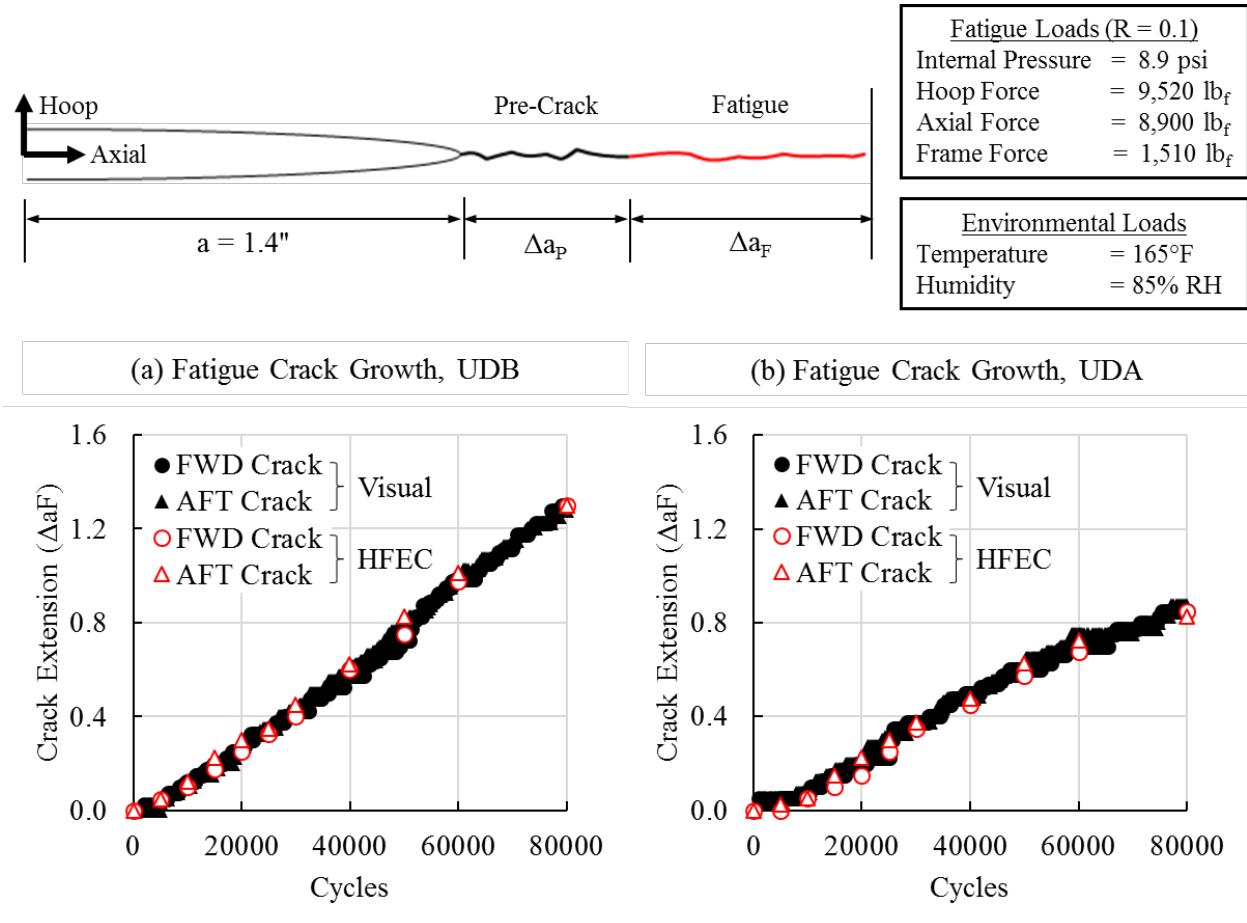

Figure 40. Fatigue crack-growth measurements: (a) B/EP repair, UDB; and (b) aluminum repair, UDA

A comparison of the results from panel 2 tested under ambient conditions [5, 7] with those from the current panel-3 results, tested under hot-wet (165°F and 85% humidity) conditions, reveal differences in which the environment may be a contributing factor on fatigue performance (see figure 41). Although the difference in results from the two panel tests was certainly a result of other factors, including inherent scatter from applied loads and the location, geometry, and installation of the repairs, temperature and humidity also played a role. Results for the B/Ep composite repairs shown in figure 41a reveal slower crack growth under hot-wet conditions compared to those under ambient lab conditions for which the average measured rates were 1.71×10^{-5} in./cycles and 1.99×10^{-5} in./cycles, respectively. In addition, stable crack growth did not occur until after 5000 cycles under hot-wet conditions. Mismatches in the coefficient of thermal expansion of the composite patch and aluminum fuselage skin resulted in the residual thermal stresses ahead of the notch due to the initial patch installation curing process. At elevated temperatures, these residual stresses were relaxed, as shown in figure 42a. As shown, the hoop strains measured from two notch gauges located the same distance from the crack tip were approximately 10% lower under hot-wet conditions as compared to ambient conditions after 20,000 fatigue cycles.

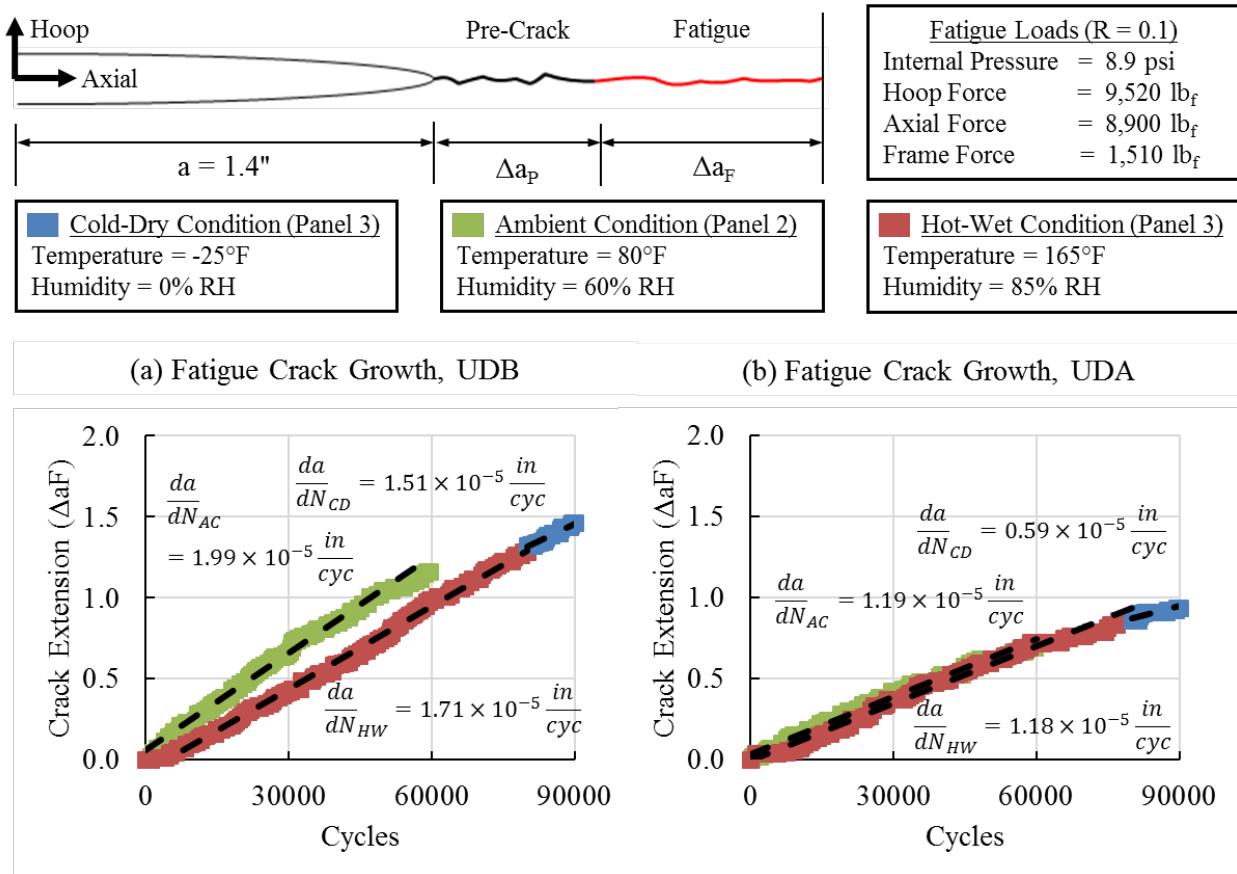

Figure 41. Effect of repair quality on fatigue crack growth in B/Ep and aluminum-bonded repairs

Results for the aluminum repair indicated limited effect of environment on the fatigue crack growth, as shown in figure 41b. As shown, the fatigue crack-growth behavior was similar for hot-wet and ambient conditions for which the average measured rates were 1.18×10^{-5} in./cycle and 1.19×10^{-5} in./cycle, respectively. Because both the repair and the fuselage skin were made of aluminum, the coefficients of thermal expansion were comparable, resulting in limited thermal residual stresses after the initial patch installation curing process. As shown in figure 42b, the hoop strains measured from two notch gauges ahead of the crack tip were similar for both conditions.

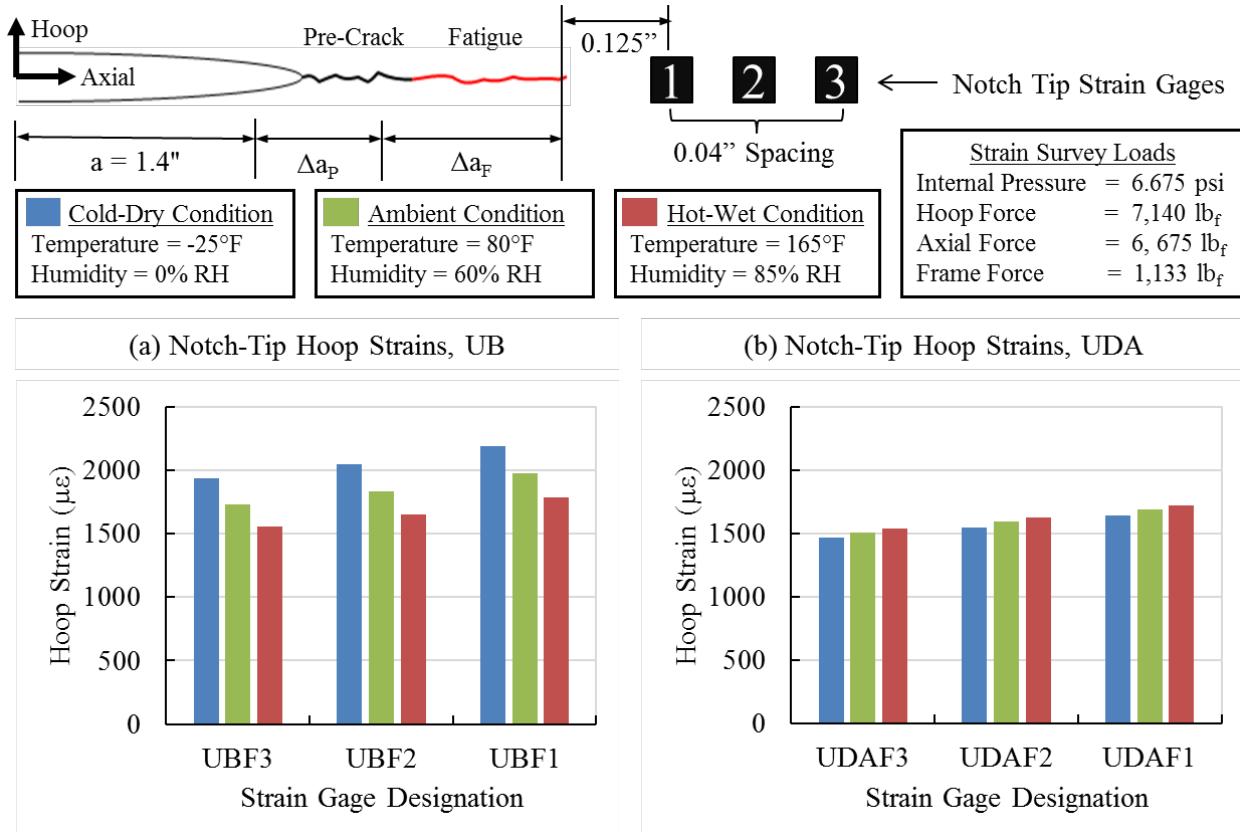

Figure 42. Effect of environment on the notch-tip region strains after 80,000 cycles:
(a) B/Ep repair, UB; and (b) aluminum repair, UDA

On the contrary, under cold-dry conditions, the hoop strains were approximately 10% higher than those under the ambient conditions. However, the crack-growth rate under cold-dry conditions was slower than that under ambient and hot-wet conditions. The summary of the crack-growth rate under various environmental conditions for type-3 repairs is shown in table 8. It is noted that an MSD formed on the lower skin of the lap joint was discovered at approximately 97,000 cycles, which may cause this slow crack-growth behavior. Therefore, the crack-growth rate under cold-dry conditions was inconclusive.

Table 8. Crack-growth rate for the type-3 B/Ep repair and aluminum repair

	UDB da/dN (10^{-5} in/cycles)	UDA da/dN (10^{-5} in/cycles)
Ambient Conditions	1.99	1.19
Hot-Wet Conditions (0 – 80,000 cycles)	1.71	1.18
Cold-Dry Conditions (80,000 – 90,000 cycles)	1.51	0.59

Finally, a comparison of the effectiveness of various repair patches, in terms of both pre-cracking and fatigue crack-growth rates, is shown in figure 43. The results indicate that repair patches were effective in reducing crack-growth rate. The highest crack-growth rate was 1.99×10^{-5} in./cycle for the underdesigned B/Ep repair with intentionally inserted disbonds, as compared to 5.45×10^{-5} in./cycle for the average pre-cracking growth rate. The results also show that the effectiveness decreased as the repair quality degraded. A very limited crack growth was observed from the properly designed repairs and reference repairs, and a higher crack-growth rate was observed from the underdesigned repairs. As expected, the underdesigned repairs with intentionally inserted disbonds showed the highest crack-growth rate.

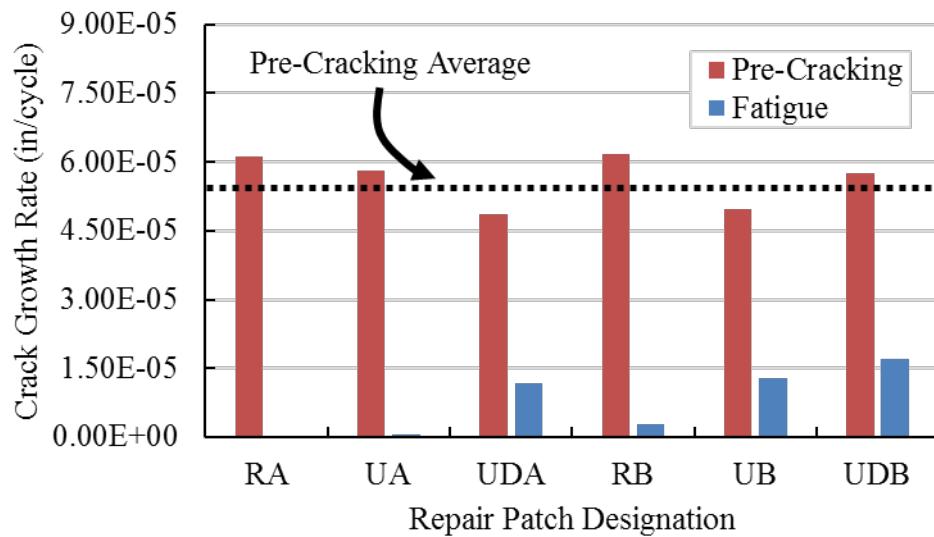

Figure 43. Comparison of the crack-growth rate before and after six repair patches

4.5 DISBOND INSPECTIONS USING NDI

Flash thermography and resonance ultrasonic were used to monitor for disbonds in the repair patches in 10,000 cycle intervals. Correlations of disbond detection were made with full-field strains measured using the DIC. Representative results are discussed in the following sections.

Flash Thermography

The flash thermography system worked effectively on all B/Ep composite repairs. Figure 44 shows the representative results from type-2 and type-3 B/Ep repair with 20,000 cycle intervals. Note that for the type-3 B/Ep repair, UDB includes intentional disbond inserts at the patch boundary and at the notch-tip regions. Photographs in the figure show the results after an exposure time of 2.5 sec. The flash thermography clearly indicated the disbond inserts, the notch location, and crack growth from the notch tips. In general, there was no indication of disbond growth in all B/Ep composite repairs using the flash thermography.

Resonance Ultrasonic

The resonance ultrasonic system was used for all repairs. Calibration standards with known disbond defects were designed and built for both B/Ep and aluminum repairs to adjust the settings of the resonance ultrasonic system for flaw detection. Figure 45 shows representative results for type-3 aluminum repair, UDA, in which the central disbond region outlined in red was readily detected. In general, there were no indications of disbond growth for all four types of repairs using the resonance ultrasonic.

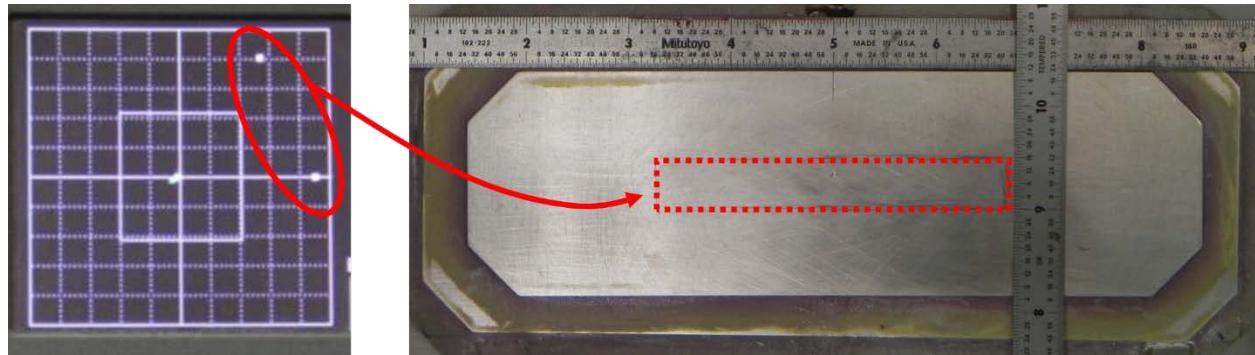

Figure 45. Detection of disbond insert using resonance ultrasonic for type-3 aluminum repair, UDA

NDI-DIC Correlations

Correlations between disbond detection and the full-field strains measured using the DIC is shown in figure 46 for the type-3 B/Ep repair, UDB. The full-field strains and strain variation across the repair measured using DIC revealed a dispersed compression region outlining the width of the disbond area at the notch region. The width of the compression region measured was 0.5 inch, which was the same as the intentional disbond insert.

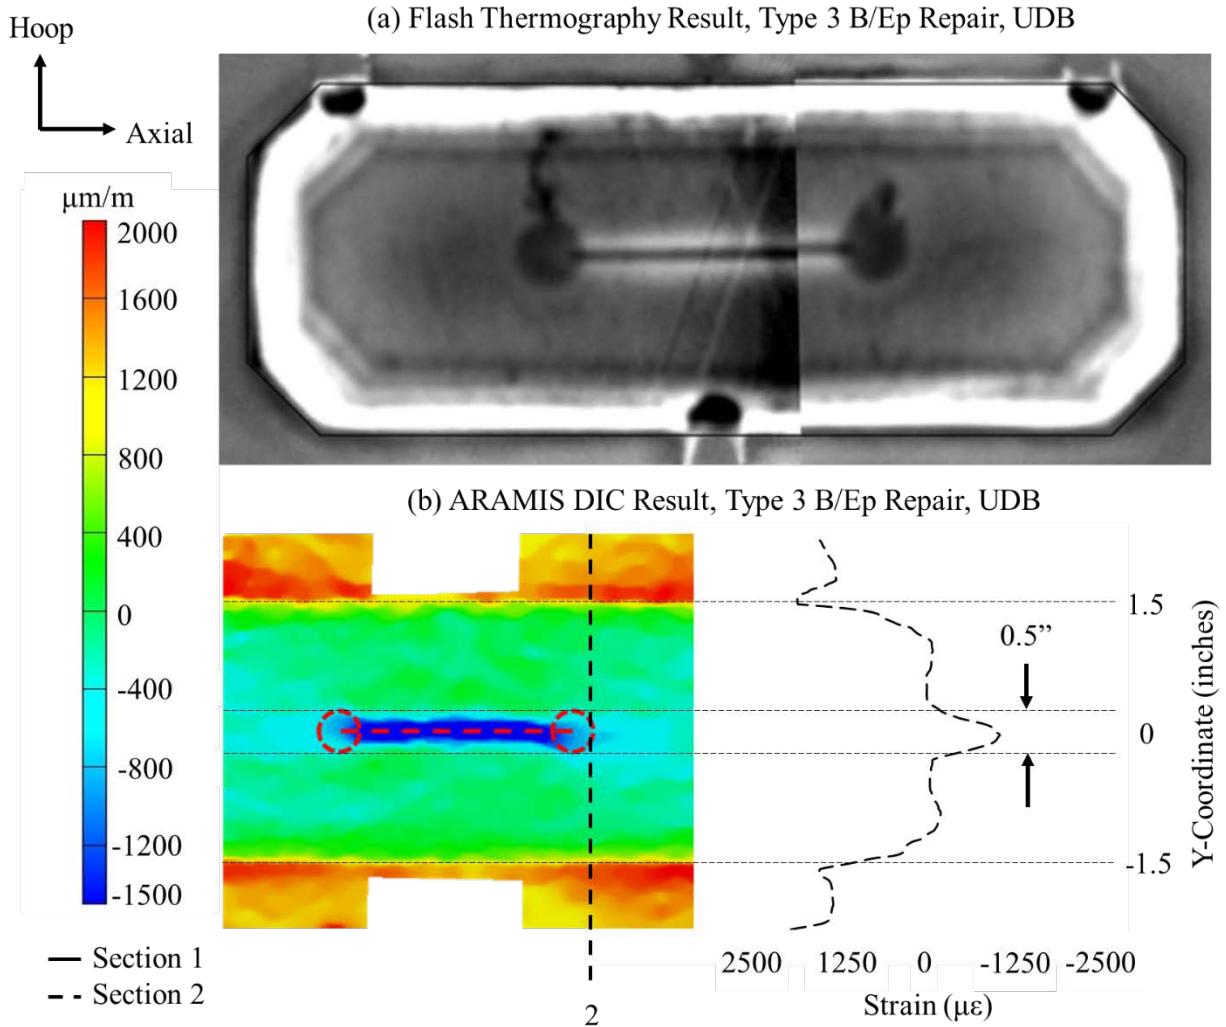

Figure 46. NDI-DIC correlation, type-3 B/Ep repair with known disbond inserts: (a) flash thermography, and (b) ARAMIS DIC

Correlations between disbond detection and the full-field strains measured using the DIC is shown in figure 47 for the type-3 aluminum repair, UDA. For this repair, a 3.5 by 0.5 inch FEP tab was inserted over the notch location to create disbond between the repair patch and the fuselage panel skin. The outline of the disbond is indicated from the resonance ultrasonic (see figure 45). The corresponding full-field strains and strain variation across the repair measured using DIC revealed a dispersed compression region outlining the width of the disbond area. The width of the compression region measured was 0.5 inch, which was the same as the intentional disbond insert. Therefore, a good correlation was found between the strain distribution and disbond indication for this repair.

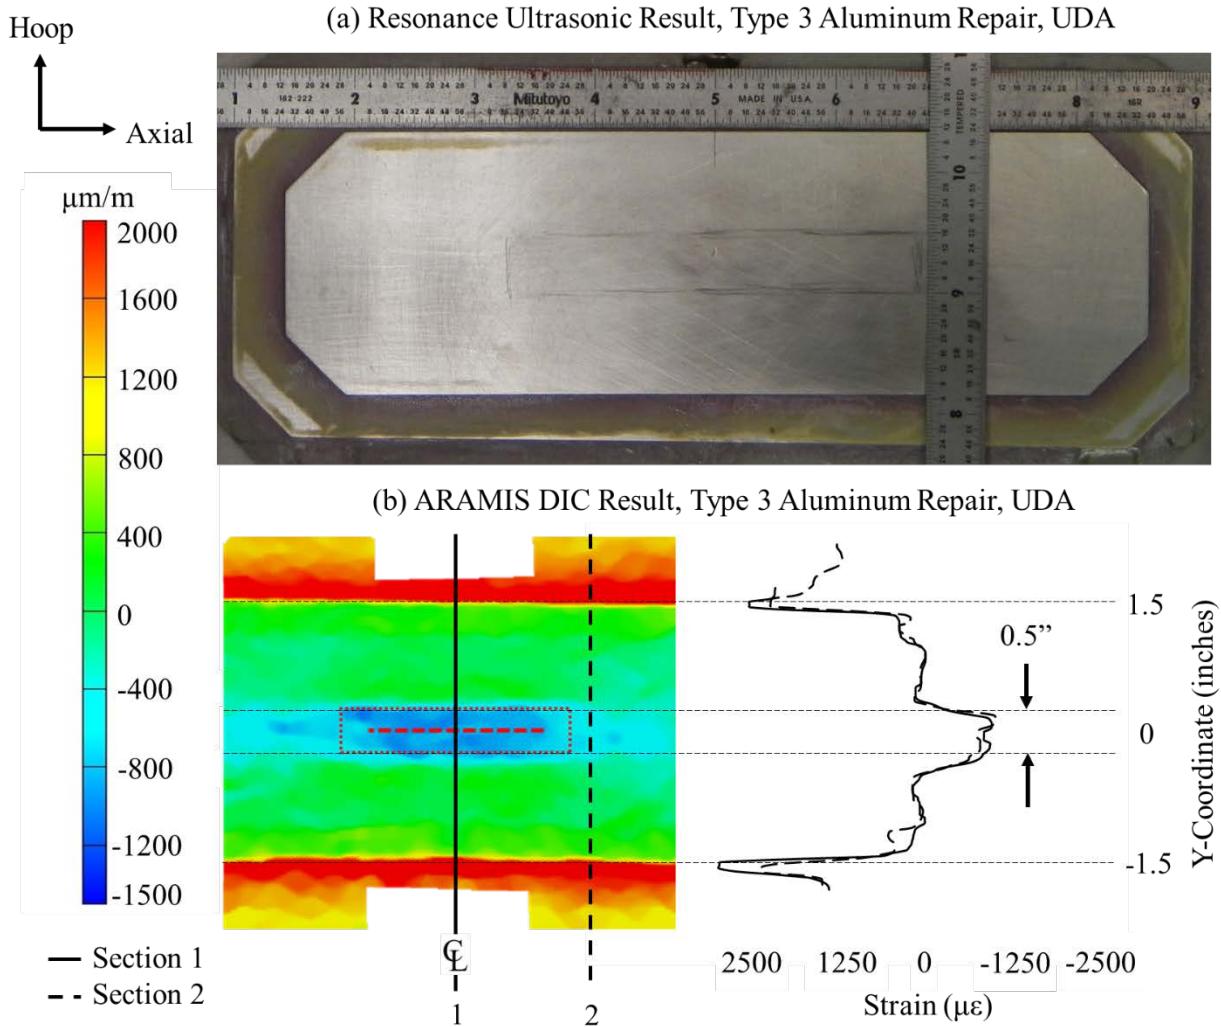

Figure 47. NDI-DIC correlation, type-3 aluminum repair with known disbond inserts: (a) resonance ultrasonic, and (b) ARAMIS DIC

4.6 DAMAGE MONITORING USING SHM

Eleven SHM data packages were collected during the 80,000 cycles of fatigue testing. The crack correlation model developed during panel 2 testing was improved and successfully applied to the panel 3 patches. Figure 48 shows the crack-growth measurements at each data interval performed by the SHM system for both the UB and UDB patch.

As shown in figure 48, crack growth was accurately predicted by the SHM system within the tolerance of conventional crack-length measuring techniques such as HFEC. Further, the correlation of SHM signals to physical damage in the host structure was shown to be accurate and reliable even when the host structure and repair patch system have undergone extreme hot/wet conditions.

