Wind energy has become an important new and rapidly growing source of renewable energy. However, many issues for efficient energy production and use of wind energy are unresolved. Wind resource assessment requires accurate profiles of both the wind speed and turbulence statistics to identify the most promising locations for efficient wind production with minimal damage to the turbines from high shear and turbulence. Optimal control of the turbine blades requires high quality wind information upstream of a wind farm or at each individual turbine. Accurate short-term forecasts of power production require accurate wind profiles at various distances upstream of the wind farm. Scanning coherent Doppler lidar is the most attractive instrument for high quality measurements of the wind fields for the conditions of interest for wind energy research. New results are presented from a field campaign at the National Wind Technology Center to evaluate coherent Doppler lidar for wind energy research. Lidar derived wind and turbulence estimates are compared with results from a nearby instrumented tower for various conditions.

"MAXIMUM LIKELIHOOD ESTIMATES OF VORTEX PARAMETERS FROM SIMULATED COHERENT DOPPLER LIDAR DATA"

Journal of Atmospheric and Oceanic Technology, Vol. 22, February 2005, pp. 117-130

The performance of pulsed coherent Doppler lidar in estimating aircraft trailing wake vortices by scanning across the aircraft flight track is evaluated using Monte Carlo lidar simulations of a simple vortex pair in both a nonturbulent and turbulent environment. The performance estimates are based on maximum likelihood estimates of aircraft wake vortex parameters and provide a measure of the ability of the lidar to detect and track wake vortices under the best possible conditions. Two aircraft types are considered: the Boeing 737 and the Boeing 747. Rigorous error analyses are produced by comparing the estimated parameters from numerical simulations of raw lidar data with the known input parameters of the simulation. It is shown that the probability density functions for the estimates are approximately Gaussian and the bias is very small. The main source of the bias was determined to be the movement of the vortex during the lidar scan. The estimation error is increased by the effects of a background turbulent velocity field. The trade-off between lidar pulse energy and pulse repetition frequency for the standard condition of constant laser power is also presented. It is shown that these maximum likelihood estimates provide accurate detection and tracking of the key vortex parameters for a simple vortex model, with and without background turbulence.

"PERFORMANCE OF A 2-MICRON COHERENT DOPPLER LIDAR FOR WIND MEASUREMENTS"

Journal of Atmospheric and Oceanic Technology, Vol. 11, December 1994, pp. 1517-1528.

Measurements of boundary layer winds are presented using a 2-micron coherent Doppler lidar and the optimal performance of the maximum likelihood estimator. The systematic error for single-shot

estimates was estimated as 3.6 cm/s using measurements from a stationary hard target. The estimation error for measurements of the radial component of the wind field was determined, as well as the fraction of the estimates that are randomly distributed over the velocity search space, when the signal power is low and speckle fading is important. The results from actual data are compared with the results from ideal simulations. The first direct estimation of the spatial structure function of the radial wind field and of the energy dissipation rate is presented for both horizontal and vertical directions of propagation. The rms estimation error of the velocity estimates is found to be within 30 percent of ideal performance based on simulation.

"MEASUREMENTS OF BOUNDARY LAYER PROFILES IN AN URBAN ENVIRONMENT"

Journal of Applied Meteorology and Climatology, Vol. 45, 2006, pp. 821-837.

Boundary layer profiles of mean temperature, velocity, and small-scale turbulence from in situ sensors, Doppler lidar, sodar, and rawinsondes are intercompared for an urban environment. A new Doppler lidar algorithm is presented to produce high-resolution profiles of small-scale velocity statistics. The lidar-derived profiles are robust and accurate even for challenging conditions such as stable boundary layers with a low-level jet, low turbulence, and low wind speed. Similar results are expected for other locations and convective conditions.

"PRELIMINARY TEST PLANS OF ATC CONCEPTS FOR LONGER TERM IMPROVEMENT -- HELICOPTER DEVELOPMENT PROGRAM"

FAA-RD-80-87, May 1980, Automation Industries, Inc., Silver Springs, MD

Test and simulation planning is documented for longer-term improvements in helicopter ATC concepts, which are classified into the following categories: (1) Offshore Route Structure in the Gulf of Mexico, (2) Secondary Radar, (3) Analysis of Navigation Errors in the Gulf, (4) Offshore Surveillance and Communications to 300 NM Range, (5) Real-Time Reporting of Aircraft-Derived Position, (6) VHF Communications Study in the CONUS, (7) ATC Implications of Alternate Airports for Helicopters, and (8) Wake Vortex Separation.

"POTENTIAL BENEFITS OF A TIME-BASED SEPARATION PROCEDURE TO MAINTAIN THE ARRIVAL CAPACITY OF AN AIRPORT IN STRONG HEAD-WIND CONDITIONS"

Fifth EUROCONTROL/FAA ATM R&D Seminar, June 2003, Budapest, Hungary

This paper describes a different approach to separating aircraft during the final approach phase. It is based on the fact that, under strong head-wind conditions (>15kt.), the ground speed of the aircraft is

reduced and so there is a loss of runway capacity. Because of this, each aircraft needs more time to fly a given separation distance at the runway threshold. Under headwind conditions, the actual distance-based separation procedure may thus be not fully satisfactory. Moreover, according to current characterization studies of wake vortices, which are the main hazards limiting capacity, the actual distance separation thresholds have been proved to be too conservative under strong wind conditions. We thus propose to replace the actual distance-based separations by time-based separations. Without reducing safety, such a process could maintain and increase runway capacity in a shorter term than the wake vortex advisory systems that will require more technology before they can be implemented. Let us note that both tools should be used anyway to get optimal and safe separations in the future.

Freythum, P.

"THREE-DIMENSIONAL VORTEX SYSTEMS OF FINITE WINGS"

Journal of Aircraft, Vol. 25, No. 10, October 1988, pp. 971-972

The vortex strands of a finite three-dimensional vortex system must be connected in accordance with Helmholtz's law. It is shown that flow visualization documents the connecting and reconnecting of the strands.

Freythum, P., Finaish, F. and Bank, W.

"VISUALIZATION OF WING TIP VORTICES IN ACCELERATING AND STEADY FLOW"

Journal of Aircraft, Vol. 23, No. 9, September 1986, pp. 730-733

A streakline method was used to visualize complex two- and three-dimensional vortical structures over an airfoil. The method was extended to visualize wing tip vortices in unsteady and steady flows.

Fridman, J. D.

"AIRBORNE WAKE VORTEX DETECTION"

FAA-RD-74-46, March 1974, Raytheon Company, Sudbury, MA

Active and passive remote sensing systems were assessed to determine the feasibility of detecting aircraft trailing vortices using instrumentation on-board an aircraft. It was found that a modification of the front-end receiver of a 10 GHz weather radar system or a change of frequency to 35 GHz may allow vortex identification over a range of several kilometers. The CO₂ laser coherent Doppler radar technique and passive radiometric techniques (8-14 microns) show considerable promise. Other airborne systems (incoherent Lidar, Raman shift techniques, fluorescence scattering, acoustic radar, ultraviolet emissions) were shown not to possess sufficient sensitivity.

Fridman, J. D. and Hallock, J. N.

"AIRBORNE WAKE VORTEX DETECTION"

Proceedings of the Sixth Conference on Aerospace and Aeronautical Meteorology, American Meteorological Society, 1974, pp. 399-404.

Active and passive remote sensing systems have been assessed