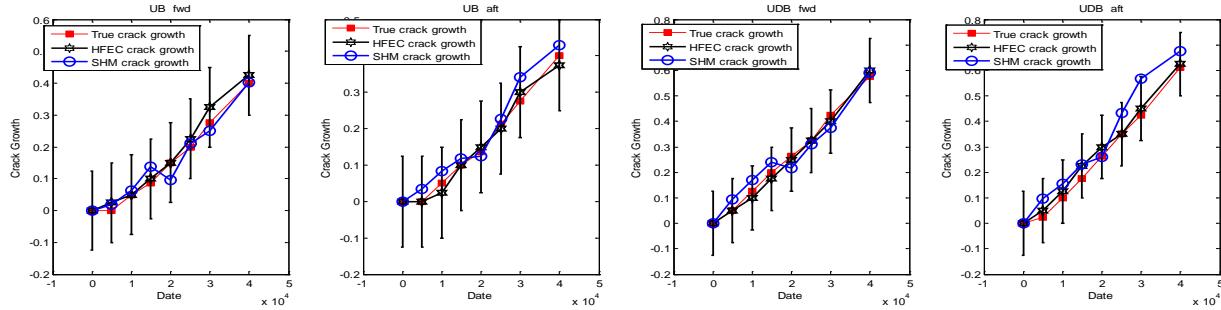

Figure 48. SHM crack-growth measurements for UB and UDB repairs

Additionally, Boeing, the FAA WJHTC, and North Carolina State University collaborated on the SHM data processing. The motivations for working together include:

1. Boeing provided data collected during the full-scale panel testing and provided engineering consultation to the FAA WJHTC to build a technical partnership in this area. Both Boeing and the FAA WJHTC benefit from this partnership for future testing efforts.
2. Survey state-of-the-art methods and techniques developed by Fuh-Gwo Yuan (NC State), a leading expert in NDI and SHM.
3. Satisfy Master's degree requirements for David Westlund (FAA WJHTC), with Fuh-Gwo Yuan acting as project advisor.

Damage indices were processed by the FAA WJHTC, including the energy damage index, the scatter energy damage index, and the correlation damage index. This computed information from raw SHM data was compared to the independent results obtained by Boeing and showed good correlation.

5. TEST AND ANALYSIS CORRELATION

The previous test-analysis correlations [6] revealed that there was a need to improve the prediction capability of the CRAS closed-form method for the thermal residual stresses in a boron patch repair because of the thermal expansion coefficient mismatch between the aluminum skin and a boron patch. For simplicity, the effect of thermal stresses was previously always estimated by using the CRAS method, whereas the effect of the mechanical loads was predicted by both CRAS and FE analysis. Therefore, a full finite element analysis of a curved panel with under-design and reference boron (UB and RB) patches under both thermal and mechanical loads was conducted in this study, and the results were compared with strain gauge data. The objectives here were: (1) to assess the prediction capabilities of the FE analyses using commercial codes, such as Nastran or ABAQUS, to accurately determine the thermal stresses in a boron patch repair and (2) to seek a remedy for CRAS closed-form method.

The under-designed and reference boron (UB and RB) patches were modeled ply by ply with solid elements. The skin underneath the patch and the rest of the curved panel were modeled by shell elements, whereas the adhesive layer was by solid elements. A 3-inch crack was introduced into the skin and the adhesive. The detailed FE model with the UB and RB patches, skin crack, and adhesive crack are shown in figures 49–51.

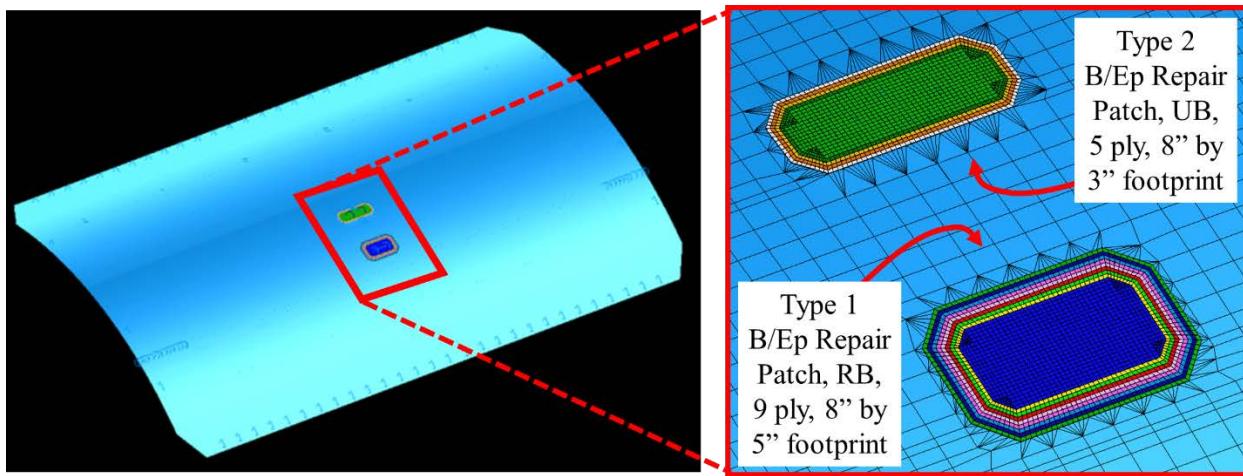

Figure 49. FE meshes for under-designed (UB) and reference B/Ep (RB) patches

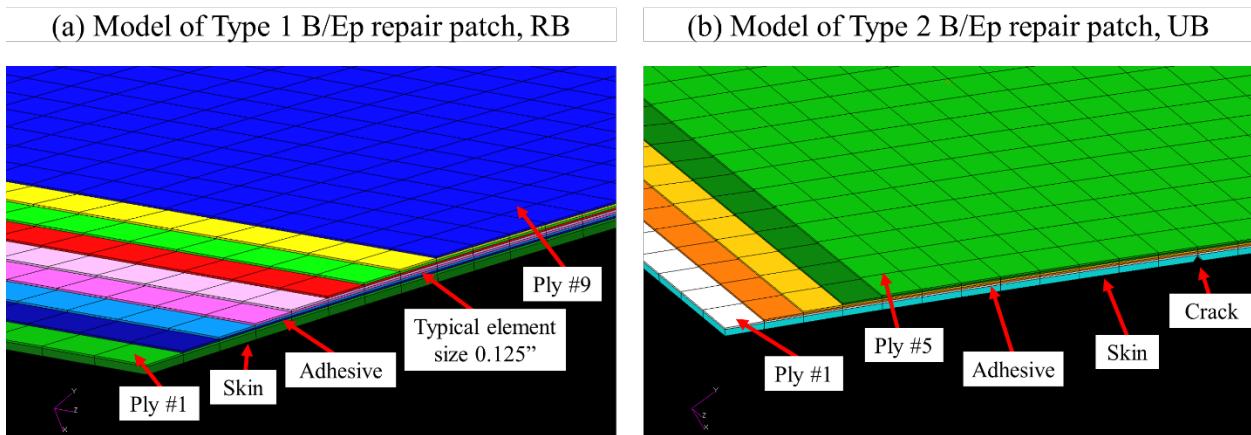

Figure 50. Detailed ply-by-ply models of B/Ep patches: (a) UB patch and (b) RB patch

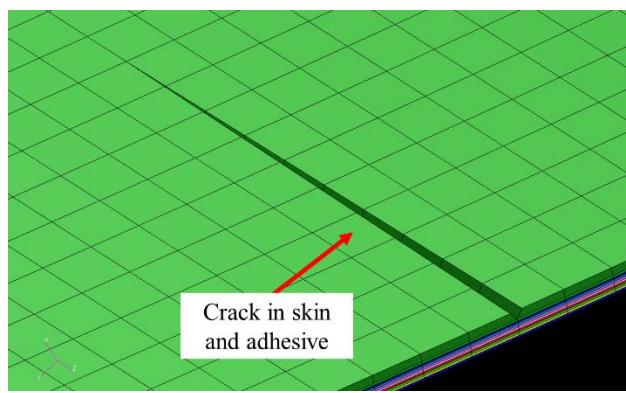

Figure 51. A view of crack in skin and adhesive

The FE analyses were geometrically nonlinear and performed using Nastran SOL 106 for three operating temperatures (e.g., room temperature, -25°F, and 165°F), each under a simultaneous applied static load at 75% of the maximum fatigue loads corresponding to a 6.75 psi pressure

loading, as conducted in the strain surveys. Figures 52–54 show the comparison between analytical predictions and test data from the strain surveys at gauges IS14, IS15, S13, S14, and S15 for the UB patch at three operating temperatures. Locations of these gauges are shown in figure 55. Good correlation was found for a room temperature case, except for gauge S14 located directly over the crack center. The discrepancy at gauge S14 might be attributed to the fact that the finite width of the crack was modeled as a line in an FE analysis. However, the correlation was fair for only a low -25°F case. Again, the comparison was worst for gauge S14. In contrast, strain predictions by the analytical method at gauges S13, S14, S15, IS14, and IS15 under a 165°F operating temperature seemed to shift uniformly upward when compared with the test results. Therefore, it appears that thermo-elastic FE analyses of a full curved panel may still not be adequate to capture the effect of thermal stresses in boron patches. Further study is needed.

Conversely, for simplicity, the effect of thermal stresses on crack growth between a thin and thick boron patch (UB versus RB) was measured qualitatively in terms of crack-opening displacements. A larger crack opening displacement would result in a larger crack growth. The ratio of the crack-opening displacements of the RB patch to the UB patch at three operating temperatures (room temperature, -25°F, and 165°F) was found to be 0.57, 0.54, and 0.6, respectively. Because the ratios for the cases of -25°F and 165°F were roughly the same as those for a room-temperature case, the FE analysis may also fail to predict the greater effect of thermal stresses in a thick boron patch on crack growth as observed from the test.

6. SUMMARY

In this study, the environmental effects on the fatigue performance of bonded repairs to the mid-bay cracks of the metallic fuselage panel were investigated. The goal was to collect experimental data using the various types of repairs to verify the ability of analytical tools to predict the behavior of bonded patches. Both boron-epoxy (B/EP) and aluminum patch repairs were intentionally made deficient to allow damage growth in the form of crack propagation and disbonding during fatigue cycling. Full-scale fatigue tests were performed using a Boeing 727 fuselage panel. For all phases, a digital image correlation method was used to obtain full-field displacement and strain measurements in the patch and surrounding regions. Several nondestructive inspection methods were used to monitor crack and disbond growth, including flash thermography, resonance ultrasonic, and eddy current.

In general, the representative results revealed that hot-wet environmental conditions (165°F and 85% humidity) had a limited impact on fatigue performance. Fatigue performance was reduced for the defective repairs as compared to the reference. Globally, strains remained relatively the same throughout the testing up to 80,000 cycles. Local strain redistribution occurred with crack growth. In the B/Ep composite repair patches, crack growth was slower under hot-wet conditions than in the ambient conditions. Mismatches in the coefficient of thermal expansion of the composite patch and aluminum fuselage panel skin resulted in the development of tensile residual stresses ahead of the notch during the initial patch-installation curing process. At elevated temperatures, these tensile residual stresses were relaxed, resulting in slower crack growth. On the contrary, tensile residual stress increased under cold-dry conditions, resulting in faster crack growth. Results for the aluminum repairs indicated that environment had a limited effect on the fatigue crack growth under hot-wet or cold conditions. With both the repair and the fuselage skin being aluminum, residual strains due to thermal mismatch do not occur. Data from this program will be used to assess tools and methods for evaluating and monitoring the repair integrity over the life of the part.

APPENDIX A—PANEL ENGINEERING DRAWINGS

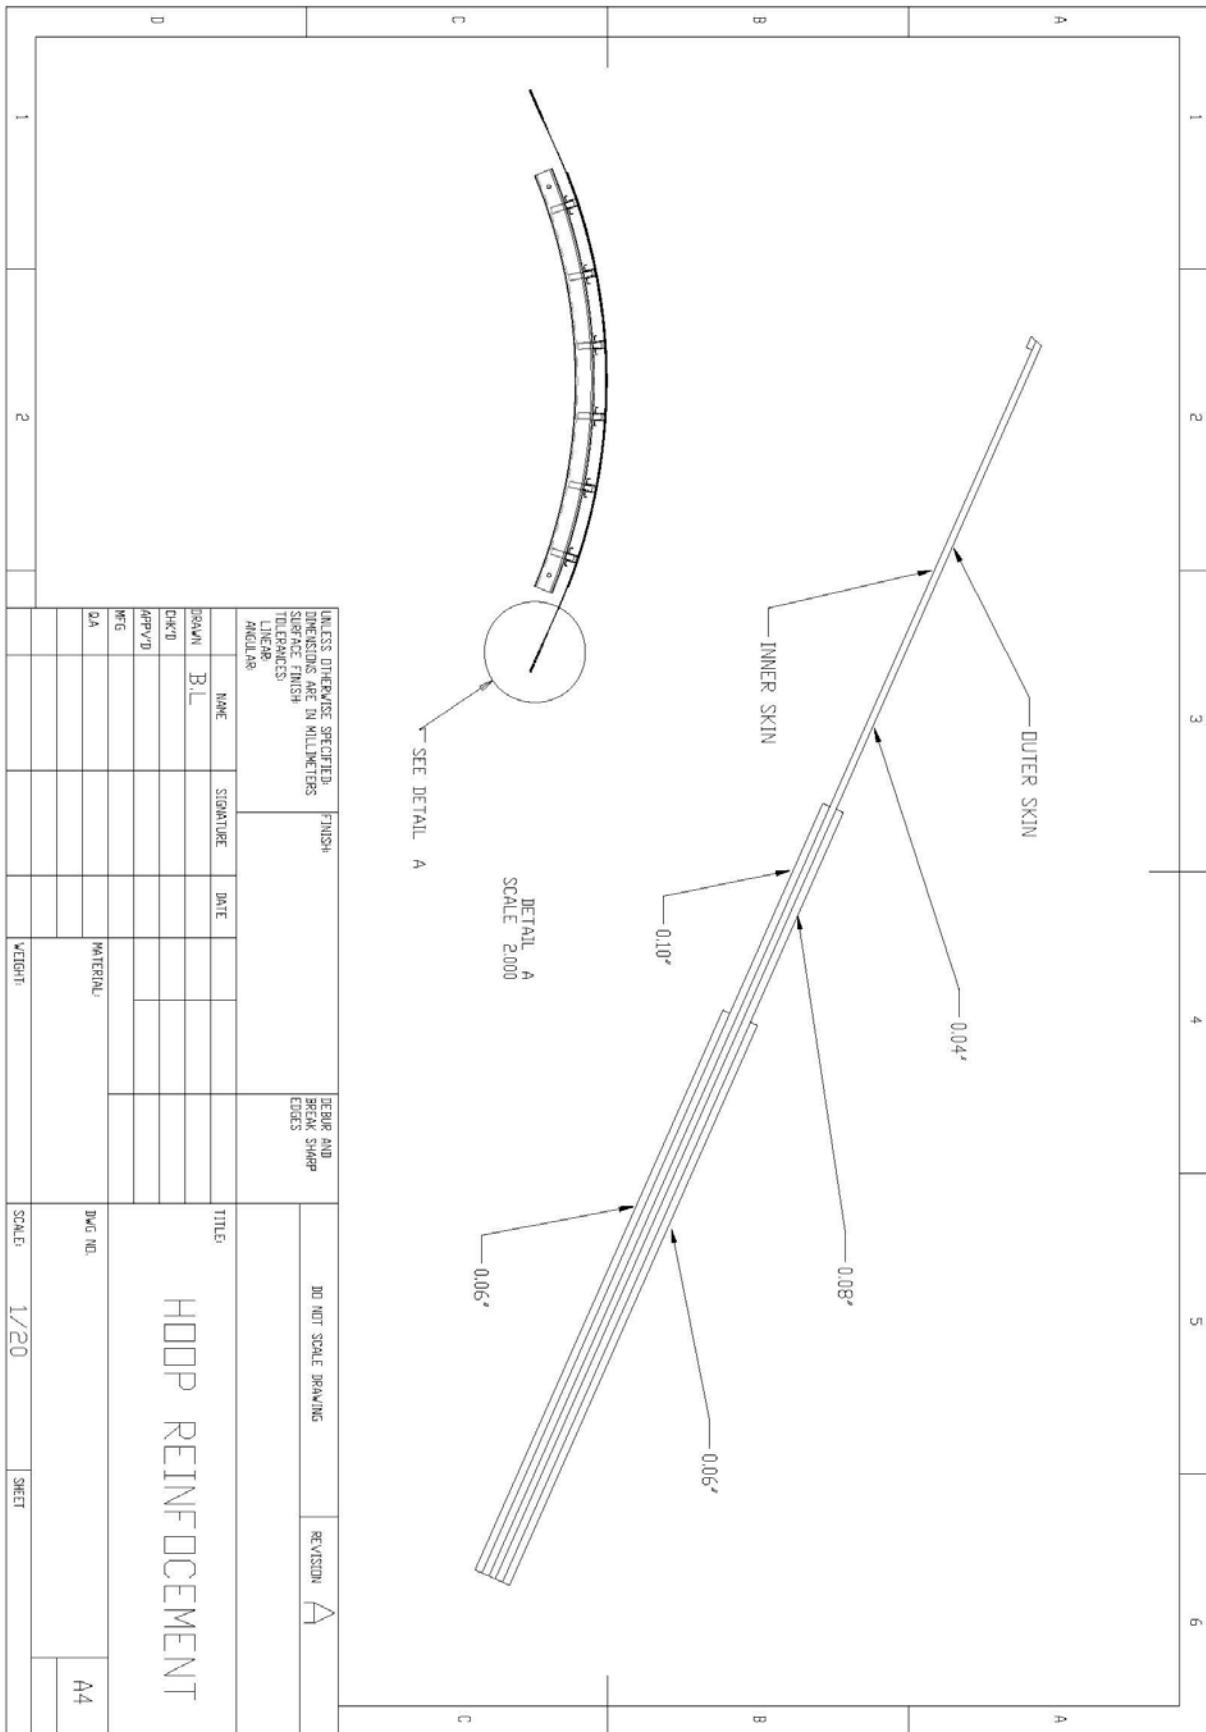

Detailed engineering drawings for the panel tested are included in the appendix. The selected panel configurations represent a generic fuselage structure from a retired passenger service airplane, specifically a Boeing 727-225 with serial number 22553, and registration tail number N675MG. While the airplane was in service, it accumulated 29,821 flight cycles and 48,579 flight hours. The airplane was owned and operated by Champion Air Lines, was well-maintained and stored, and had a well-documented and accessible service history.

The panel was removed from the crown of the airplane having dimensions of 125 by 73 inches and a radius of 74 inches. The substructure included six stringers (S), S-2R to S-5L, in the longitudinal direction with 9.5-inch spacing; and six frame stations (FS), STA560 to STA660, in the hoop direction with 20-inch spacing. The Z-shaped frames, stringer clips, and hat-shaped stringers are made from 7075-T6 aluminum.

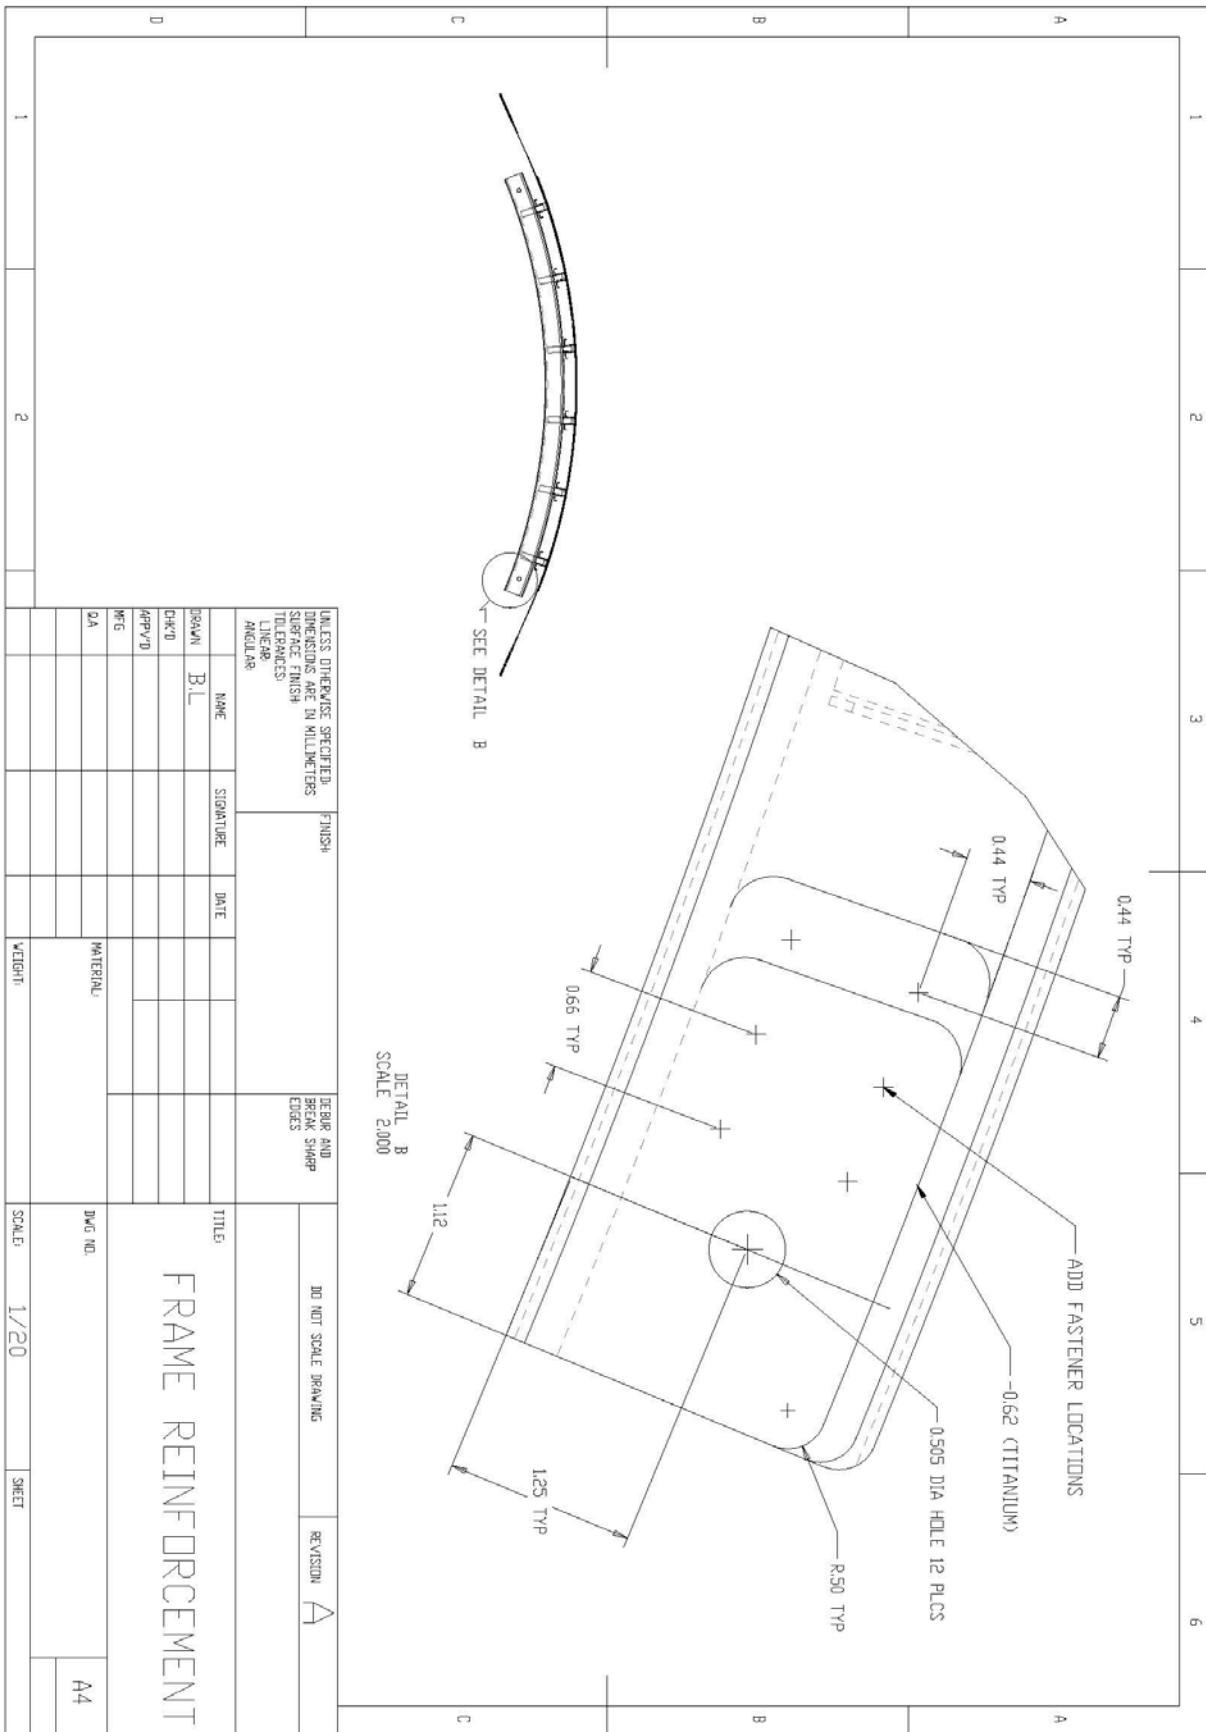

The panel skin was 2024-T3 aluminum with a thickness 0.04 inch at all bays. A longitudinal lap joint was located along stringer S-4L, which were connected together by three rows of rivets. The doubler was bonded to the outer skin, and there was a sealant between the doubler and the inner skin of the lap joint.

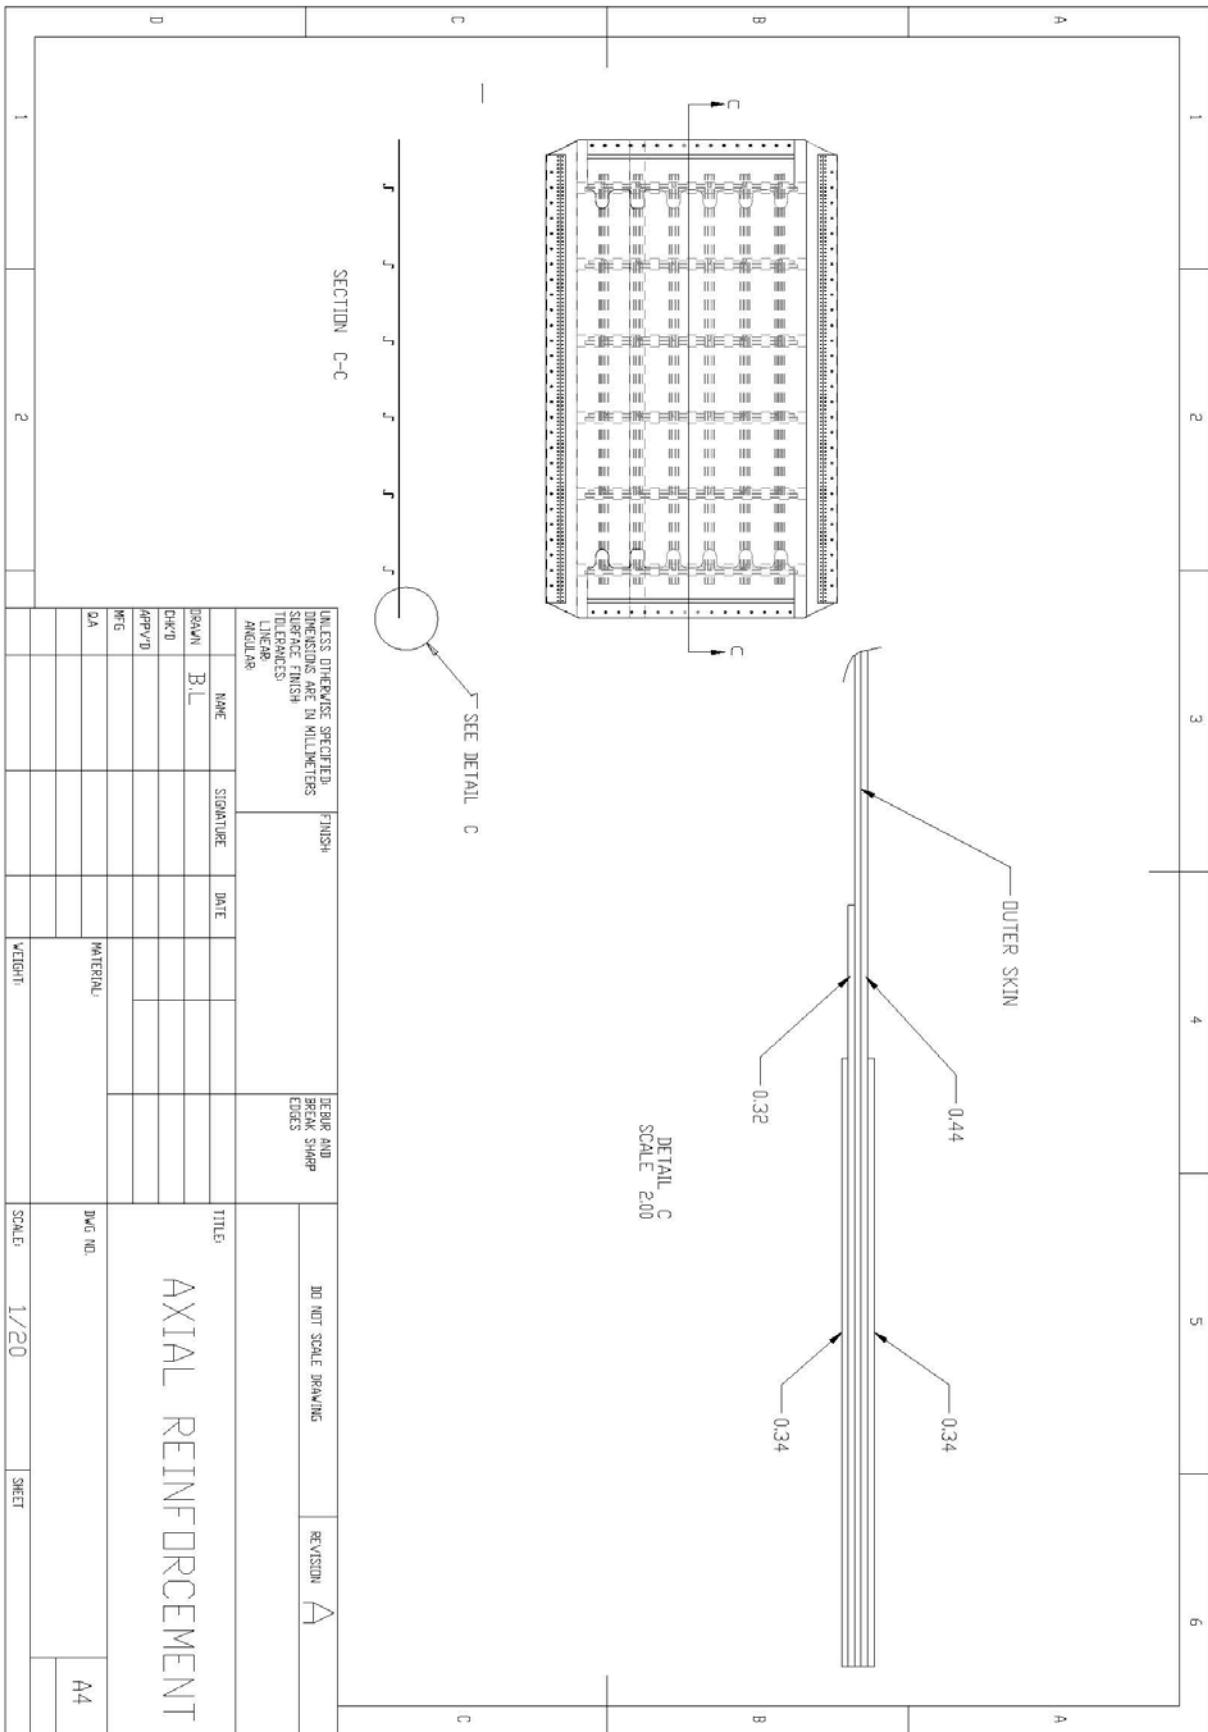

The panel was reinforced along the four edges with aluminum doublers. In both longitudinal doublers, 28 0.5-inch-diameter holes were inserted, spaced 4 inches apart. In both hoop doublers, 16 0.5-inch-diameter holes were inserted, spaced 3.5 inches apart. These holes were used to attach the edges of the panel to the loading mechanisms of the Full-Scale Aircraft Structural Test, Evaluation and Research (FASTER) fixture, which has seven hoop loaders on each side and four longitudinal loaders on both ends. Each actuator is attached to the panel at four holes using a whiffle tree assembly. The two ends of each frame, where the frame load is applied, were also reinforced with aluminum doublers. An elastomeric seal was bonded along the perimeter of the inner surface of the curved panel to attach to the pressure box of the FASTER fixture.

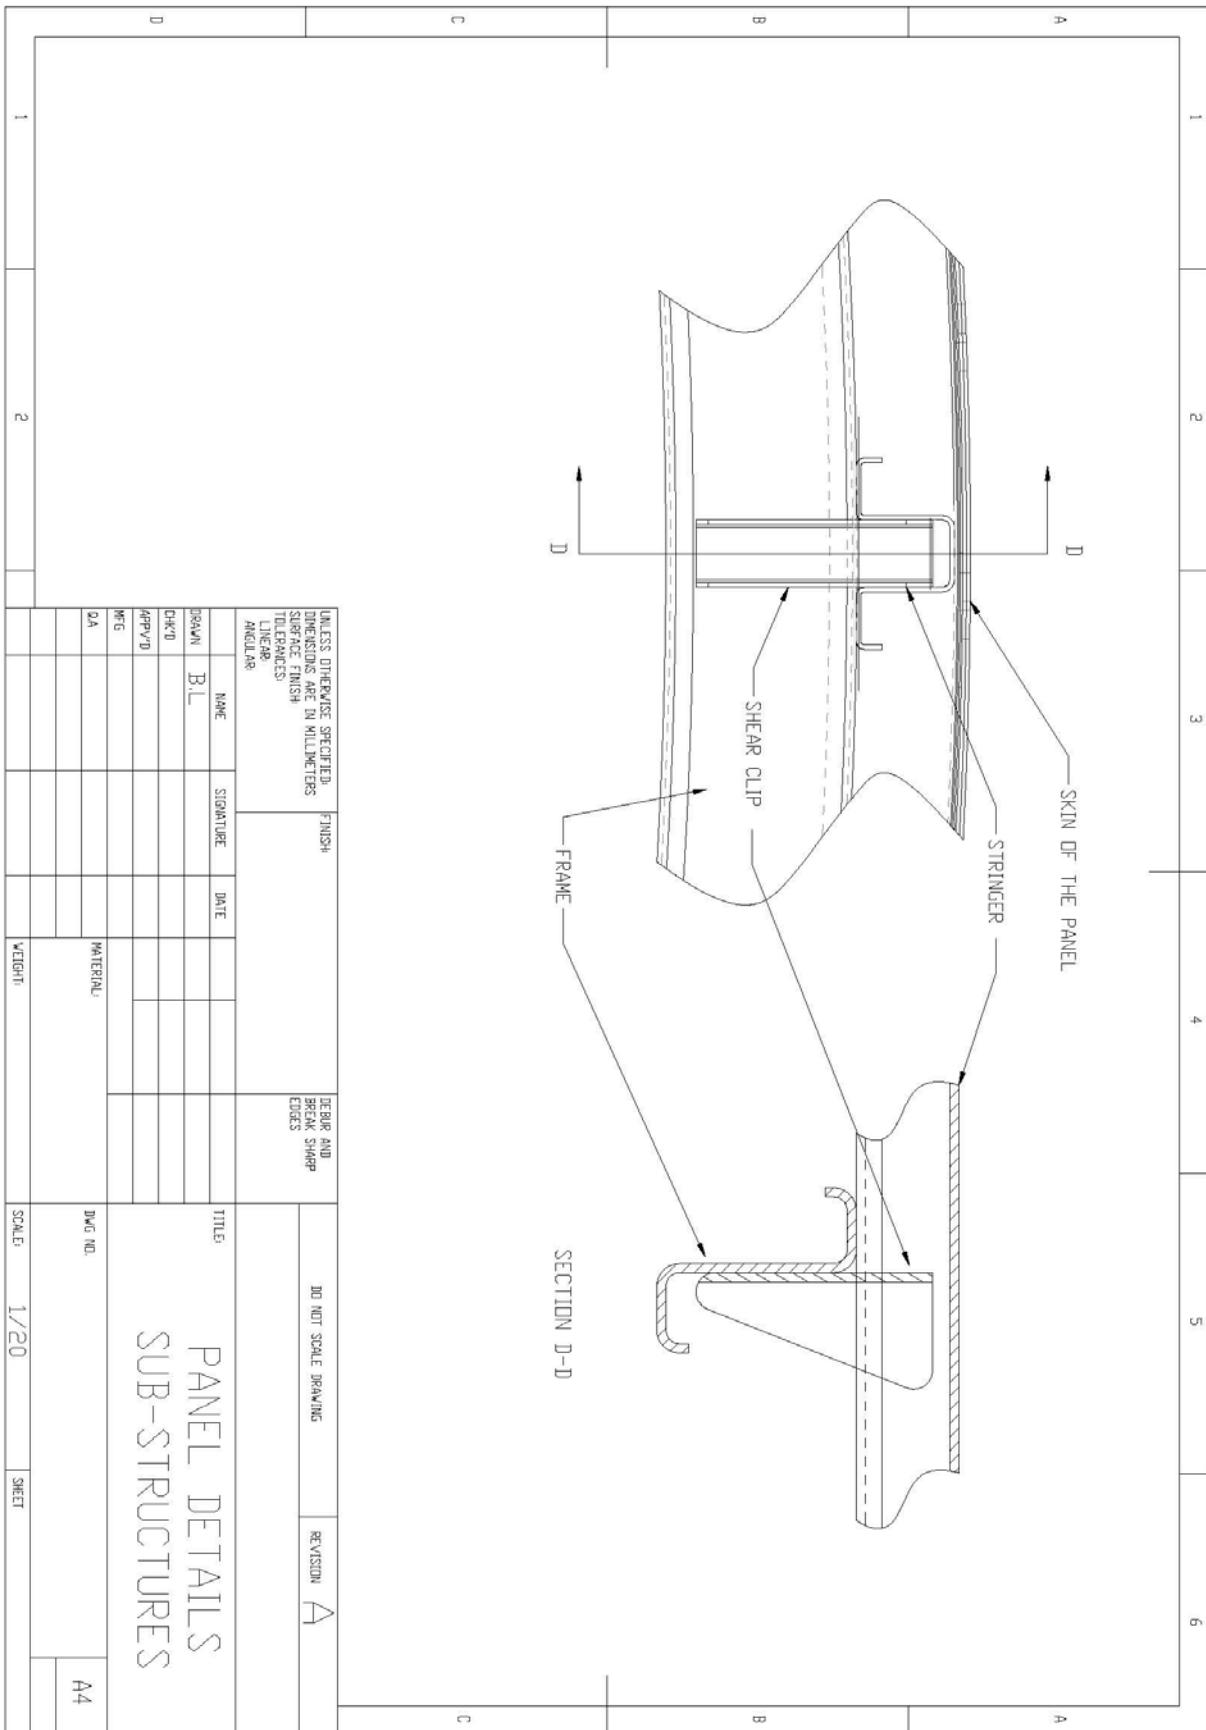

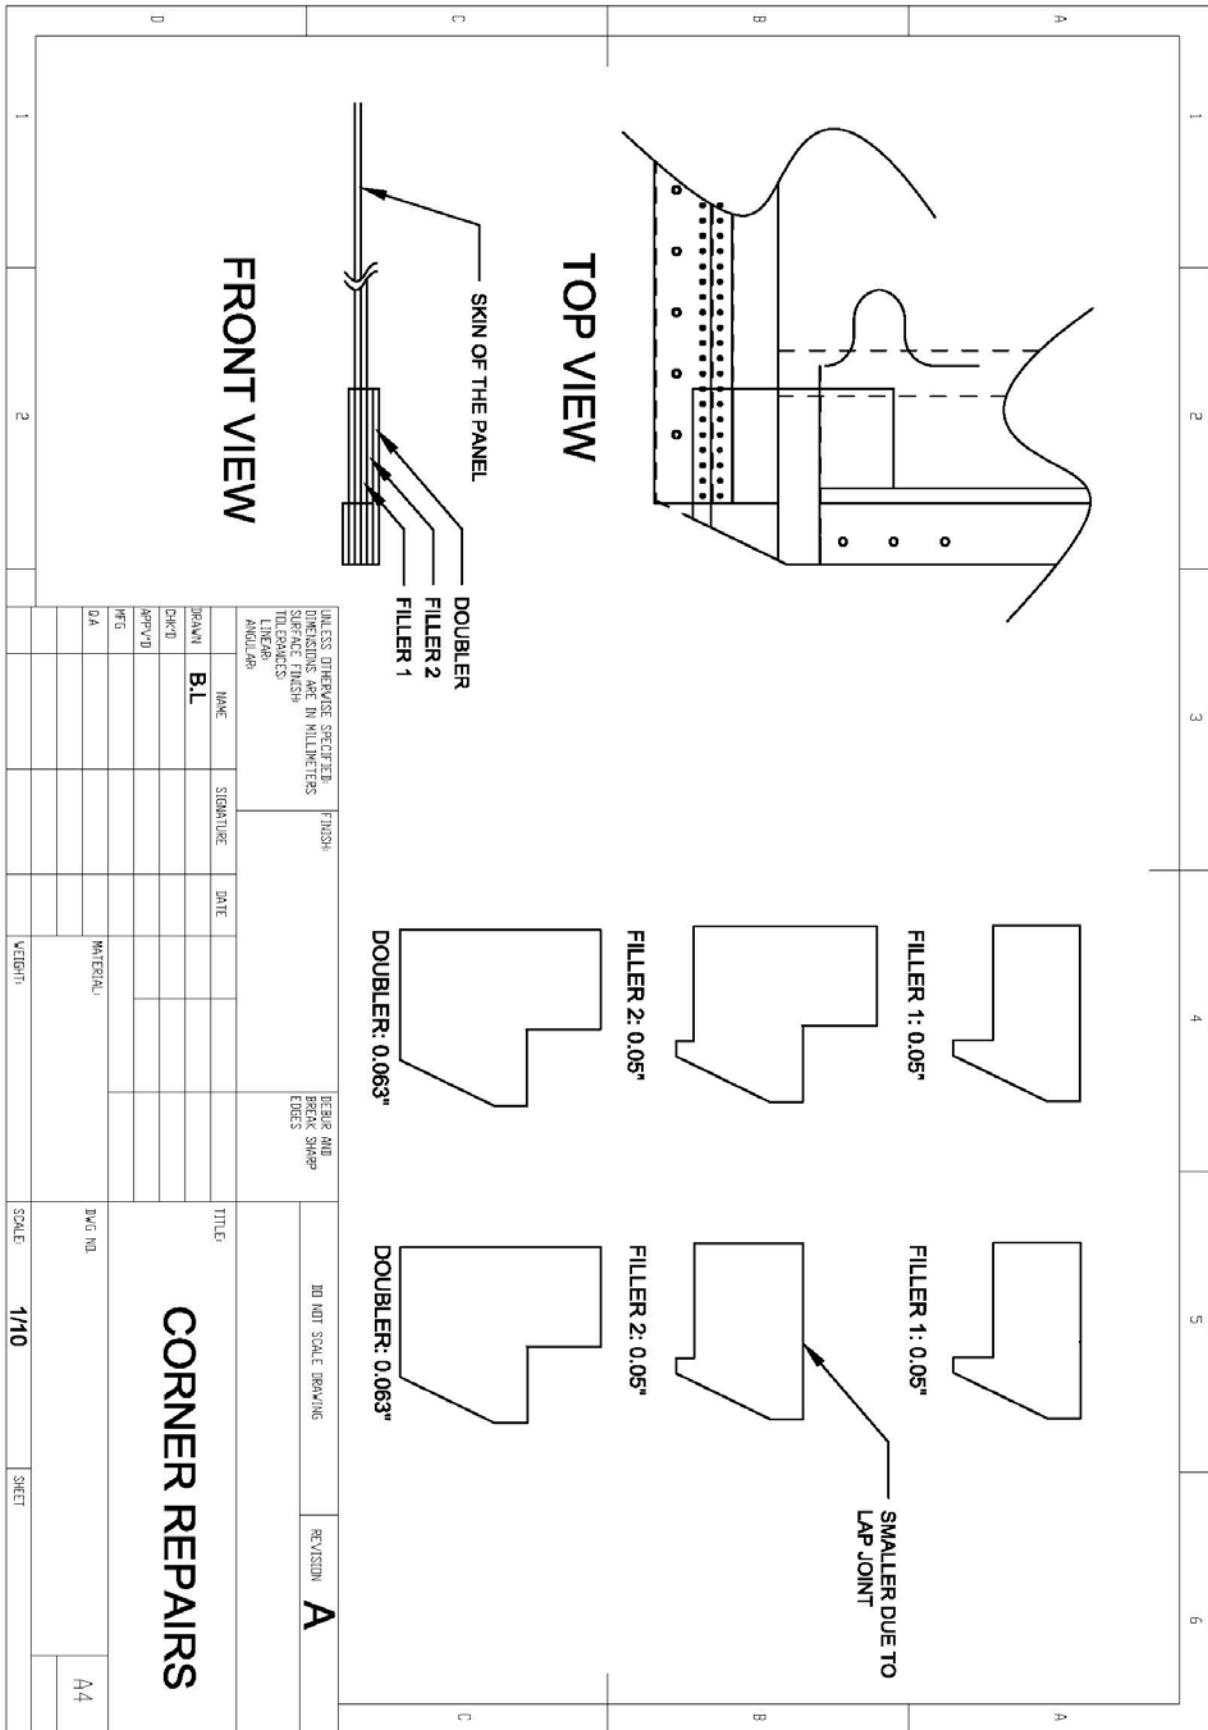

A-3

APPENDIX B—RATIONALE BEHIND REPAIR TYPES

Several types of boron/epoxy (B/Ep) composite and aluminum-bonded repairs were considered in this study and are categorized as type 1 (reference repairs), type 2 (under-designed), type 3 (under-designed and partial disbond), and type 4 (hand sanded), as summarized in table B-1. Note that type 1–3 repairs are identical to those used in the previous second panel test [5, 7]. These repair configurations were retained in this study for comparison purposes to assess the effects of hot-wet environmental conditions (165°F and 85% humidity) on repair performance. For the four types of patches, the rationale behind repair types is described below.

Type-2, Under-Designed Repairs

A good design B/Ep patch was considered as the basis for under-designing the repairs. To achieve the under-designed B/Ep repair configuration, the following procedure was followed:

1. Determine stresses at the prospective crack location using global finite element analysis.
2. The stresses at the prospective crack location were used in the Composite Repair of Aircraft Structure (CRAS) software developed by The Boeing Company under U.S. Air Force funding to develop the reference patch sizing.
3. The under-designed patch was designed by reducing the number of plies from nine to five and the maximum width of the B/Ep patch from 5 inches to 3 inches (hoop direction), and reducing the number of doublers of the aluminum patch from three to two layers. Details of repair patch configurations and dimensions are shown in table B-1.

Type-3, Partial Disbond Repairs

The type-3 repairs had the same configuration as the type-1 B/Ep patch and aluminum patch. To further reduce the effectiveness of the repair patches, intentional partial disbonds were introduced on the repairs at the patch edges and crack tips. The disbonds were located between the patches and the aluminum skin. The disbonds were typically of two types—one at the crack tip and one at the patch boundary. Details of repair patch configurations and dimensions are shown in table B-1.

1. Crack-tip disbonds: The rationale behind the crack disbonds was based on a literature survey and CRAS predictions. According to the literature, disbonds at the crack tips have a negligible effect on crack growth. However, in these studies, the crack tip was stop-drilled and the disbond does not fully cover the crack length. Furthermore, CRAS predictions showed that, for the case in which the disbond surrounds the whole crack length, the stress intensity factor at the crack tips can increase by 10–20% compared to the repair patch without any disbond surrounding the crack. For the aluminum patch, the disbond was 3.5 by 0.5 inch surrounding the crack; however, circular disbonds of 0.5 inch in diameter were located only at the two tips of the crack for the B/Ep patch. This was to avoid any unpredictable results due to the under-estimation of residual thermal stresses in the case of the B/EP repair patch.
2. Patch edge disbonds: Patch edge disbond locations were decided based on the literature survey, which showed that the edge disbonds can cause a total delamination of the substrate because of the high load transfer between the skin and the patch. The disbonds were

introduced at the patch corner as the load transfer is highest at this region. The disbond in the middle of the patch was introduced because, when the disbond grows it may link up with the disbond around the crack.

Type-4, Hand-Sanded Repair

The type 1–3 repairs were prepared using a grit blast surface preparation procedure, which provide a uniform surface roughness. Hand sanding is the preferred surface-preparation method in the field. The purpose of adding the hand-sanded repair was to extend the test perimeter and observe if the hand-sanded repairs showed any degradation in repair durability performance. Using CRAS, the configuration of repair patches designed for a 3-inch-long through-thickness crack on a 0.04-inch skin is summarized in table B-1.

Table B-1. Repair patches configurations

Types	Name	Ply layup	Dimensions and fiber directions (L x W, θ)	Thickness	Stiffness ratio

APPENDIX C—STRAIN GAUGE LOCATIONS

The panel was instrumented with approximately 200 strain gauges to monitor strains throughout the test. Strains were monitored at various locations. Strain gauges were placed on the fuselage panel skin, repair patches, and the substructures of the panel to monitor the strain distribution and ensure proper load introduction. The details of the strain gauges used are provided in the tables and figures within this appendix.

Strain gauges used throughout the test were 350 ohms with a Constantan® foil alloy (see figure C-1). A three-conductor, Teflon®-coated twisted cable was used for the connection to the strain gauges. The strain gauge, coating, cable, and adhesive types for each panel are listed in table C-1. The strain gauges installed on the outer surface of the panel were exposed to controlled temperature and humidity profiles. To avoid ingressation of humidity in the gauges, these gauges were covered using Teflon tapes and were sealed with B-1/2 sealant.

To ensure loads were transferred properly within the panel, strain gauges for the substructures were installed in the beginning of the testing, irrespective of the test phases. A total of seven strain gauges were installed at the flange of the stringers, and 8 strain gauges were installed at the outer and inner flange of the frames. The locations of these strain gauges are shown in figures C-2 and C-3. These strain gauges were removed at the later stage of the test because of the limitation of channels.

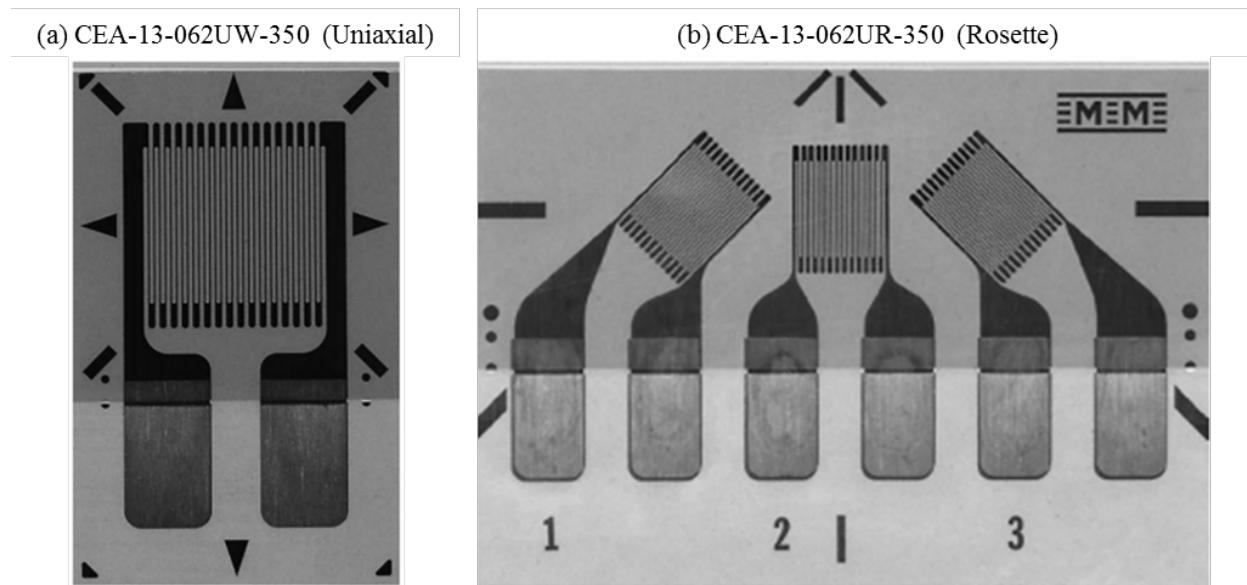

Figure C-1. Strain gauge used throughout the test (a) uniaxial, (b) rosette

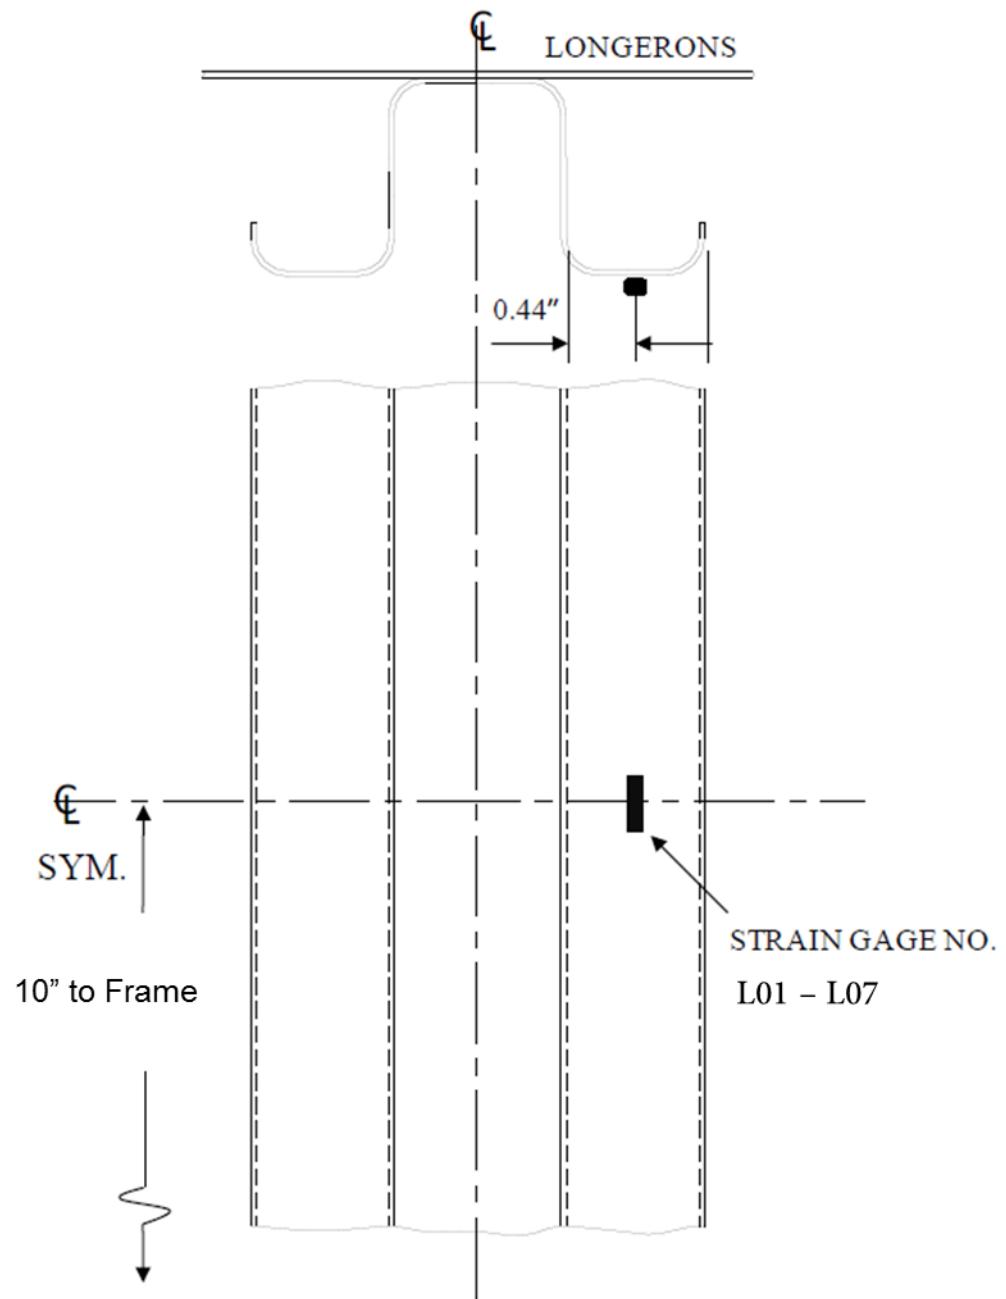

Figure C-2. Schematic of axial strain gauges at the lower cap of the stringers

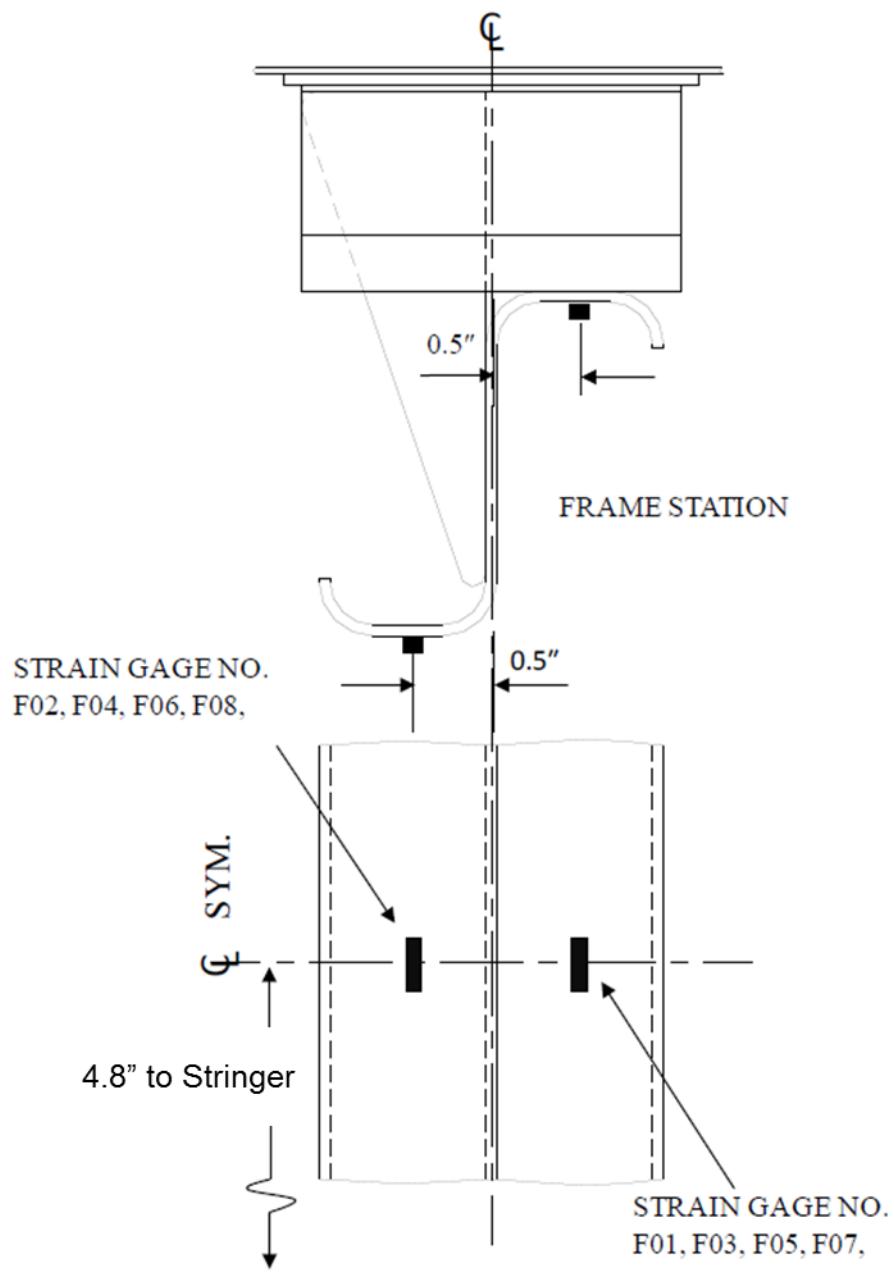

Figure C-3. Schematic of the axial strain gauges at the inner and outer cap of frames

Table C-1. General strain gauge information

	Pristine Panel	Phase I Hot-Wet	Phase II Cold-Dry
Vishay Micro-Measurement Part No., Axial		CEA-13-062UW-350	
Vishay Micro-Measurement Part No., Rosette		CEA-13-062UR-350	
Vishay Micro-Measurement Part No., Coatings		M-Coat A	
Vishay Micro-Measurement Part No., Cable		330-FTE	
Vishay Micro-Measurement Part No., Adhesive		M-Bond 200/AE-10	

To collect the baseline strain data, the strain gauges were also installed on the fuselage skin before any damage to the panel was introduced. The locations of strain gauges on the pristine panel and substructures are shown in figures C-4 and C-5, respectively.

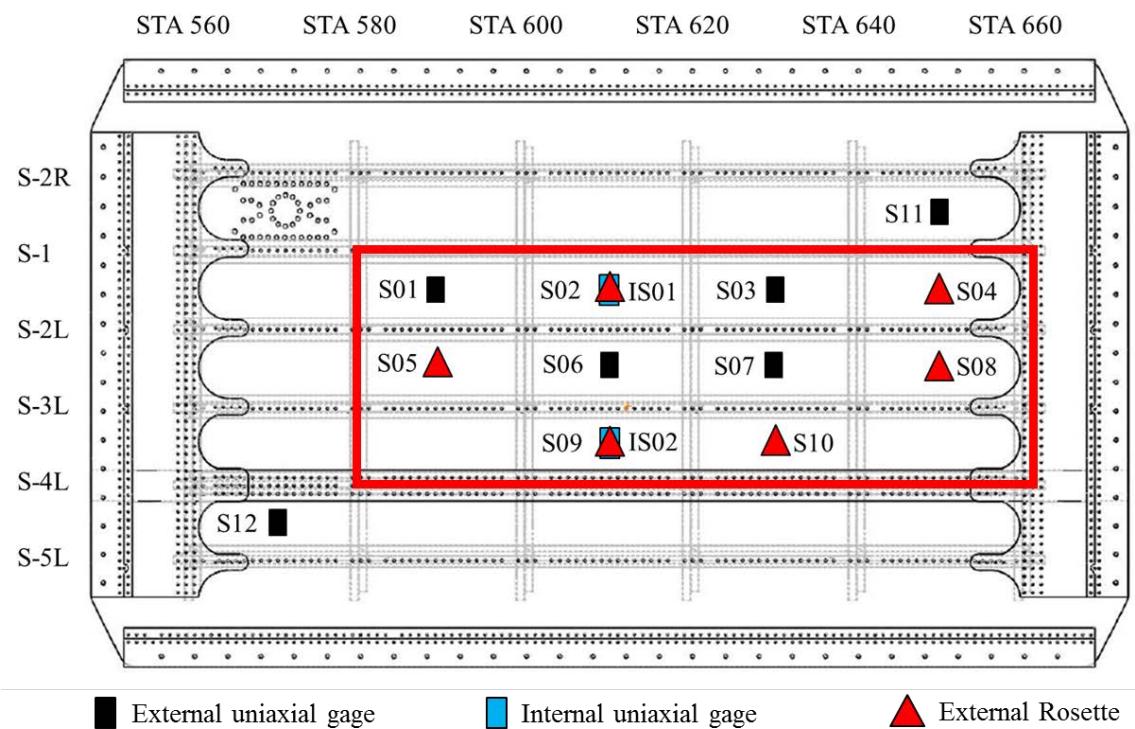

Figure C-4. Strain gauge locations for pristine panel

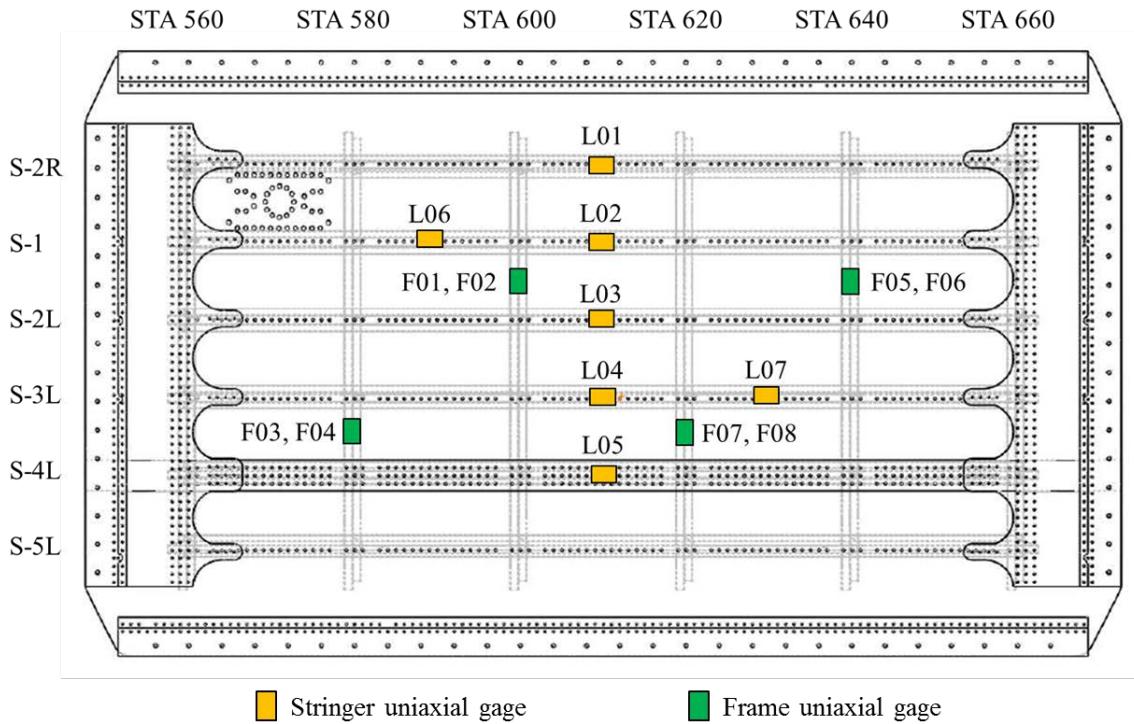

Figure C-5. Strain gauge locations for substructures

Twelve repair patches were installed throughout the test. For each repair patch, strain gauges were installed along the patch boundaries on the inner and outer skin surfaces, at the patch outer surface, and along the notch tip. Typically, each repair patch includes eight strain gauges, as shown in figure C-6. Locations of repair patches and their strain gauges are provided in figures C-7 and C-8.

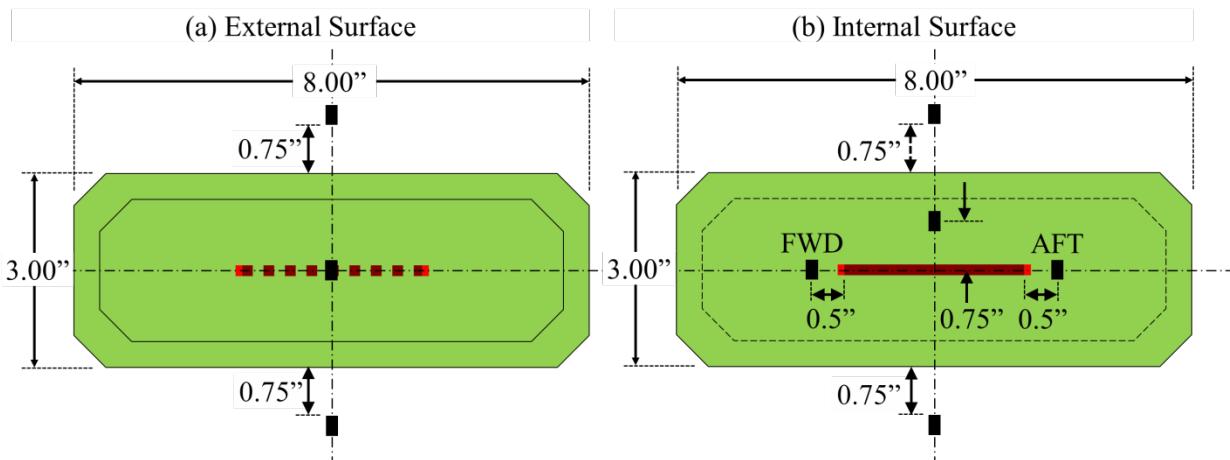

Figure C-6. Typical strain gauge layout in the vicinity of each repair patch: (a) external panel surface, and (b) internal panel surface

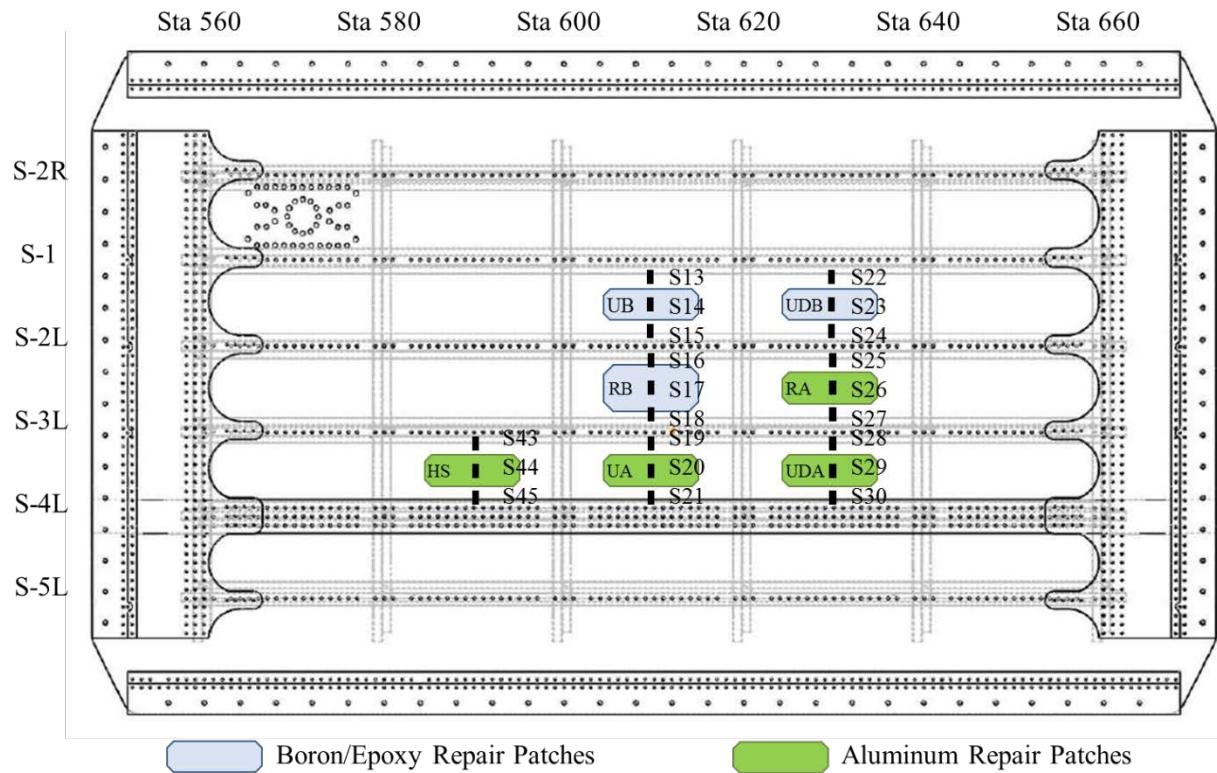

Figure C-7. External strain gauge locations for type-1, -2, -3, and -4 repairs

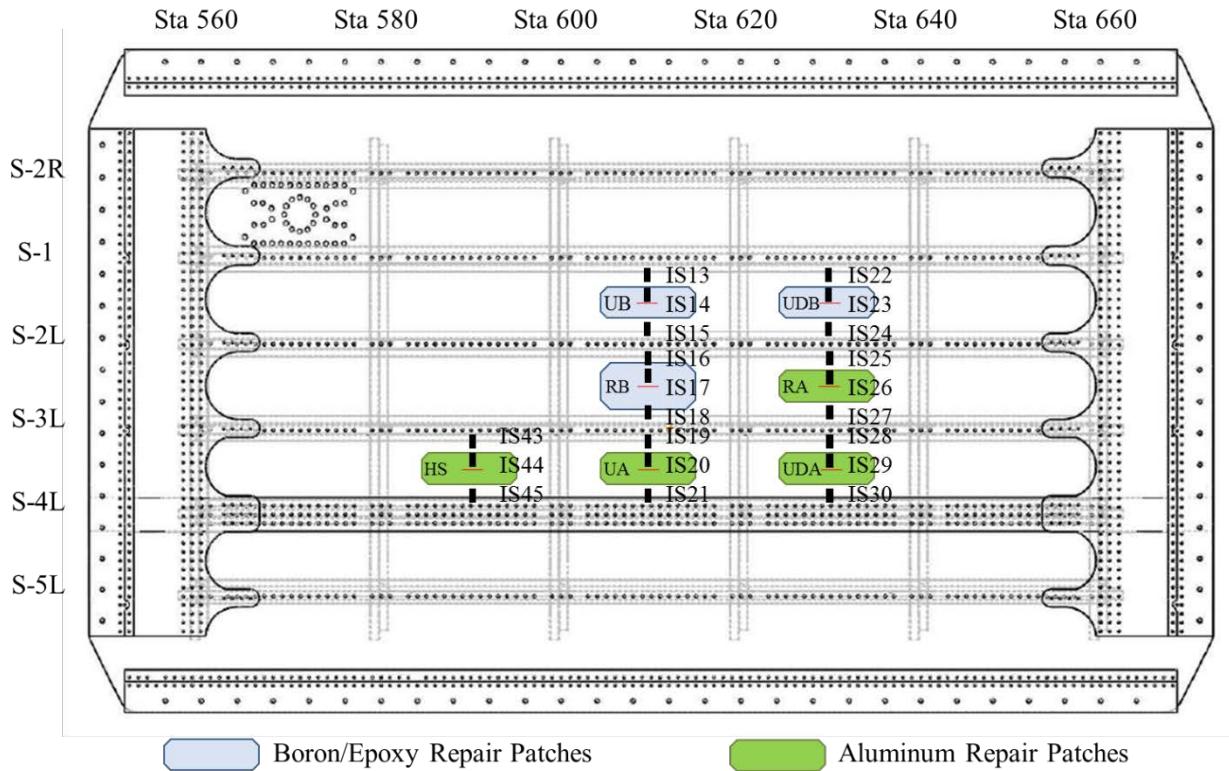

Figure C-8. Internal strain gauge locations for type-1, -2, -3, and -4 repairs

Strain Gauge Chains

After 80,000 cycles, a supplementary study using strain gauge chains was conducted. The objective of using strain gauge chains was to examine whether a single gauge was sufficient to accurately determine the SIF for a curved panel with bonded repairs. The strain gauge chain was installed at four selected repair patch locations (RB, UB, UDB, and UDA), right in front of the crack tip. A linear elastic fracture mechanics approach has been widely used to study the SIF. For the isotropic materials, a single gauge technique to determine SIF was proposed by Dally and Sanford [1]. The technique is widely employed for determination of mode I SIF from one or more strain gauges on a flat plate. Sarangi et al. conducted experiments on the verification of optimal strain gauge locations and their importance in accurately determining mode I SIF [2].

In this study, the objective was to examine whether a single gauge was sufficient to accurately determine the SIF for a curved panel with bonded repairs. The closed-form solution described the strain distribution for a flat panel. To verify whether the closed-form solution was suitable for the curved panel with bonded repairs, a higher resolution of the strain distribution was essential. The conventional strain gauge could not provide such resolution. For this purpose, a strain gauge chain (SGC) was introduced to the testing program as an independent study.

SGC was manufactured by HBM™. A single chain consists of 10 micro-strain gauges evenly distributed at a 0.36-inch (9 mm) distance. Compared to the conventional strain gauge, as shown in figure C-9, the SGC is capable of measuring approximately a three times higher resolution of the strain gradient than the conventional strain gauges.

SG model #	Gage Length, a (in)	Gage Width, b (in)	Pitch, t (in)
CEA-062UW-350	0.062	0.12	N/A
1-KY-23-1/120	0.032	0.032	0.04

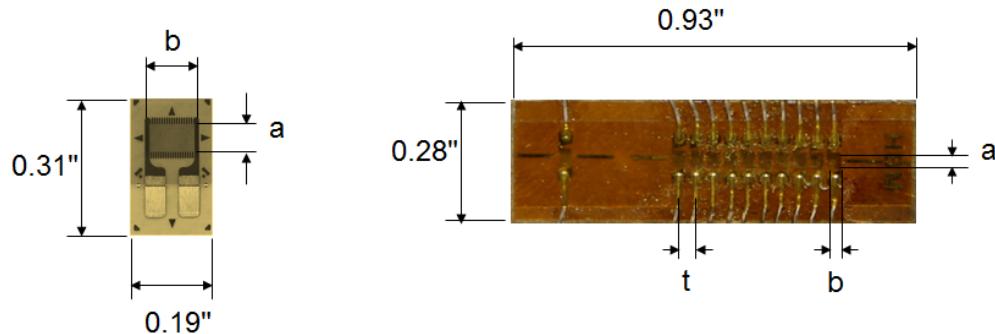

Figure C-9. Strain gauge dimensions and details: (left) conventional strain gauge and (right) strain gauge chain

Strain gauge chains were installed on the RB, UB, UDB, and UDA patch locations, and strain surveys with the SGCs were conducted after the 80,000-cycle and 90,000-cycle inspections. Additionally, variation in local strains due to thermal conditioning (under zero load) was measured in all locations. The typical setups for the strain gauge chains are shown in figure C-10. Finally, strain surveys were conducted under combined mechanical and environmental loading conditions. The local strains were measured during fatigue loading between 80,000 and 90,000 cycles.

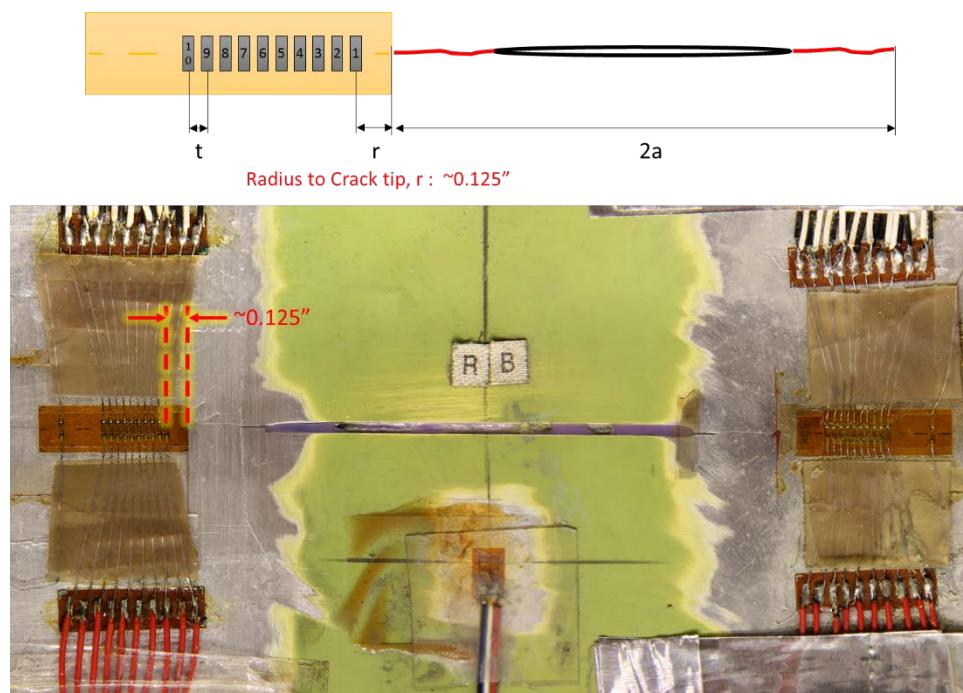

Figure C-10. Typical setup for SGC and the SGC installation on RB patch

APPENDIX D—PATCH INSTALLATION AND STRAIN MONITORED DURING CURING PROCESS

The patch-installation procedures and the strain monitored during the curing process are provided in this section. The patch-installation procedure involves five major steps, and detailed procedures are provided in section D.1 and its subsections. Strain data recorded as function of time are provided in section D.2.

D.1. PATCH INSTALLATION

D.1.1. CLEANING AND PREPARATION OF SURFACE

- 1) The part's surface areas and adjacent surfaces were solvent-cleaned, and all contaminants were removed.
- 2) All the surface coatings and residual adhesive residues were removed down to bare metal.
- 3) The bare metal surface was solvent-cleaned, and all contaminants were removed.

D.1.2. DEOXIDIZATION

There are two deoxidization methods used in the test. For most of the repairs, the skin of the panel was deoxidized using grit blasting. Other repairs were designated “hand sand,” in which the surface of the skin was deoxidized using wheel grinding.

1. Grit Blasting
 - a. A region slightly larger than the bond area was grit-blasted. Figure D-1 shows the grit-blast procedure.
 - b. Loose grit residue was removed with clean, dry compressed air or nitrogen.

Figure D-1. Grit blasting

2. Hand Sanding

- a. A region slightly larger than the bond area was grit-blasted. Figure D-2 shows the wheel-grinding procedure.

Figure D-2. Wheel grinding

D.1.3. APPLICATION OF SOL-GEL COATING

1. Sol-gel solution was applied by brushing with a natural bristle brush. The surface was kept wet during application, as shown in figure D-3.
2. Sol-gel parts were left to dry under ambient conditions for a minimum of 60 minutes.

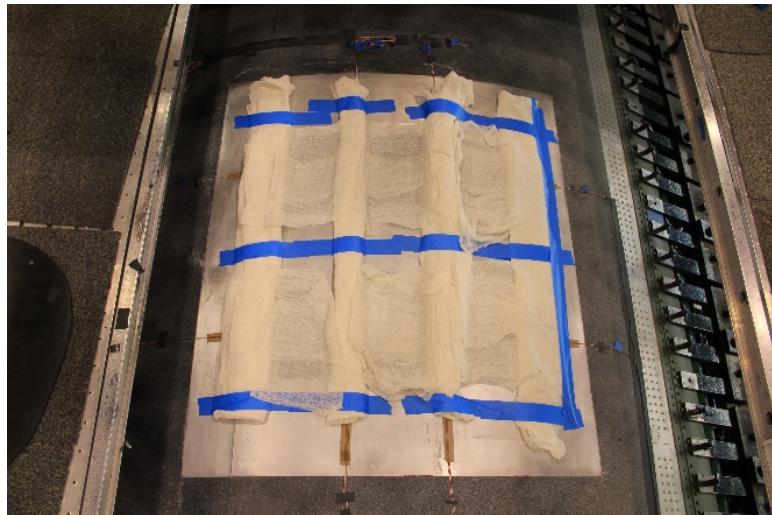

Figure D-3. Applying sol-gel solution

D.1.4. APPLICATION OF BOND PRIMER

1. Cytec Fiberite, Inc. adhesive primer was thoroughly mixed by agitation in the original container.
2. The primer was transferred to a reservoir with continued agitation during application.
3. The adhesive primer was applied to the bond surface to obtain a cured film thickness of 0.00015–0.00040 inch (0.15–0.40 mil).
4. Primed parts were allowed to dry at 135°F using a heat gun for 60 minutes before curing.

D.1.5. CO-CURING

1. The Henkel EA9696 OST (one tacky side) mat carrier, grade 10 film adhesive and patch were applied to the sol-gel-treated and primed surface using standard bond procedures.
2. Both the adhesive and primer were co-cured for 90 minutes at $250^{\circ} \pm 10^{\circ}\text{F}$ using standard heat blanket and vacuum bag processes, as shown in figure D-4.

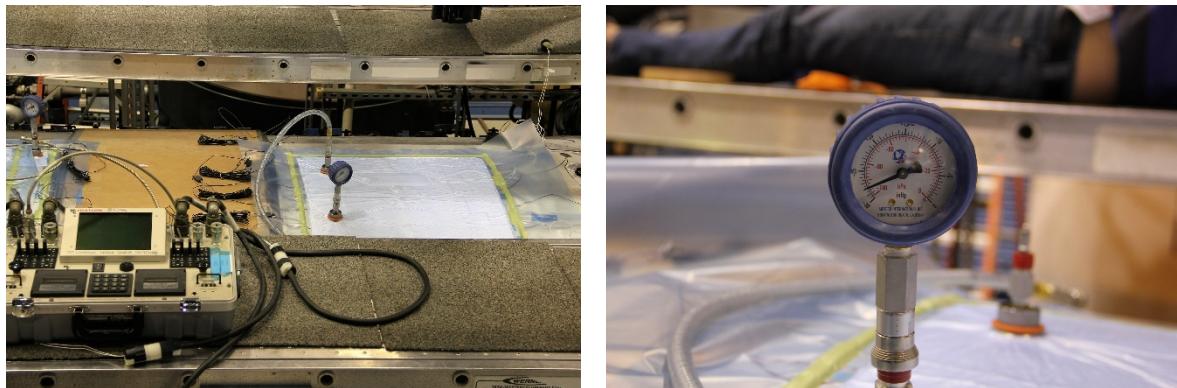

Figure D-4. Co-curing process

D.2. STRAIN MONITORING

Strains were monitored during the curing process on both exterior and interior surfaces of the panel. The strain and the temperature of each repair patch, plotted as a function of time, are provided in the figures below.

Repairs installed at 0 cycles (Type-1, -2, and -3 repairs)

Figures D5 through D-10 show the strains during the curing process for RA, RB, UA, UB, UDA, and UDB repairs, respectively. The figure also shows the location of the strain gauges during the curing process, on both the exterior and interior surfaces of the fuselage panel.

Repairs installed at 60,000 cycles (Type-4 repairs)

Figure D-11 shows the strains during the curing process for the HS repair. The figure also shows the location of the strain gauges during the curing process, both on the exterior and interior surfaces of the fuselage panel.

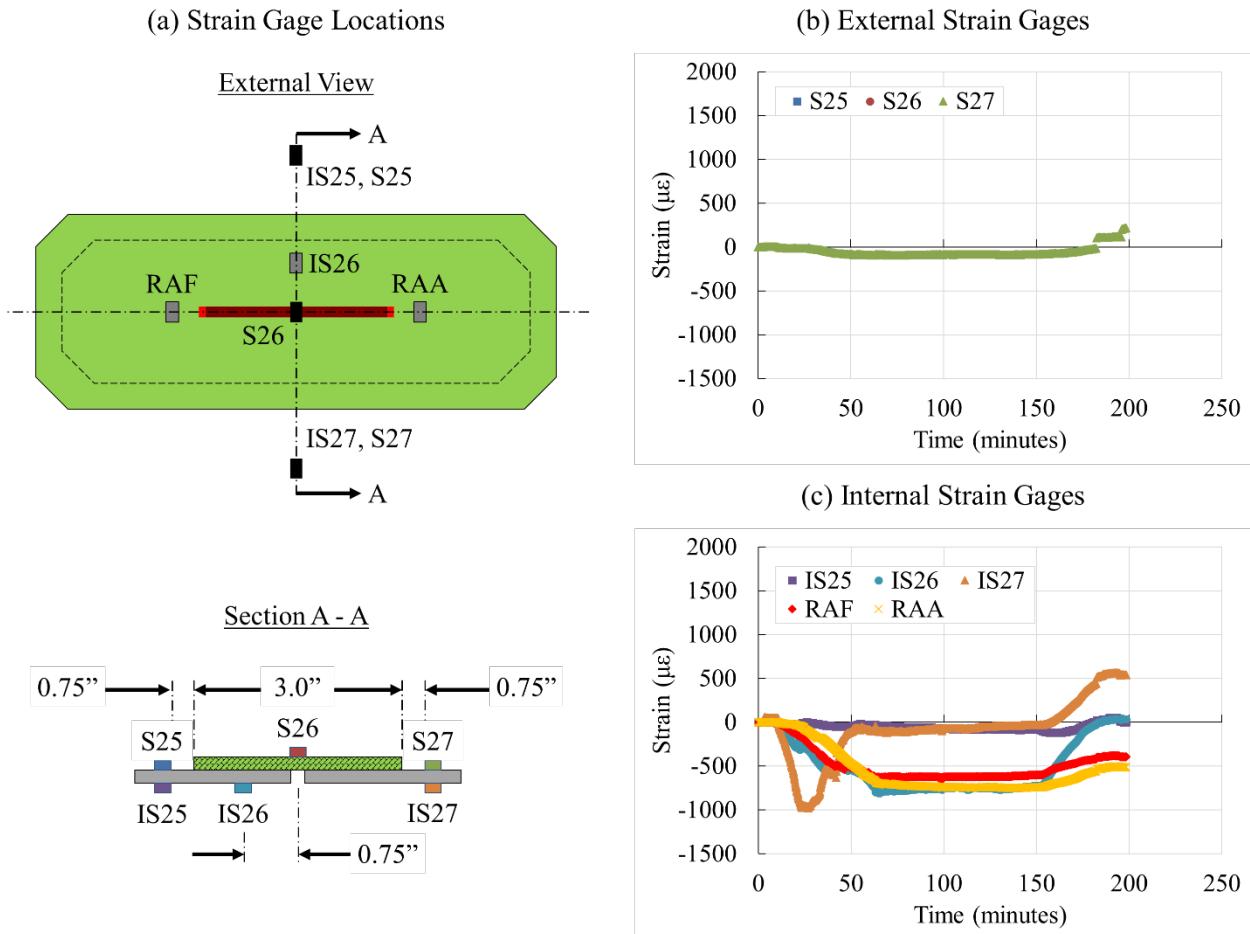

Figure D-5. Strain monitored during the RA repair curing

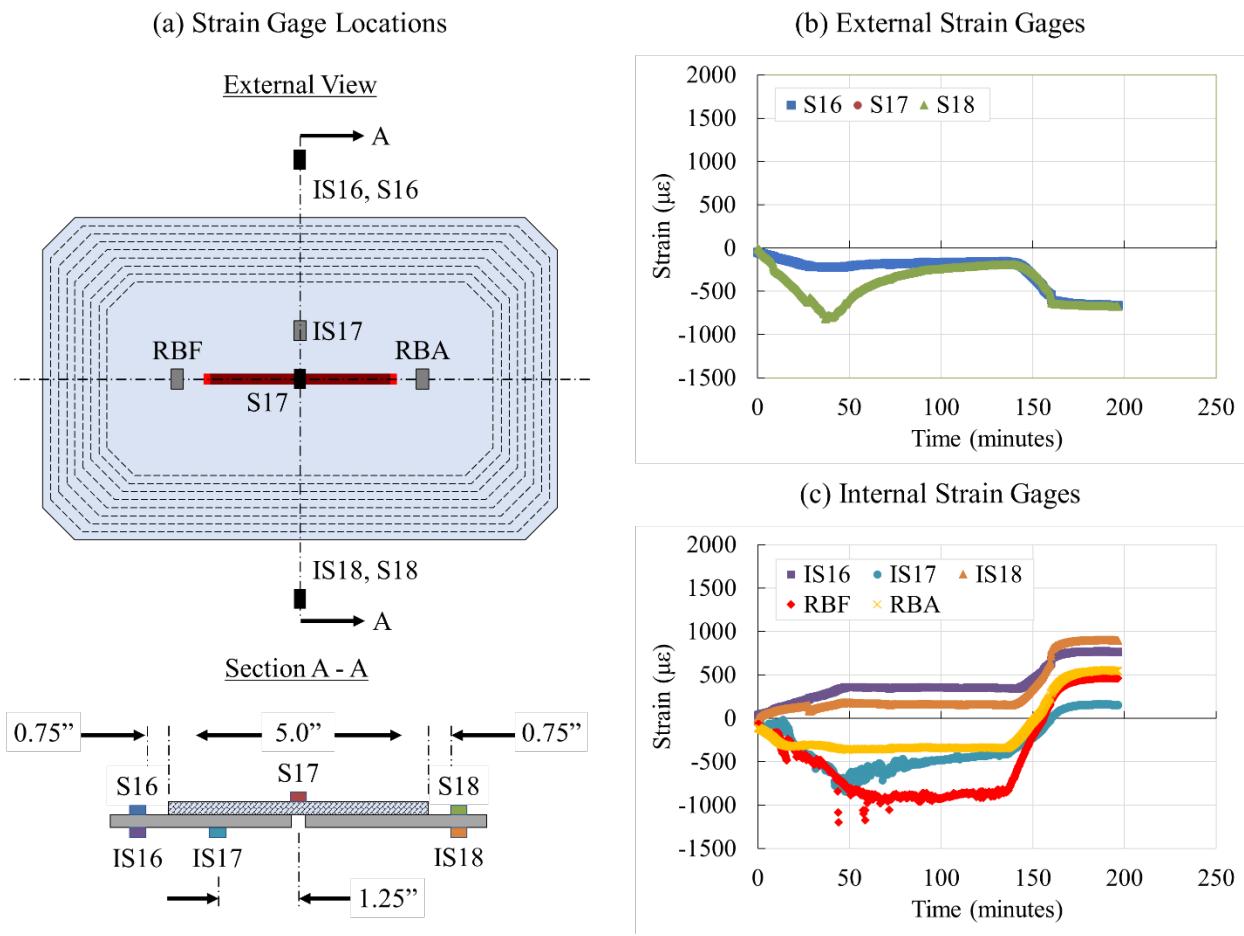

Figure D-6. Strain monitored during the RB repair curing

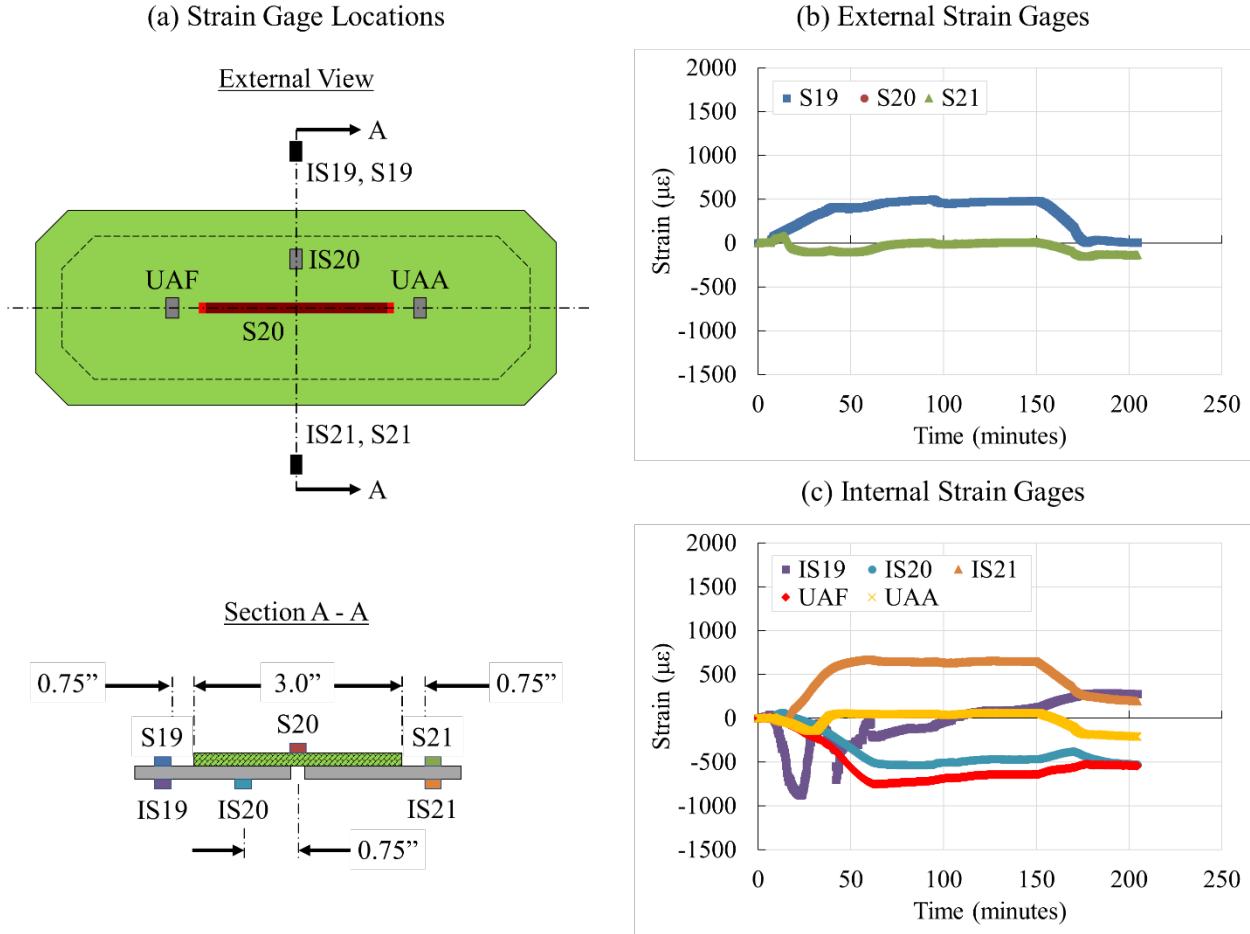

Figure D-7. Strain monitored during the UA repair curing

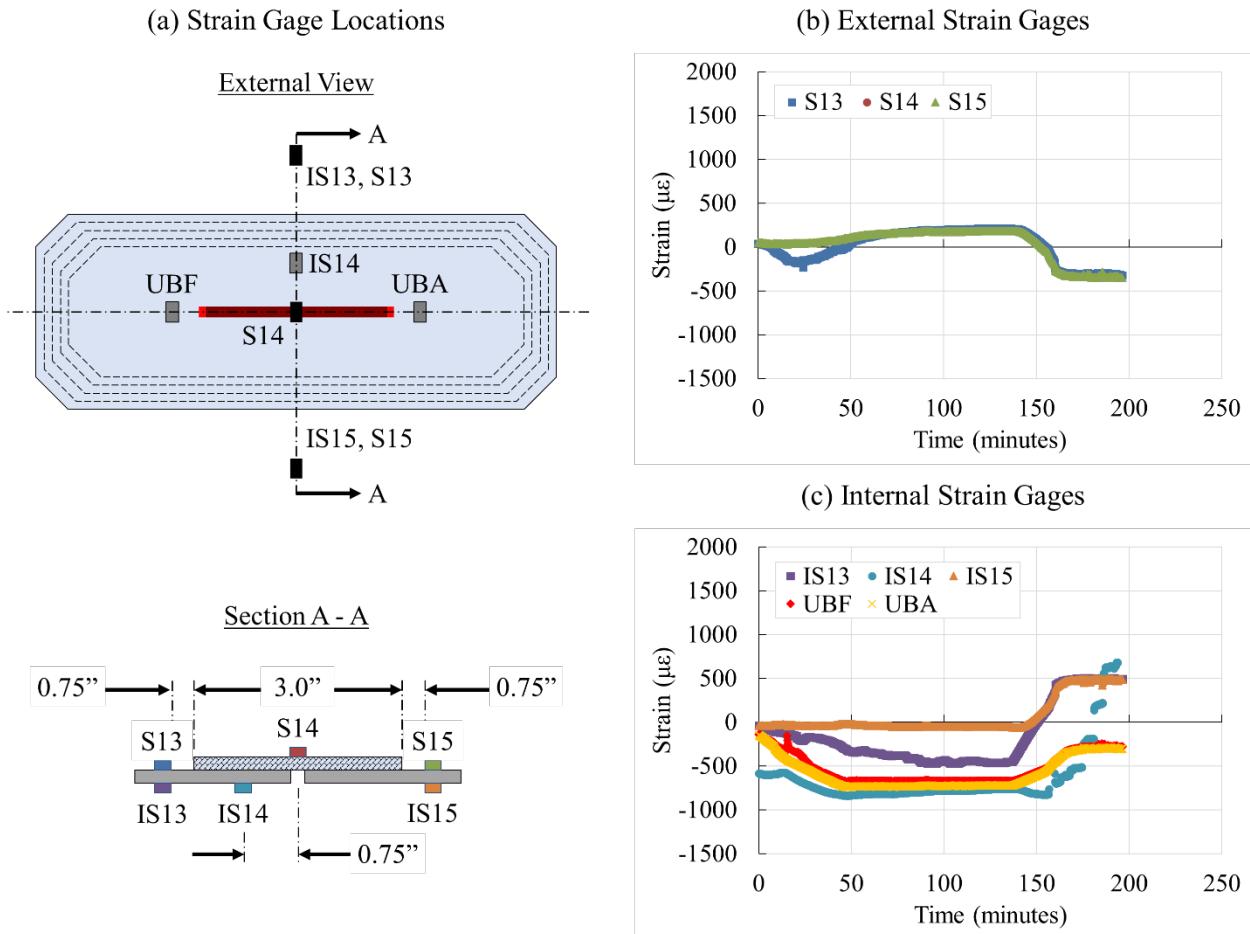

Figure D-8. Strain monitored during the UB repair curing

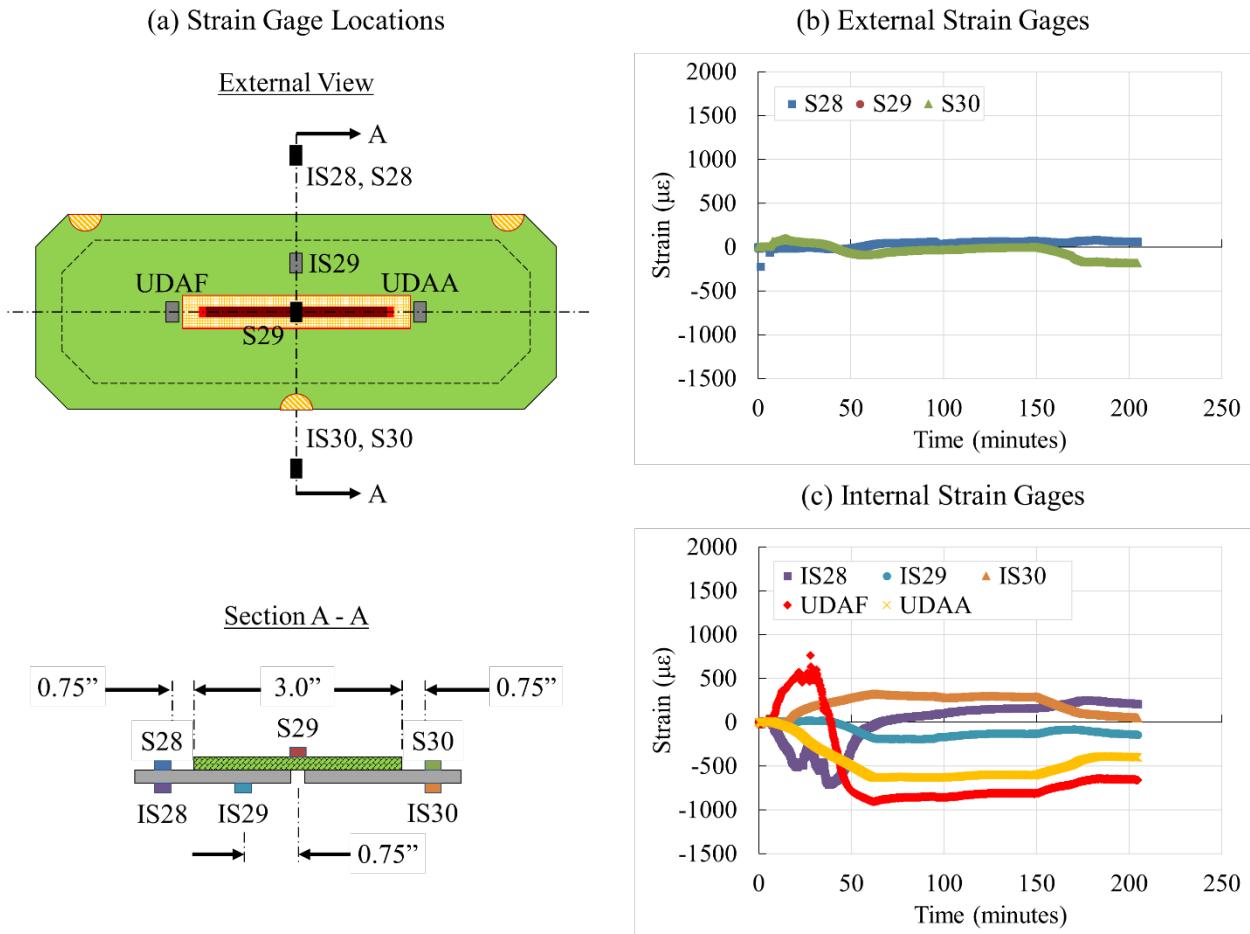

Figure D-9. Strain monitored during the UDA repair curing

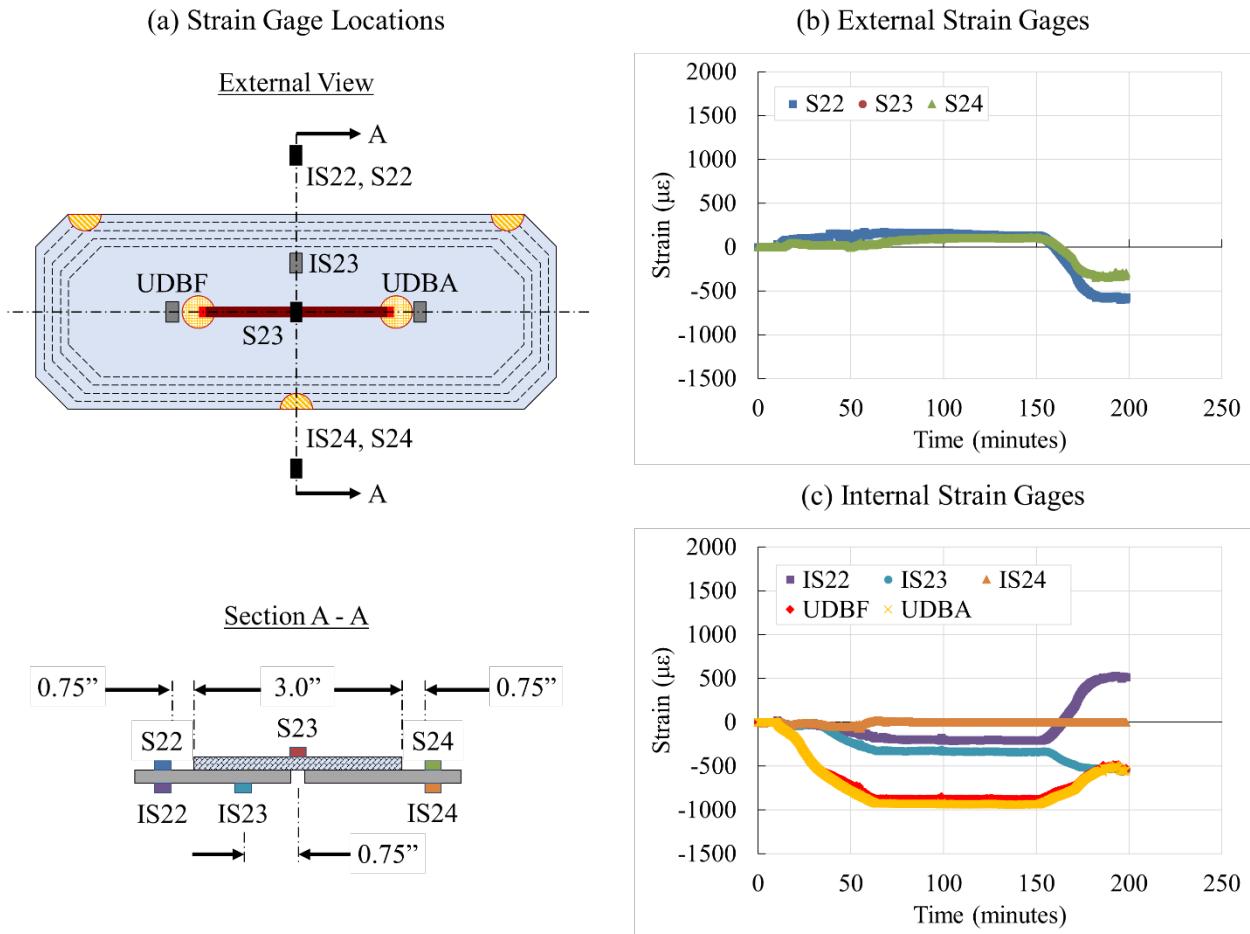

Figure D-10. Strain monitored during the UDB repair curing

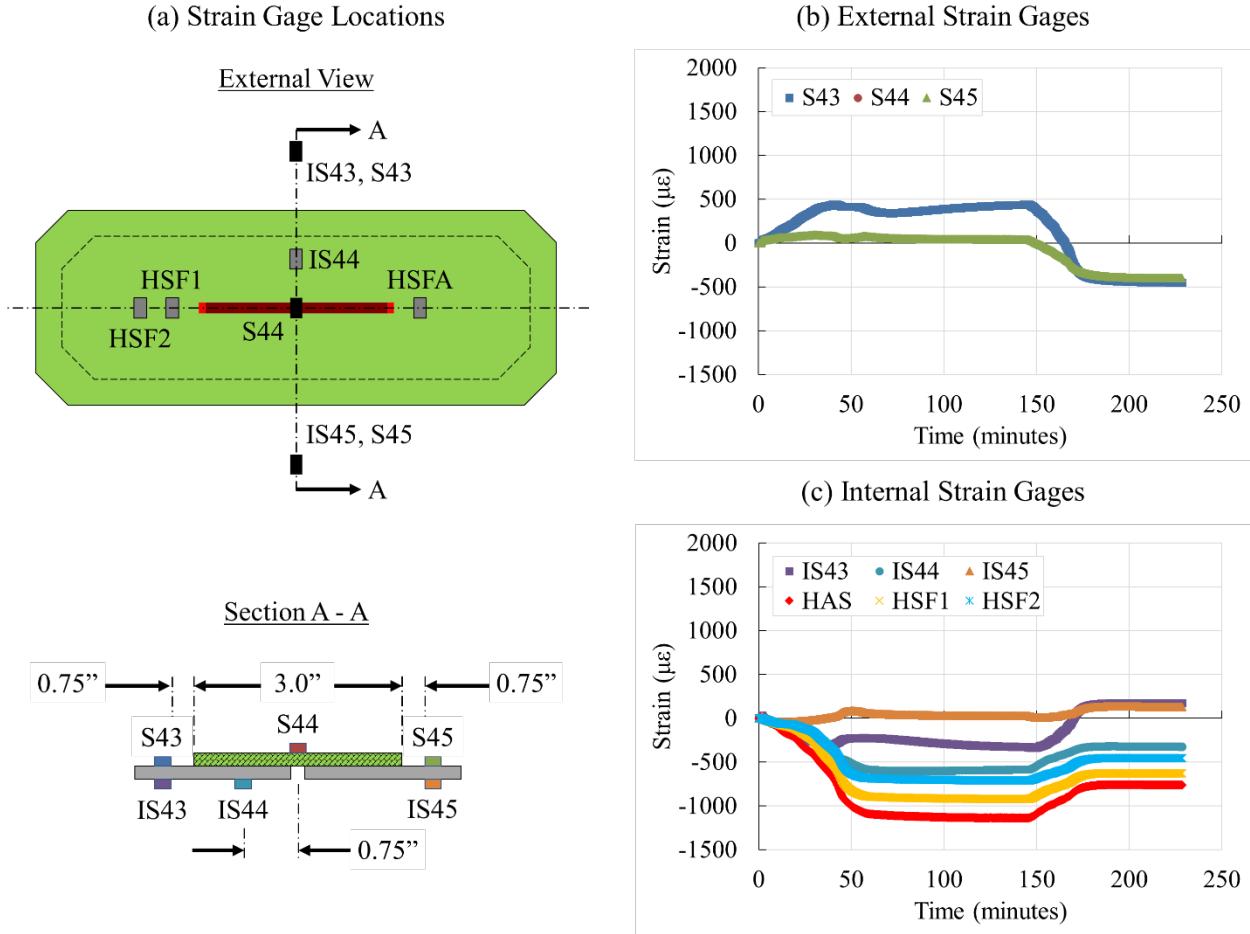

Figure D-11. Strain monitored during the HS repair curing

APPENDIX E—RAW STRAIN DATA

Strain surveys were taken at 75% of the simulated service load condition periodically throughout the fatigue test. Each strain survey was repeated three times to verify the repeatability, and quasi-static loadings were applied in ten increments up to the maximum loads. The loading conditions for the strain survey are summarized in table E-1.

Table E-1. Loading condition of the strain survey

Strain Survey	Cycles	Maximum Mechanical Load				Environmental Load (constant)	
		Pressure (psi)	Hoop (lb)	Frame (lb)	Longitudinal (lb)	Temp. (°F)	Relative Humidity (%)
Baseline	0	6.7	7140	1,133	6675	80	60
Hot-Wet	0 – 80,000	6.7	7140	1,133	6675	165	85
						Laboratory ambient	
Cold-Dry	80,000 – 10,000	6.7	7140	1,133	6675	-25	-
						Laboratory ambient	

The raw data from the strain survey for the strain gauges for each repair are provided in the tables below. For each load condition, applied loads and strains were measured at each gauge at each of the ten-equal-load increments up to the maximum loads listed. For the applied loads, the pressure is in units of psi; 12-frame load assemblies (frames 1–12) are in units of lb; 14-hoop load assemblies (hoops 1–14) are in units of lb; and longitudinal load assemblies (longitudinals 1–8) are in units of lb. The strains measured at the gauges are in units of $\mu\epsilon$.

For the entire test, the applied loads were within $\pm 2\%$ of the prescribed values listed in table E-1. Valid strain readings were obtained for most of the gauges, with the exception of a few gauges (particularly substructure gauges and internal skin gauges), which short-circuited because of moisture absorption from the environmental chamber. These gauges show scattered readings or the values dropped as the test progressed with fatigue cycling.

The strain survey was conducted every 5000 cycles in the first 20,000 cycles, and every 10,000 cycles between 20,000 and 100,000 cycles. To avoid overcrowded data, the raw strain data of each repair for every 20,000 cycles are provided in this appendix, namely pristine panel, baseline, 20K cycles, 40K cycles, 60K cycles, 80K cycles, and 90K cycles.

Note that the missing strain gauge values in tables E-2–22 are due to either removal of strain gauges or faulty strain values.

APPENDIX F—STRAIN DATA REDUCTION PROCEDURE

The raw strain gauge data in appendix E were reduced to remove the strain gauge offset due to preloading after the panel was installed in the fixture. In the strain gauge data reduction, the first data point was removed to minimize the effects of preloading. A second-order regression using a least-squares method was used to curve-fit the remaining dataset to a second-order polynomial:

$$\varepsilon = Ax^2 + Bx + C \quad (\text{F - 1})$$

where ε is the dependent strain value, x is the independent load increment variable, A is the quadratic coefficient, B is the linear coefficient, and C is the constant term or ordinate intercept. Parameter C was used to define the zero load offset, which was used to shift all data in the set and finally obtain the shifted values. Following the procedures defined above, the raw strain data in appendix E were reduced.

The crack-tip strain data of RB patch were selected as an example of the data-reduction procedure.

1. The raw strain data of three runs of strain survey are provided in figure F-1a.
2. After the first reading of each strain survey was removed (see figure F-1b), strain data were curve-fitted using equation F-1 and plotted as functions of applied pressure (see figure F-2a).
3. The hoop strains were shifted using the constant C obtained by following the data-reduction procedure. Finally, the reduced hoop strain data are shown in table F-2c and figure F-2b.

APPENDIX G—COMPARISON OF STRAIN SURVEYS AT THREE ENVIRONMENTAL CONDITIONS

Comparisons of strain surveys at different environmental conditions are provided in this appendix. These strain surveys were conducted at 80,000 cycles, and the repair patches that were installed in the conditioned region (dark blue box in figure G-1) will be compared. Repair patches include: reference repairs, under-designed repairs, under-designed with partial disbond repairs, and a hand-sanded repair.

In this study, four repair patches were selected to use the strain gauge chains (see appendix C) to obtain higher resolution of strain distributions. These repairs included the reference B/E_p repair, RB; the under-designed B/E_p repair, UB; the under-designed with partial disbond B/E_p repair, UDB; and the under-designed with partial disbond aluminum repair, UDA.

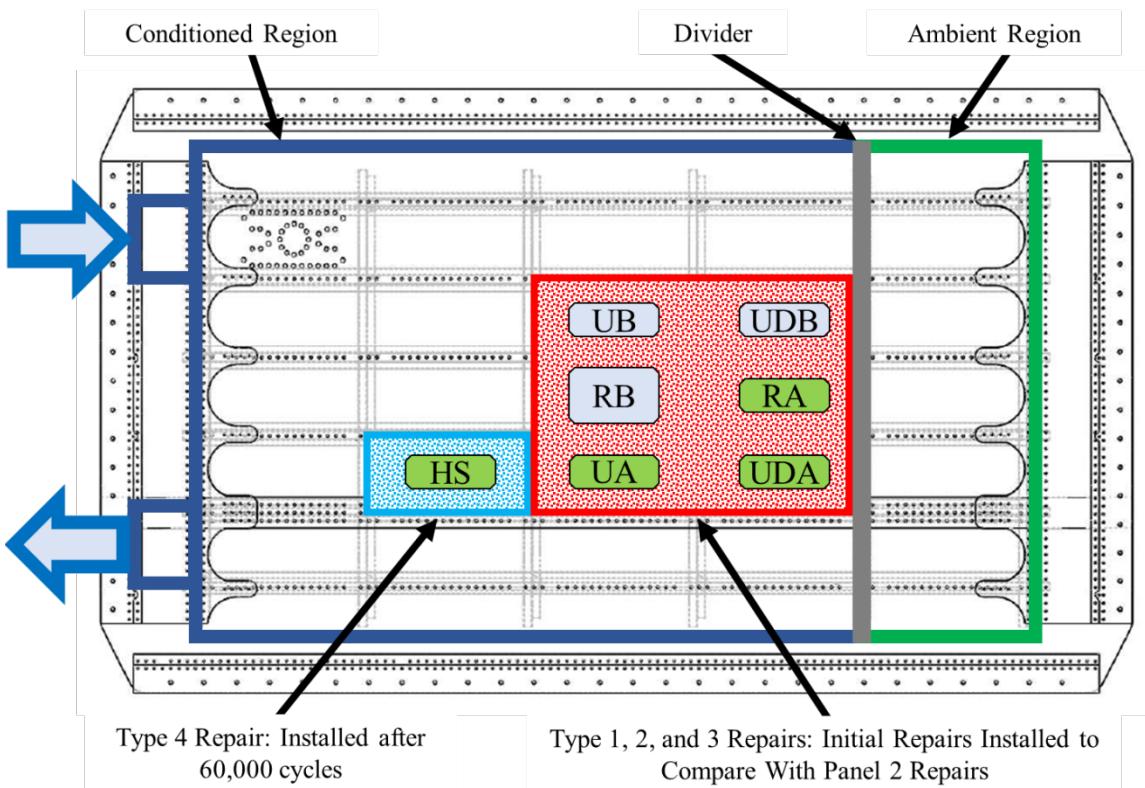

Figure G-1. Repair patches in the conditioned region are shown in the dark blue box

**Figure G-10. Raw strain gauge data at three environmental condition at 80,000 cycles
(run 3)**

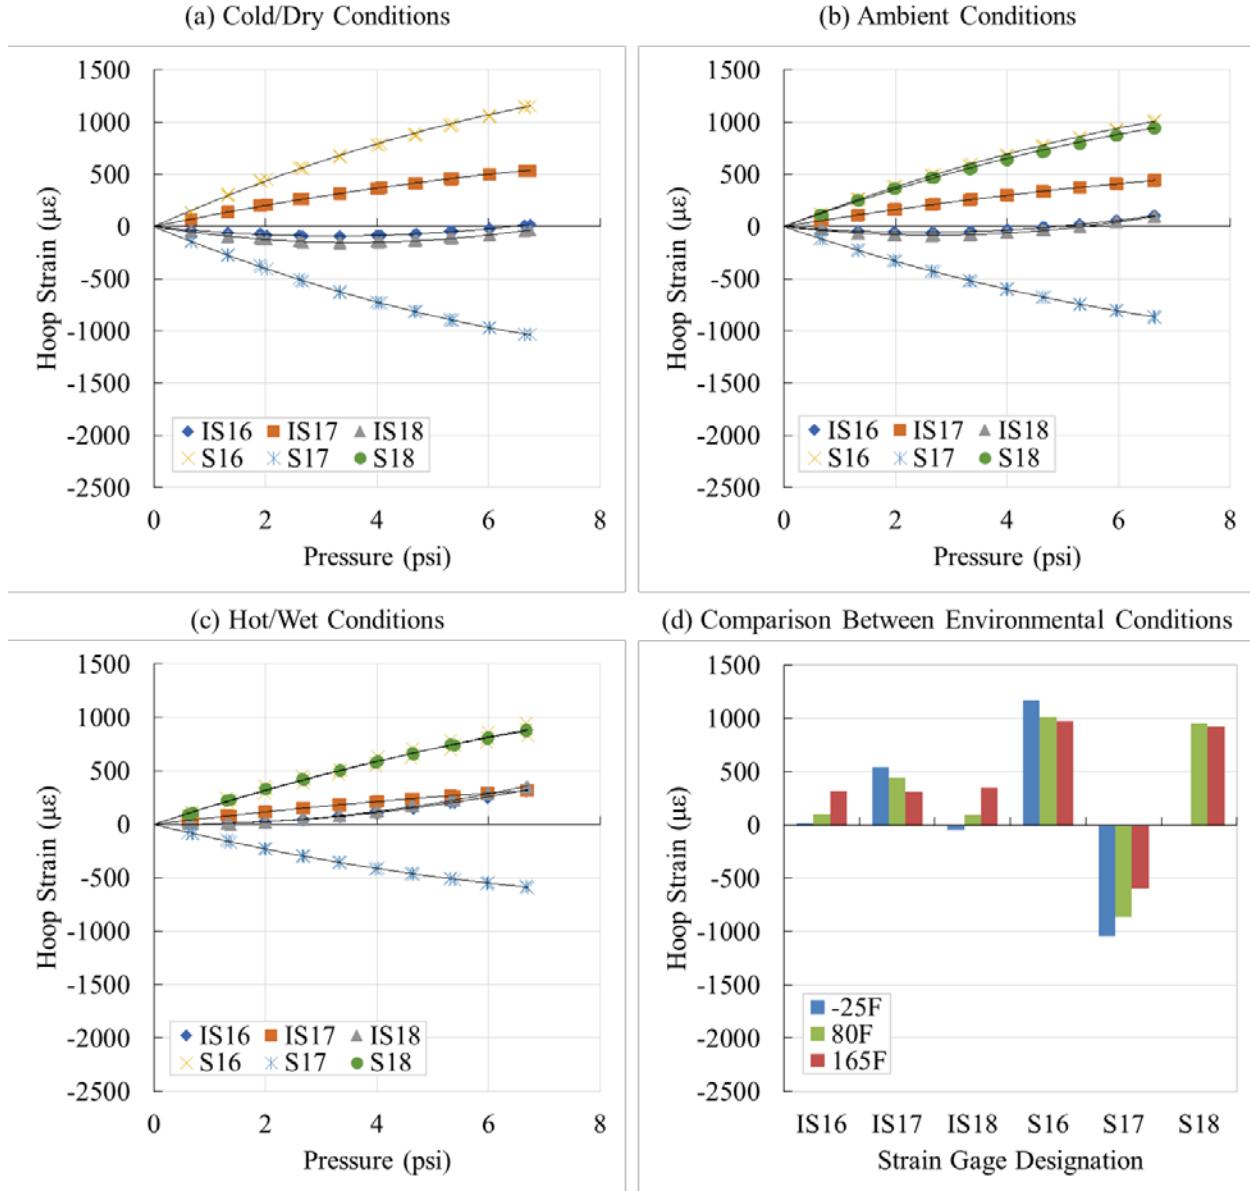

Figure G-11. Strain gauge measurements at 80,000 cycles at (a) cold-dry (-25°F) environmental conditions, (b) ambient environmental conditions, (c) hot-wet (165°F and 85% RH) environmental conditions, and (d) comparison of three environmental conditions at maximum strain survey loads

The notch-tip strain data are shown in the tables and figure below. Strain was measured at the maximum loading conditions at three different environmental conditions.

Table G-1. Strain measured at maximum loading conditions using strain gauge chain at the forward side

Strain Gauge	X Position	165°F	80°F	-25°F
RBF1	1.72	962.8	1156.8	1378.6
RBF2	1.76	891.0	1081.8	1292.6
RBF3	1.80	838.0	1025.4	1228.8
RBF4	1.84	797.0	981.2	1178.9
RBF5	1.88	767.4	950.2	1144.0
RBF6	1.92	746.5	927.2	1121.1
RBF7	1.95	729.7	908.2	1098.3
RBF8	1.99	712.0	886.6	1074.1
RBF9	2.03	698.2	870.5	1055.6
RBF10	2.07	684.2	854.4	1034.5

Table G-2. Strain measured at maximum loading conditions using strain gauge chain at the aft side

Strain Gauge	X Position	165°F	80°F	-25°F
RBA1	1.69	742.5	910.2	1093.7
RBA2	1.73	727.2	885.3	1066.9

**Figure G-27. Raw strain gauge data at three environmental conditions
at 80,000 cycles (run 3)**

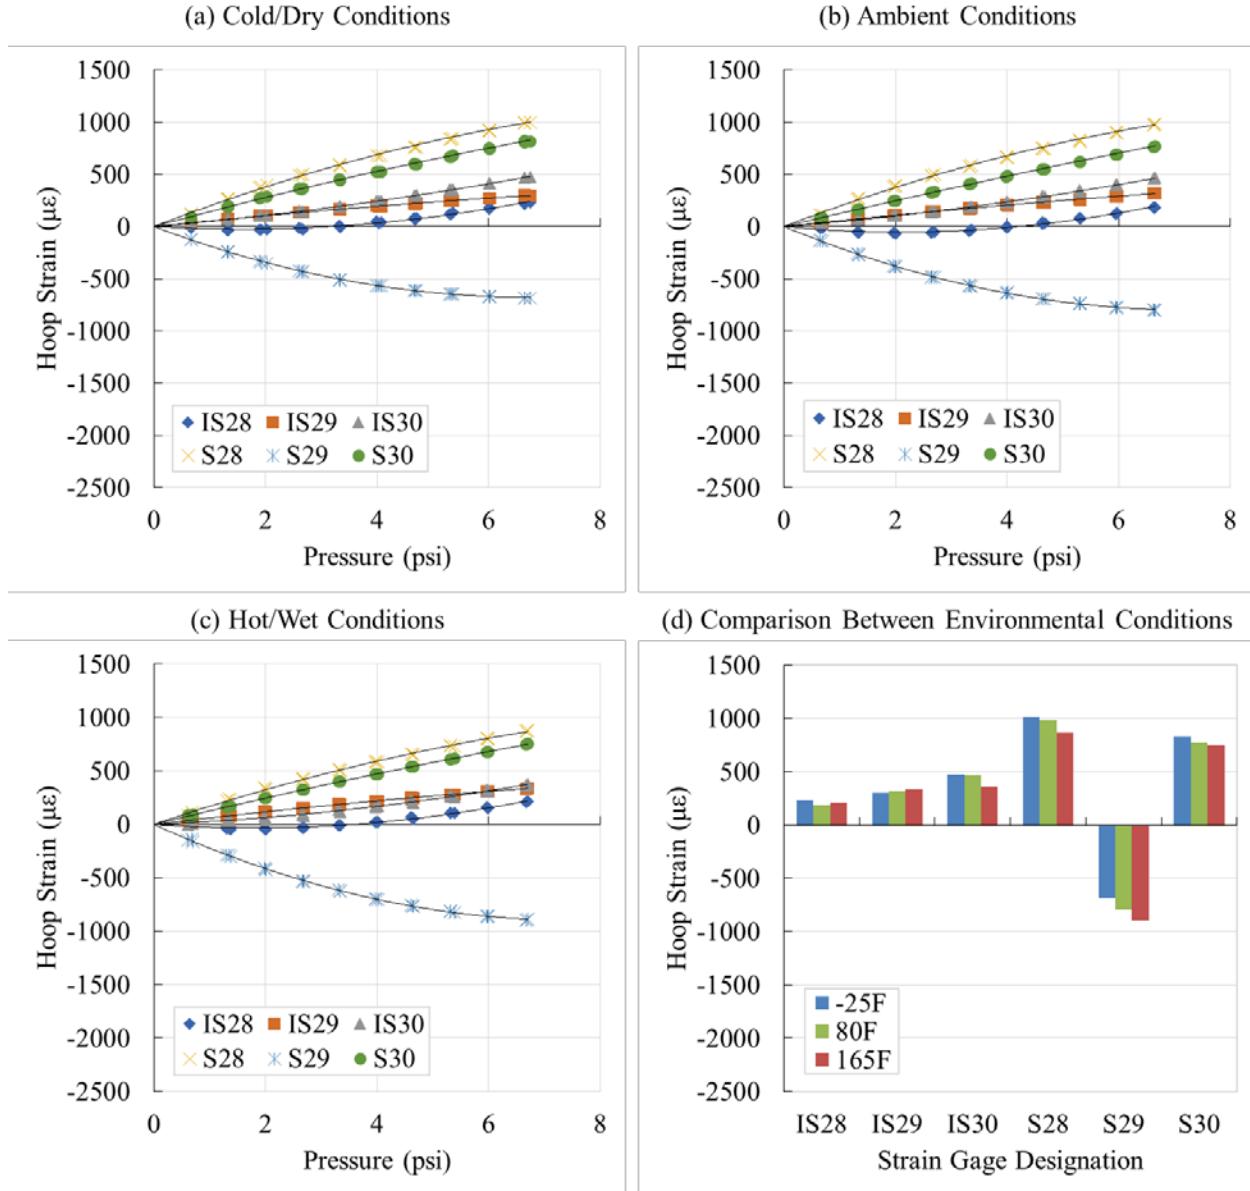

Figure G-28. Strain gauge measurements at 80,000 cycles at (a) cold-dry (-25°F) environmental conditions, (b) ambient environmental conditions, (c) hot-wet (165°F and 85% RH) environmental conditions, and (d) comparison of three environmental conditions at maximum strain survey loads

The notch-tip strain data are shown in tables G-20 and G-21, and in figure G-14. Strain was measured at the maximum loading conditions at three different environmental conditions.

Table G-5. Strain measured at maximum loading conditions using strain gauge chain at the forward side

Strain Gauge	X Position	165°F	80°F	-25°F
UDAF1	2.38	1724.4	1690.8	1646.0

Figure G-33. Raw strain gauge data at three environmental conditions at 80,000 cycles (run 3)

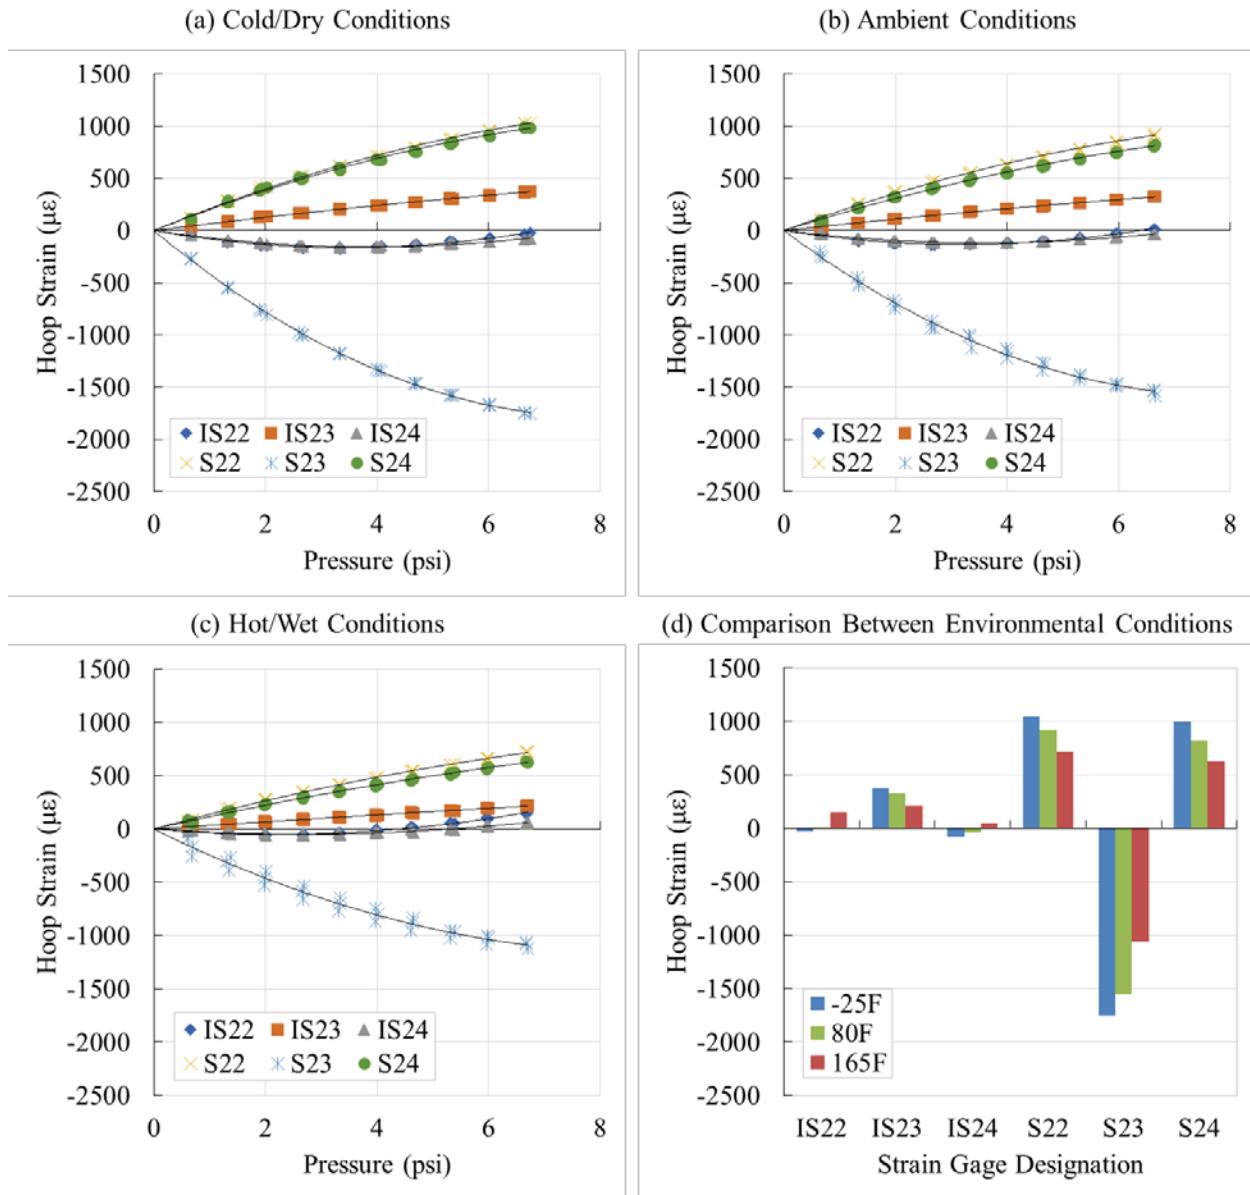

Figure G-34. Strain gauge measurements at 80,000 cycles at (a) cold-dry (-25°F) environmental conditions, (b) ambient environmental conditions, (c) hot-wet (165°F and 85% RH) environmental conditions, and (d) comparison of three environmental conditions at maximum strain survey loads

The notch-tip strain data are shown in tables G-25 and G-26, and in figure G-17. Strain was measured at the maximum loading conditions at three different environmental conditions.

Table G-7. Strain measured at maximum loading conditions using strain gauge chain at the forward side

Strain Gauge	X Position	165°F	80°F	-25°F
UDBF1	2.94

**Figure G-39. Raw strain gauge data at three environmental conditions at 80,000 cycles
(run 3)**

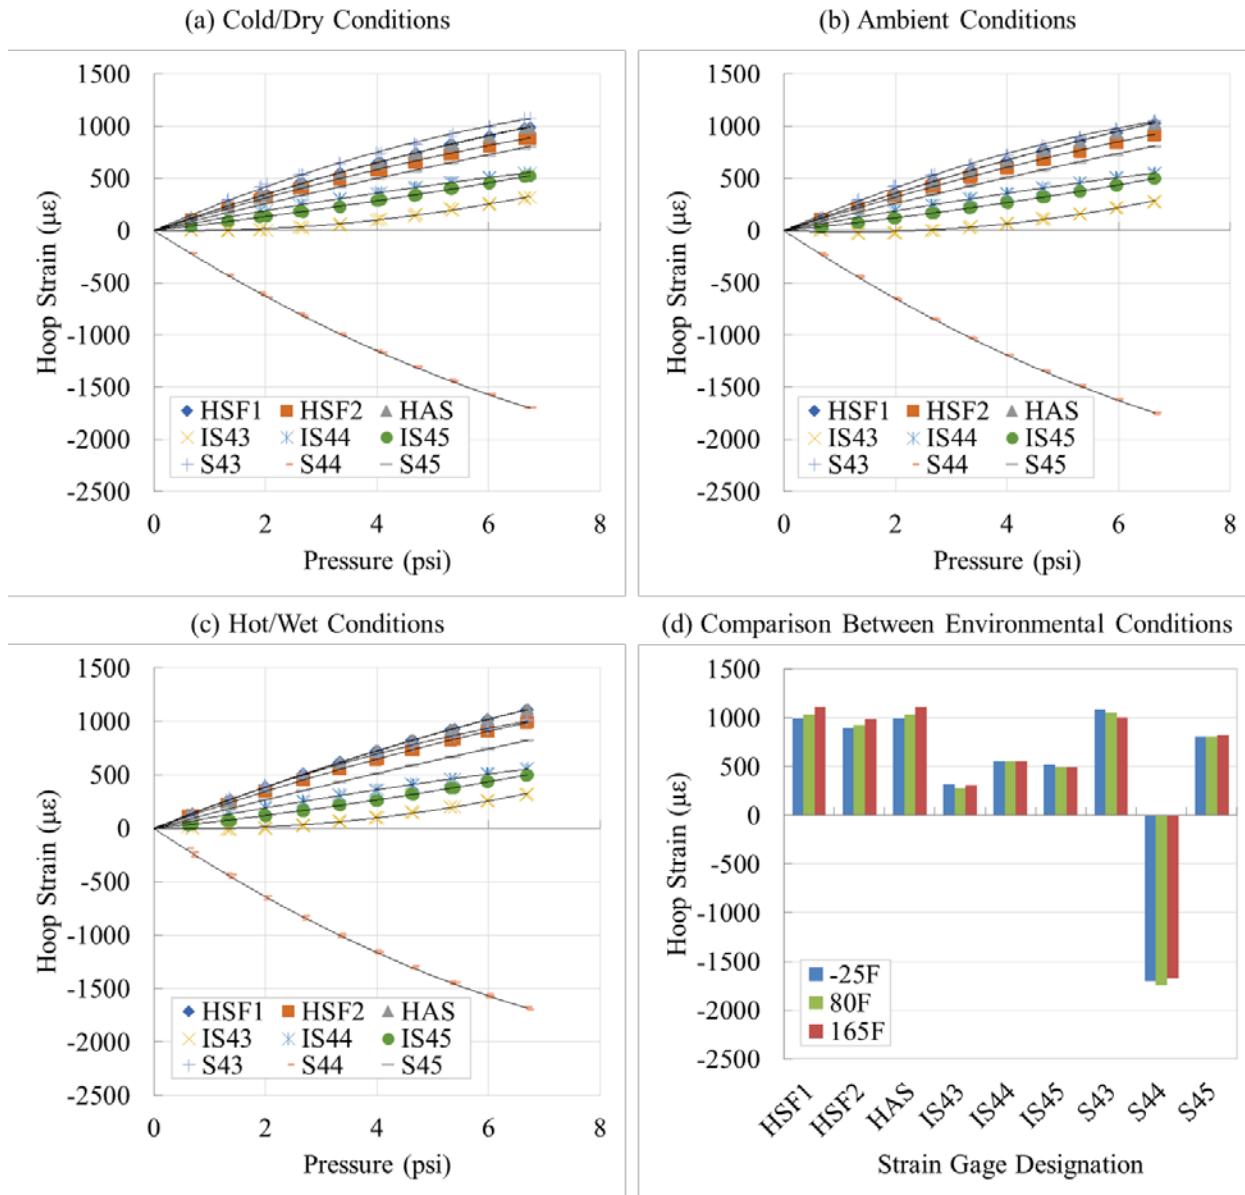

Figure G-40. Strain gauge measurements at 80,000 cycles at (a) cold-dry (-25°F) environmental conditions, (b) ambient environmental conditions, (c) hot-wet (165°F and 85% RH) environmental conditions, and (d) comparison of three environmental conditions at maximum strain survey loads

APPENDIX H—DIGITAL IMAGE CORRELATION RESULTS

During the strain survey, the digital image correlation (DIC) surveys were also conducted during all test phases. The color fringe pattern of each figure in this appendix shows the full-field hoop strain measurement around the patch area. The accompanying plots show the value of hoop strains along the vertical sections drawn in the figures. All the measurements were obtained at the maximum loading conditions (75% SL), as listed in table H-1.

Table H-1. Loading conditions during DIC strain survey

Phases	Maximum Mechanical Load				Environmental Load	
	Pressure (psi)	Hoop (lb)	Axial (lb)	Frame (lb)	Temperature	Humidity
Baseline	6.7	7140	1133	6675	Ambient	Ambient
Hot-Wet	6.7	7140	1133	6675		
Cold-Dry	6.7	7140	1133	6675		

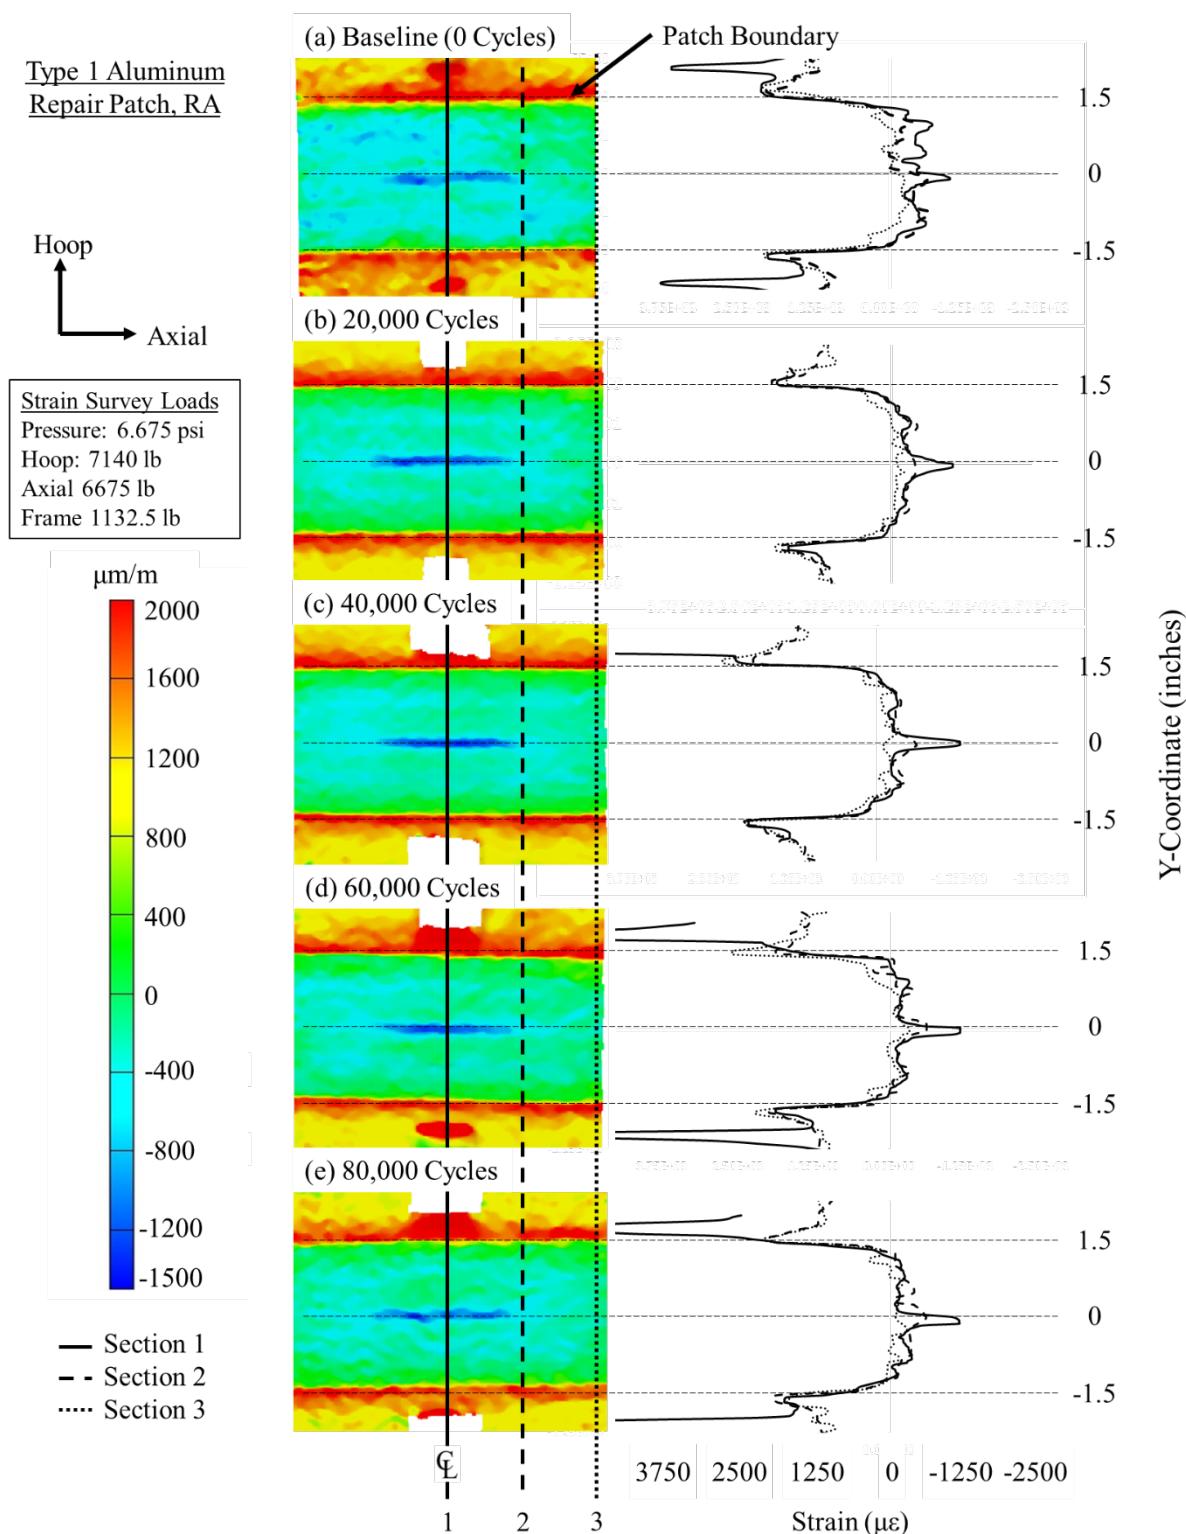

Figure H-1. The DIC results for the RA repair at (a) 0, (b) 20,000, (c) 40,000, (d) 60,000, and (e) 80,000 cycles

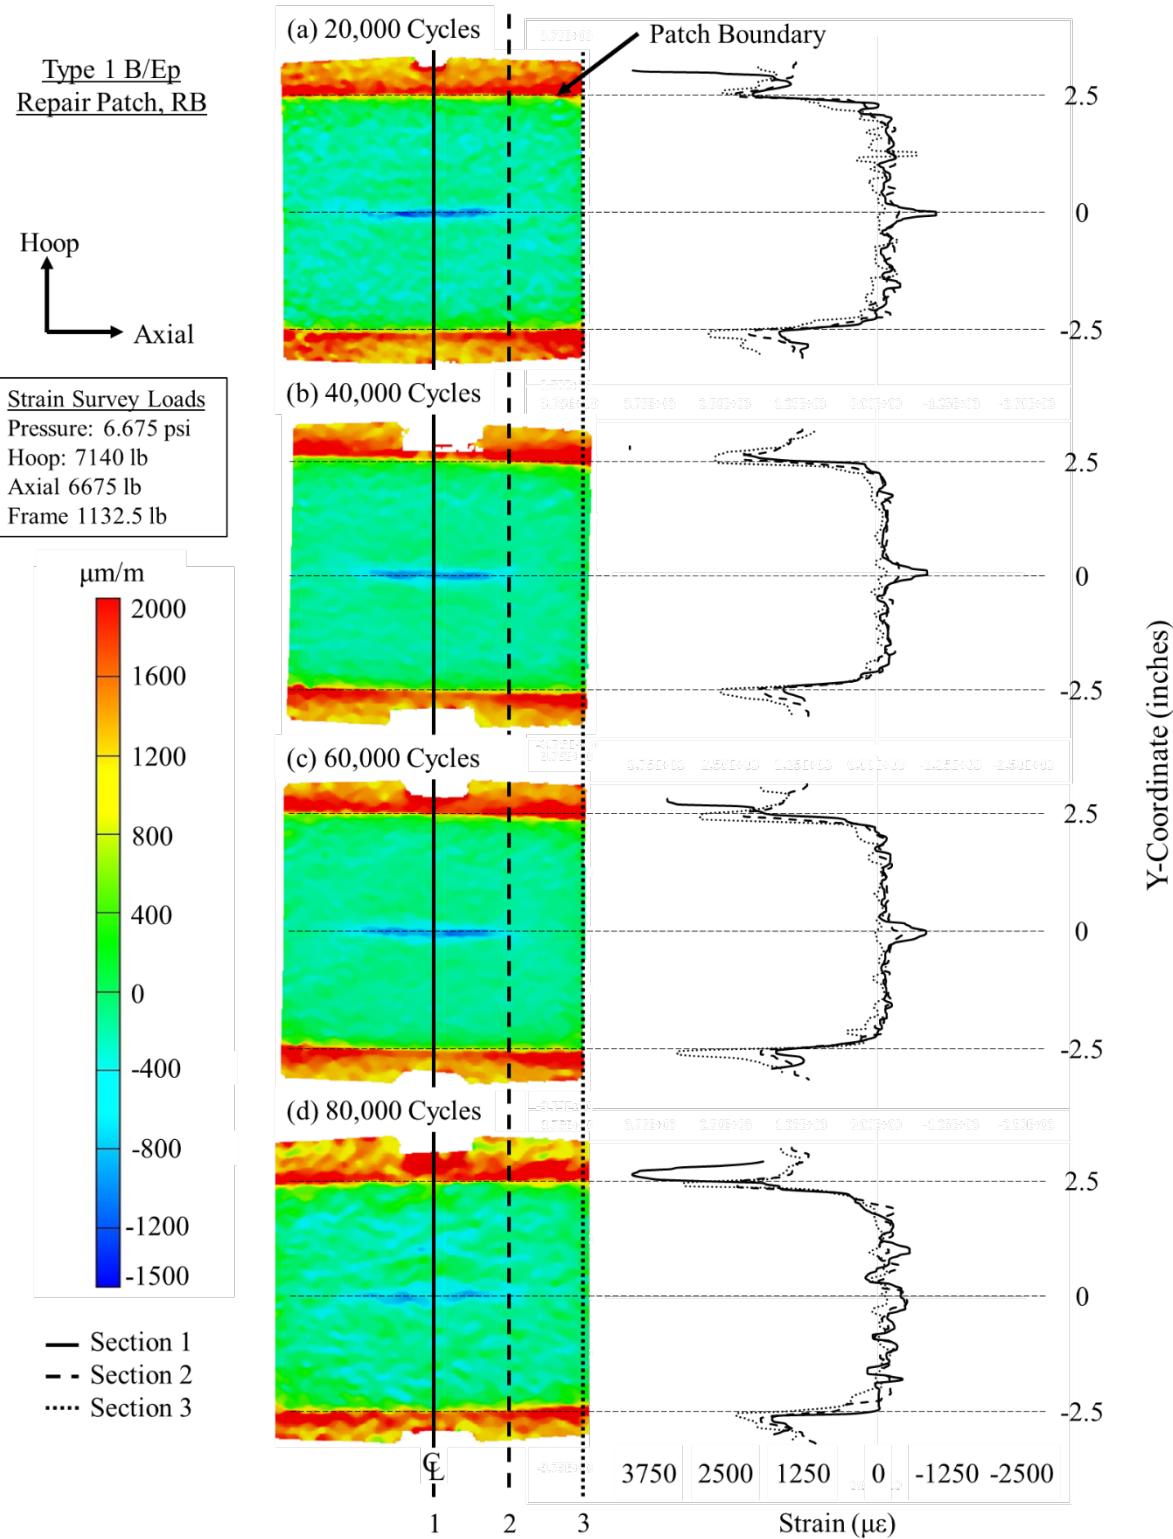

Figure H-2. The DIC results for the RB repair at (a) 20,000, (b) 40,000, (c) 60,000, and (d) 80,000 cycles (Note: the data at 0 cycles was unavailable because of a damaged file)

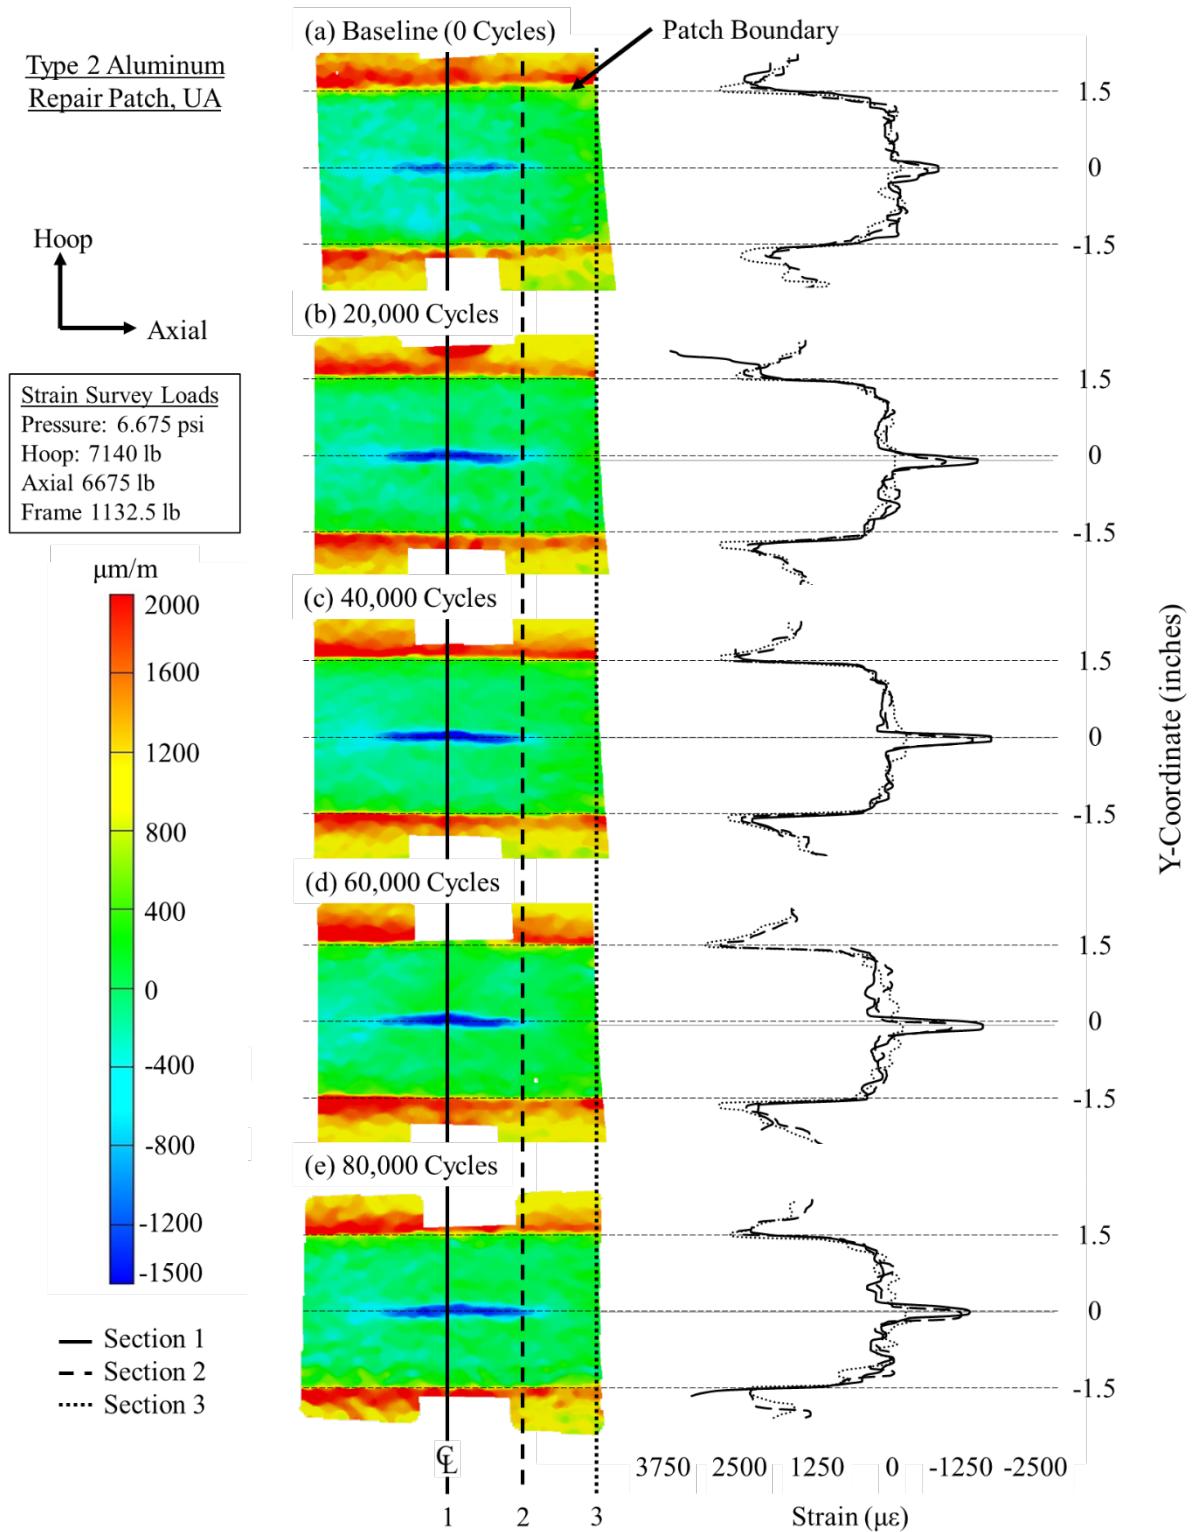

Figure H-3. The DIC results for the UA repair at (a) 0, (b) 20,000, (c) 40,000, (d) 60,000, and (e) 80,000 cycles

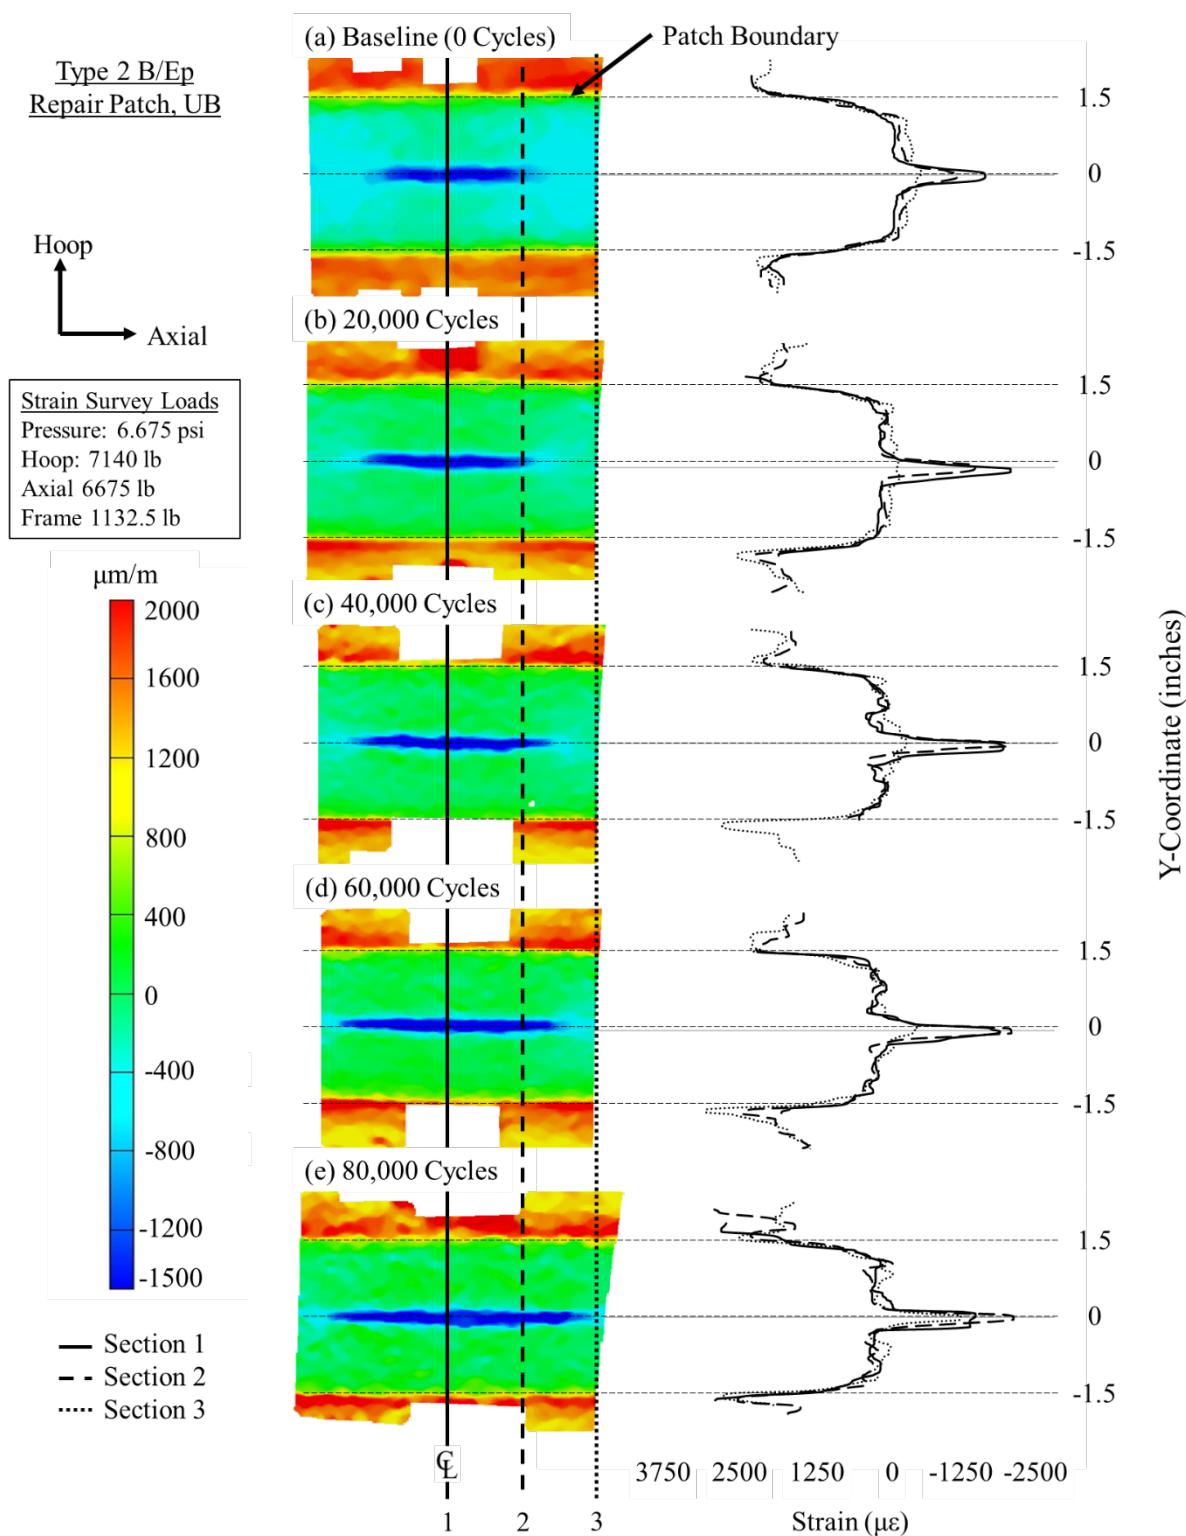

Figure H-4. The DIC results for the UB repair at (a) 0, (b) 20,000, (c) 40,000, (d) 60,000, and (e) 80,000 cycles

Type 3 Aluminum
Repair Patch, UDA

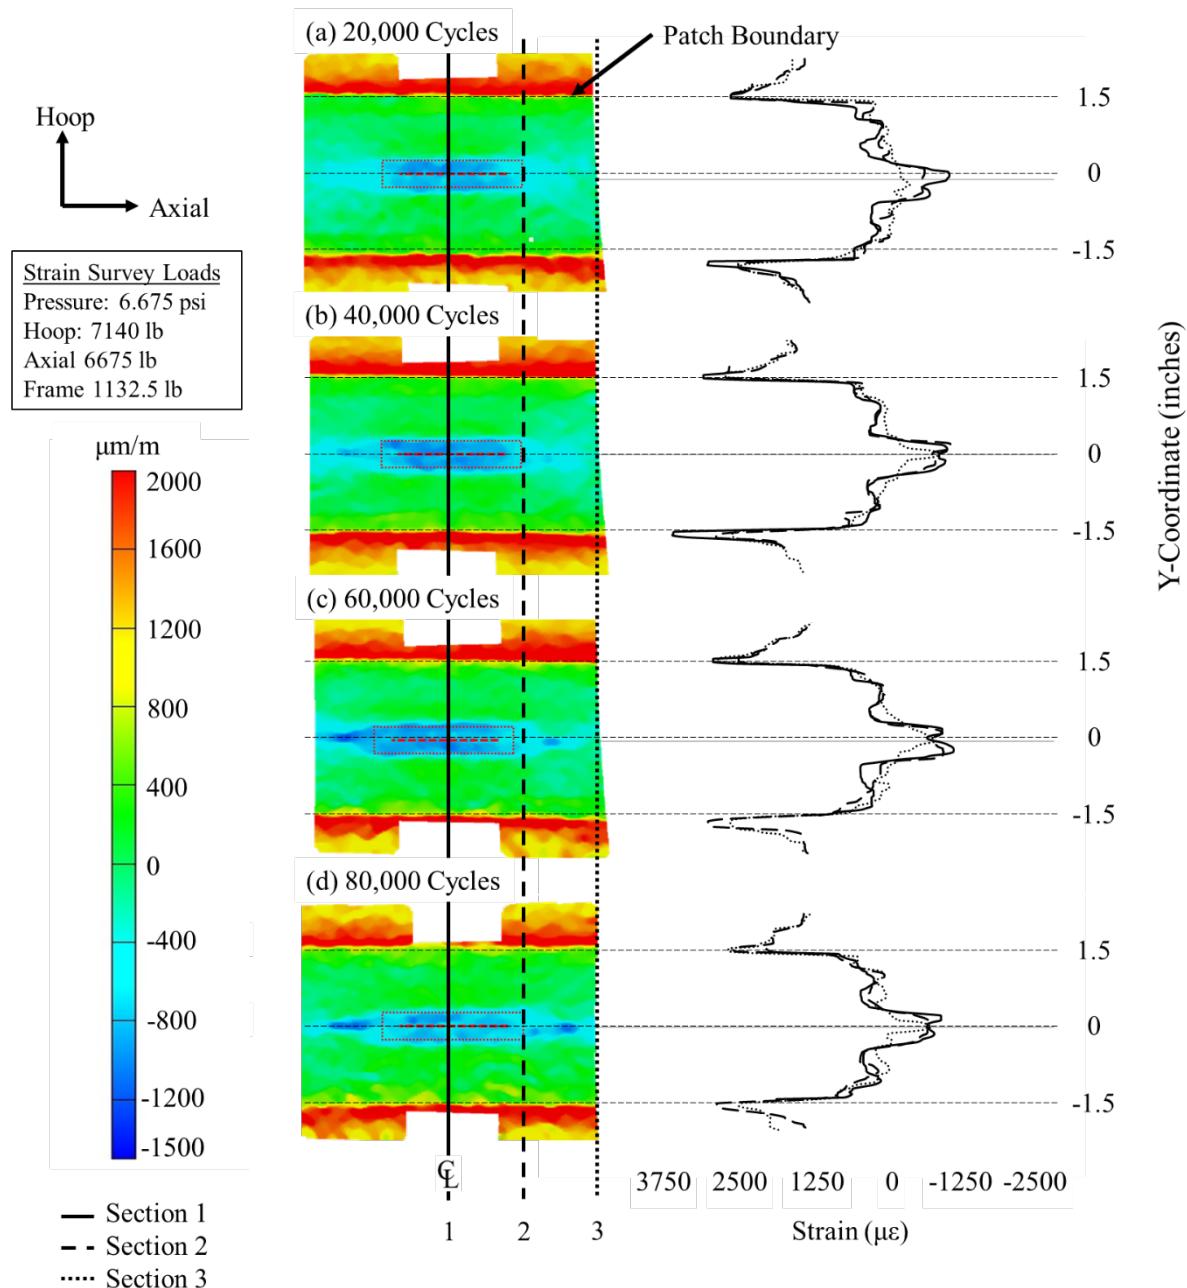

Figure H-5. The DIC results for the UDA repair at (a) 20,000, (b) 40,000, (c) 60,000, and (d) 80,000 cycles (Note: the data at 0 cycles was unavailable because of a damaged file)

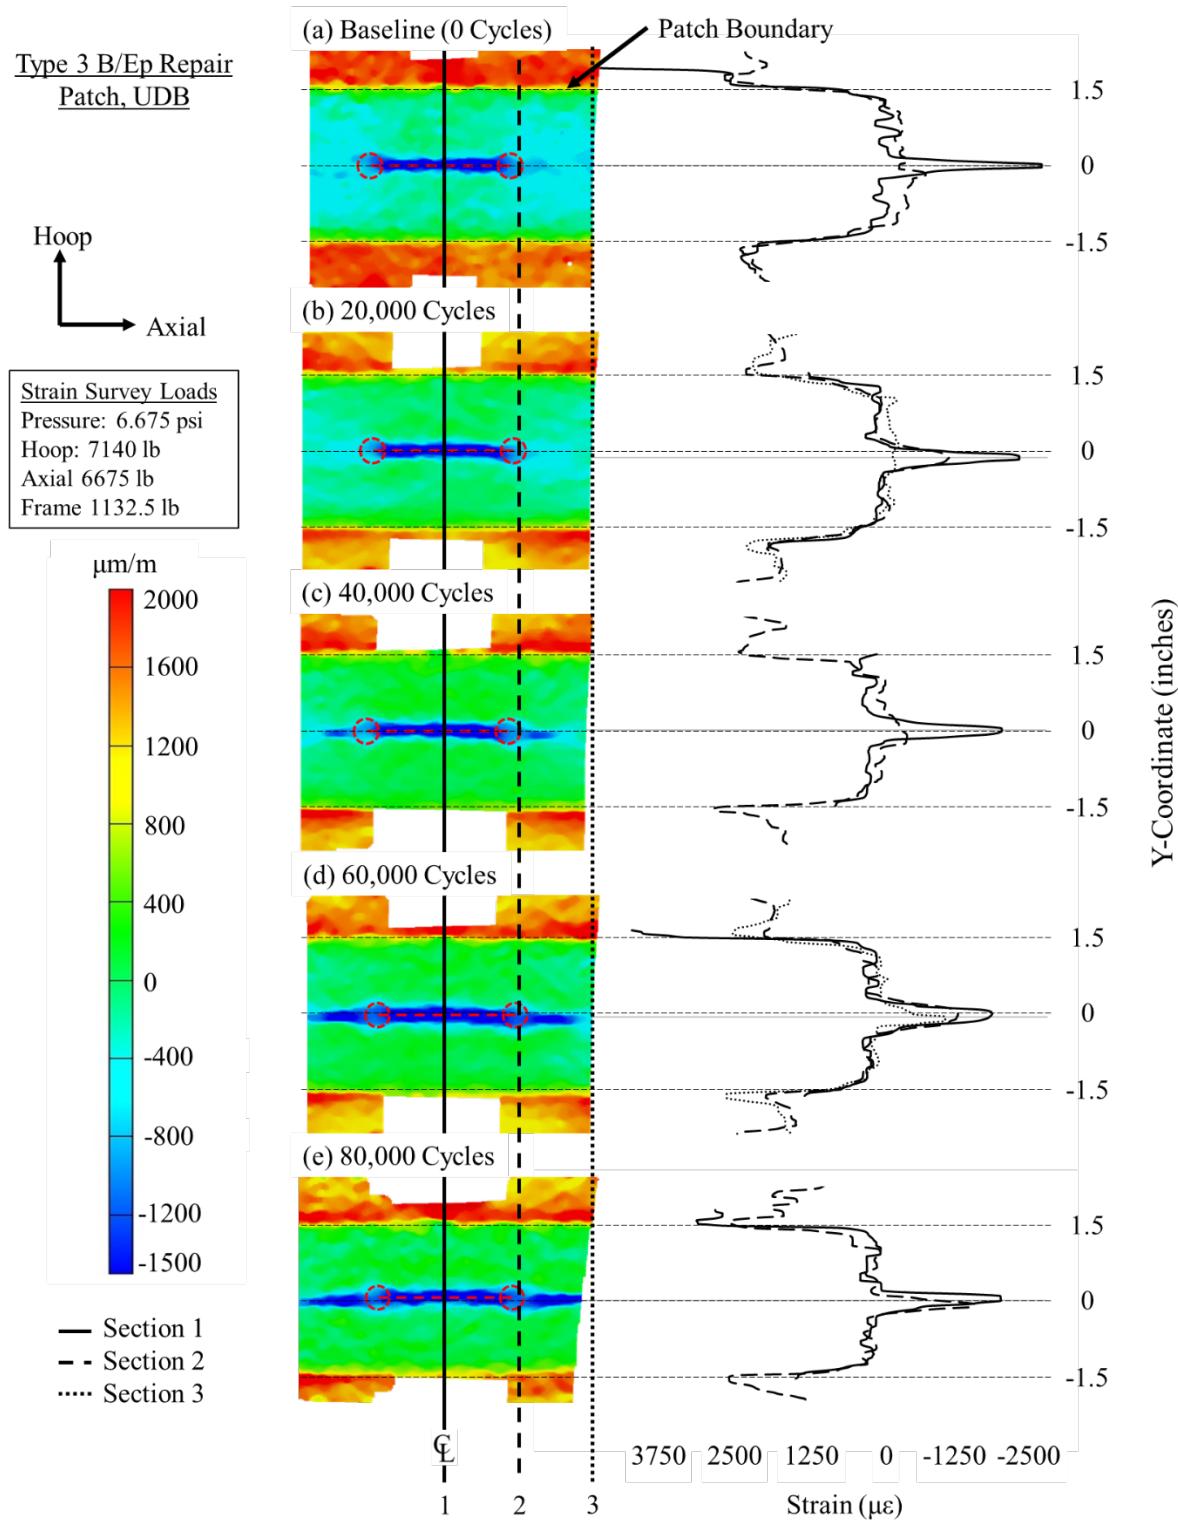

Figure H-6. The DIC results for the UDB repair at (a) 0, (b) 20,000, (c) 40,000, (d) 60,000, and (e) 80,000 cycles

Type 4 Aluminum
Repair Patch, HS

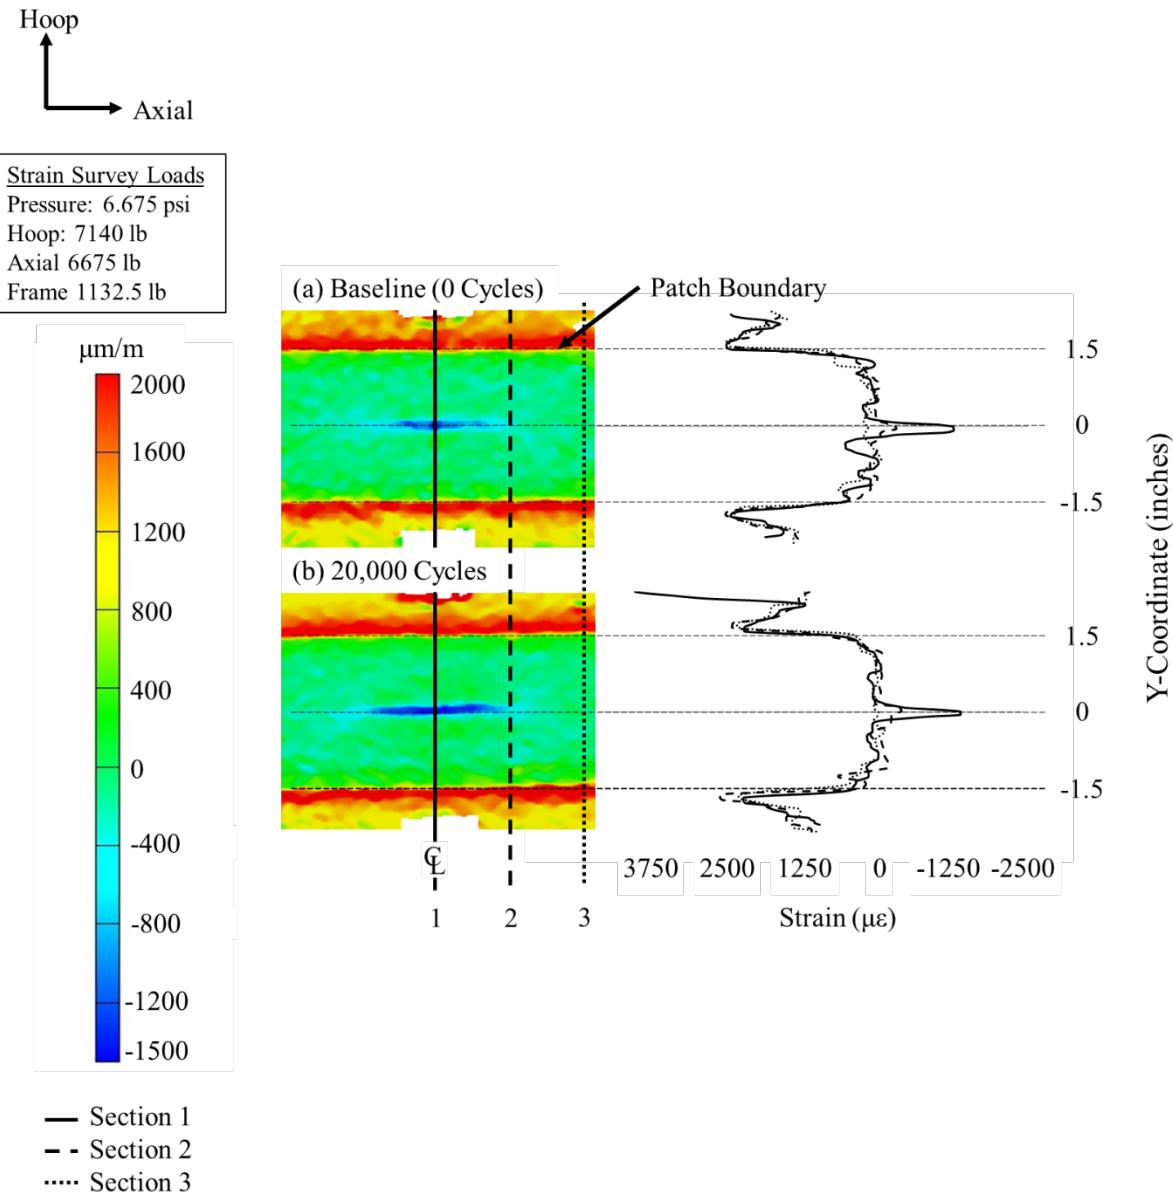

Figure H-7. The DIC results for the HS repair at (a) 0 and (b) 20,000 cycles

APPENDIX I—CRACK-GROWTH DATA

The initial notches introduced at various mid-bay locations of the panel were 2.8 inches in length ($2a = 2.8$ in). These notches were fatigue pre-sharpened using cyclic loads that were 75% of applied fatigue loads to extend the total crack length to approximately 3 inches. This appendix sums up the crack-growth data for all the notches during pre-cracking and during the fatigue tests after patch installations. The pre-cracking crack extension data were collected from the external surface of the panel using a remote-controlled crack monitoring system. During fatigue cycling, crack extension data were collected at intervals of 100, 200, or 500 cycles using the underwater camera system, which is reported as visual measurements in this appendix. The eddy current (EC) system was used every 5000 cycles to measure crack extension from the external surface of the patch and internal surface of the panel for composite repairs, and from the internal surface of the skin for the aluminum repairs. In this appendix, crack-growth data for all of the repairs during pre-cracking and fatigue tests are provided. These data are provided for forward (fwd) and aft half-crack lengths for pre-cracking, and for average half-crack length for fatigue stages.

In the figures representing pre-cracking crack-growth data, the closed and open circles represent visual measurements of the fwd and aft side of the notch, respectively. During fatigue, a solid line shows the visual measurements, the open circle shows the internal high-frequency EC results, and the open square shows the external low-frequency EC results.

REFERENCE REPAIRS

Reference aluminum and boron epoxy (B/Ep) repairs were subjected to hot-wet conditions to 80,000 cycles and to cold-dry conditions to 20,000 cycles.

REFERENCE ALUMINUM REPAIR (RA)

Table I-1 provides the half-crack length data of RA repair during pre-cracking. Figure I-1 shows the corresponding half-crack length as a function of fatigue cycles. Figure I-2 provides the half-crack length data during fatigue cycling. Figure I-3a shows the fwd and aft half-crack length, and figure I-3b shows averaged half-crack length as a function of fatigue cycles.

Figure I-2. Half-crack length data during fatigue for the RA repair (tabular)

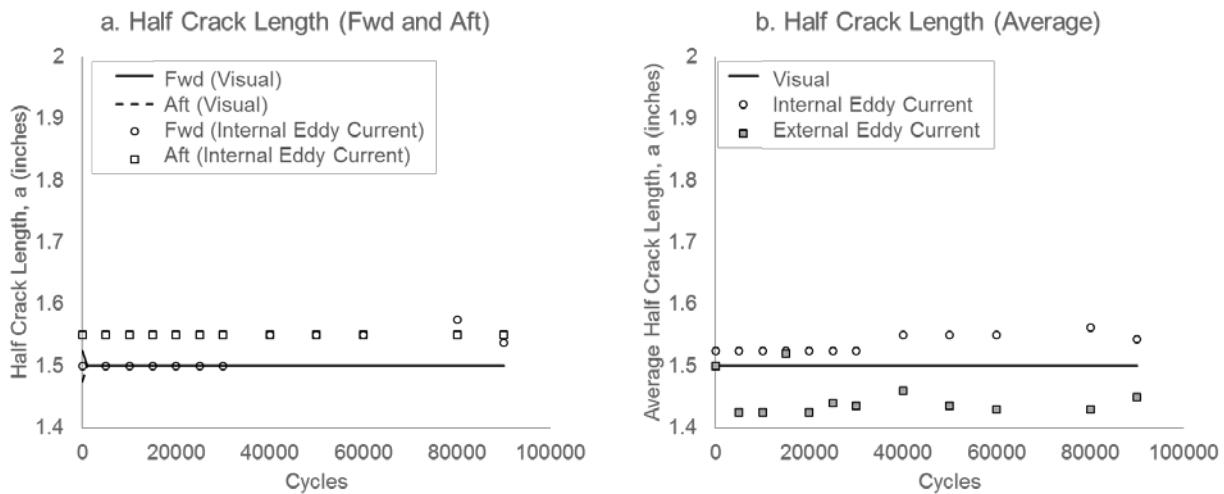

Figure I-3. The RA repair crack-growth data during fatigue (90,000 cycles): (a) forward and aft half-crack length and (b) average half-crack length

REFERENCE B/EP REPAIRS (RB)

Table I-2 provides the half-crack length data of RB repair during pre-cracking. Figure I-4 shows the corresponding half-crack length as a function of fatigue cycles. Figure I-5 provides the half-crack length data during fatigue cycling. Figure I-6a shows the fwd and aft half-crack length, and figure I-6b shows the averaged half-crack length as a function of fatigue cycles.

Figure I-5. Half-crack length data during fatigue for the RB repair (tabular)

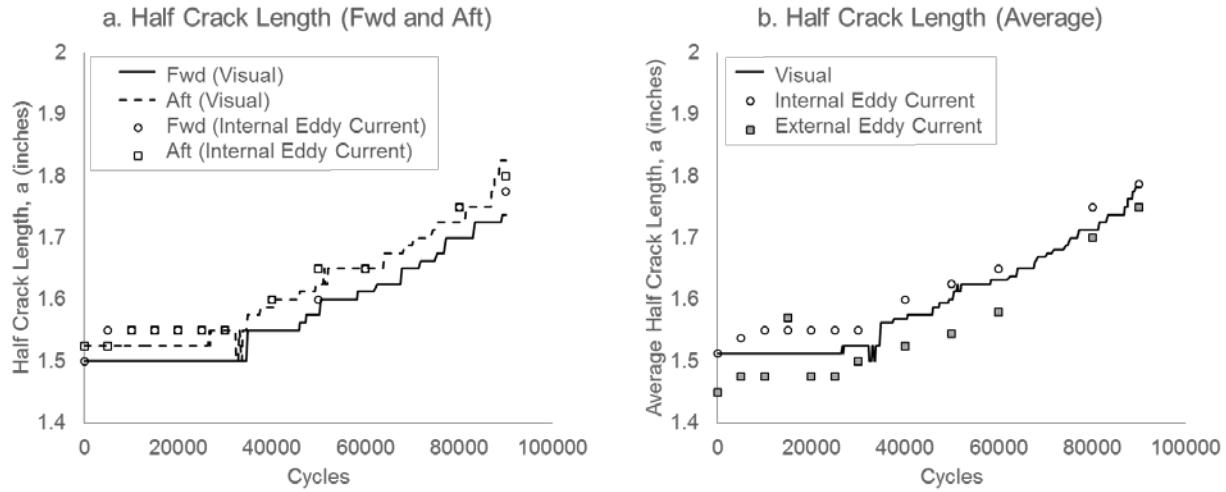

Figure I-6. The RB repair crack-growth data during fatigue (90,000 cycles): (a) forward and aft half-crack length and (b) average half-crack length

UNDER-DESIGNED REPAIRS

Under-designed aluminum and B/Ep repairs were subjected to hot-wet conditions to 80,000 cycles, and cold-dry conditions to 20,000 cycles.

UNDER-DESIGNED ALUMINUM REPAIRS (UA)

Table I-3 provides the half-crack length data of UA repair during pre-cracking. Figure I-7 shows the corresponding half-crack length as a function of fatigue cycles. Figure I-8 provides the half-crack length data during fatigue cycling. Figure I-9a shows the fwd and aft half-crack length, and figure I-9b shows averaged half-crack length as a function of fatigue cycles.

Table I-3. Half-crack length during pre-cracking for the UA repair (tabular)

Figure I-8. Half-crack length data during fatigue for the UA repair (tabular)

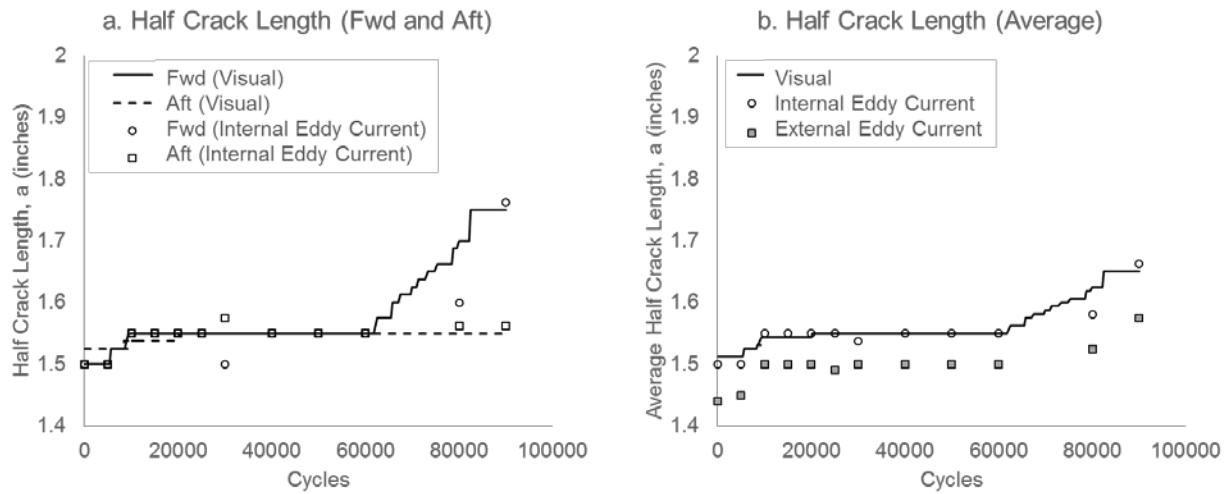

Figure I-9. The UA repair crack-growth data during fatigue (90,000 cycles): (a) forward and aft half-crack length and (b) average half-crack length

UNDER-DESIGNED B/EP REPAIRS (UB)

Table I-4 provides the half-crack length data of UB repair during pre-cracking. Figure I-10 shows the corresponding half-crack length as a function of fatigue cycles. Figure I-11 provides the half-crack length data during fatigue cycling. Figure I-12a shows the fwd and aft half-crack length, and figure I-12b shows averaged half-crack length as function of fatigue cycles.

Figure I-11. Half-crack length data during fatigue for the UB repair (tabular)

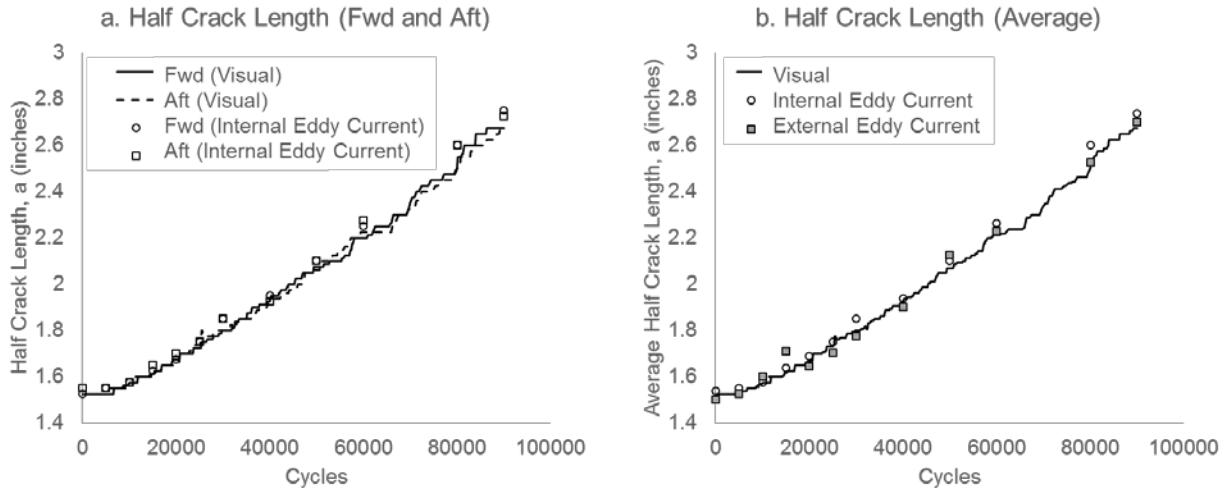

Figure I-12. The UB repair crack-growth data during fatigue (90,000 cycles): (a) forward and aft half-crack length and (b) average half-crack length

UNDER-DESIGNED DISBOND REPAIRS

Reference aluminum and B/Ep repairs were subjected to hot-wet conditions to a total of 80,000 cycles, and cold-dry conditions to a total 20,000 cycles.

UNDER-DESIGNED DISBOND ALUMINUM REPAIRS

Table I-5 provides the half-crack length data of under-designed disband aluminum (UDA) repair during pre-cracking. Figure I-13 shows the corresponding half-crack length as a function of fatigue cycles. Figure I-14 provides the half-crack length data during fatigue cycling. Figure I-15a shows the fwd and aft half-crack length, and figure I-15b shows averaged half-crack length as a function of fatigue cycles.

Figure I-14. Half-crack length data during fatigue for the UDA repair (tabular)

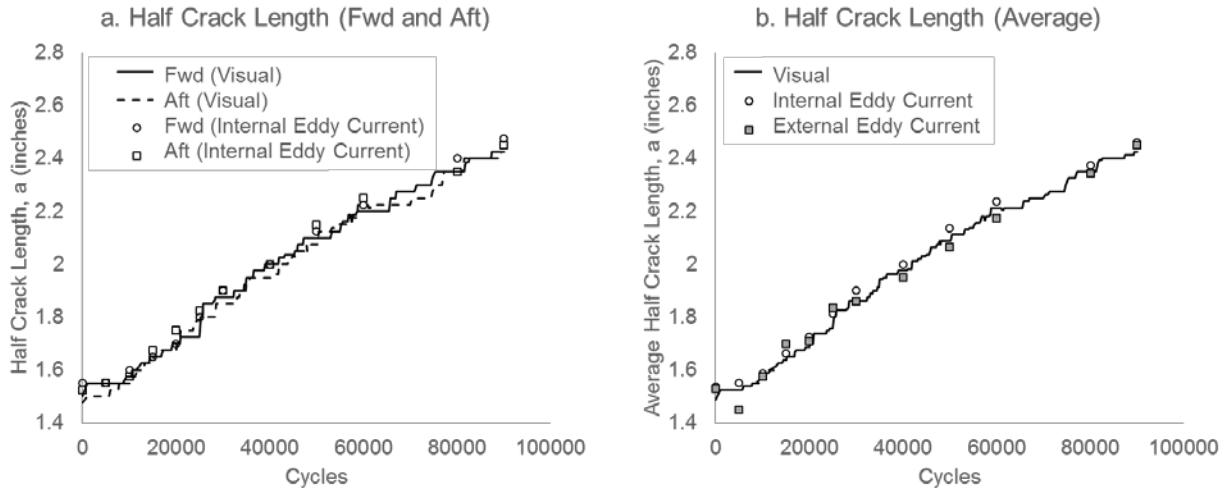

Figure I-15. The UDA repair crack-growth data during fatigue (90,000 cycles): (a) fwd and aft half-crack length and (b) average half-crack length

UNDER-DESIGNED DISBOND B/EP REPAIRS

Table I-6 provides the half-crack length data of under-designed disband (UDB) B/Ep repair during pre-cracking. Figure I-16 shows the corresponding half-crack length as a function of fatigue cycles. Figure I-17 provides the half-crack length data during fatigue cycling. Figure I-18a shows the fwd and aft half-crack length, and figure I-18b shows the averaged half-crack length as a function of fatigue cycles.

Figure I-17. Half-crack length data during fatigue for the UDB repair (tabular)

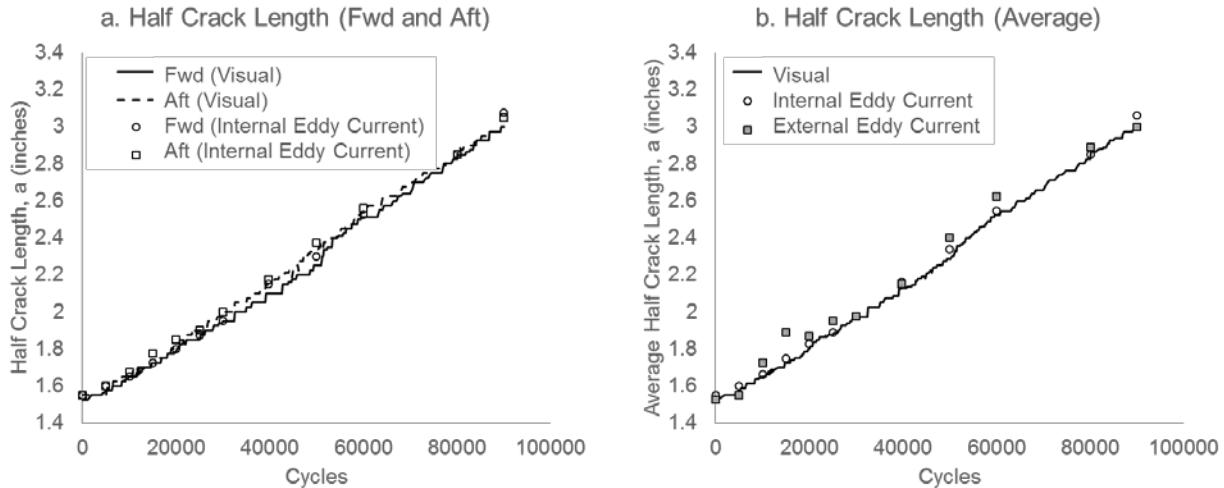

Figure I-18. The UDB repair crack-growth data during fatigue (90,000 cycles): (a) forward and aft half-crack length and (b) average half-crack length

HAND-SANDED REPAIRS

Hand-sanded (HS) aluminum repairs were subjected to hot-wet conditions to 20,000 cycles and cold-dry conditions to 20,000 cycles.

HS ALUMINUM REPAIRS

Table I-7 provides the half-crack length data of HS repair during pre-cracking. Figure I-19 shows the corresponding half-crack length as a function of fatigue cycles. Figure I-20 provides the half-crack length data during fatigue cycling. Figure I-21a shows the fwd and aft half-crack length, and figure I-21b shows averaged half-crack length as a function of fatigue cycles.

Table I-7. Half-crack length during pre-cracking for the HS repair (tabular)
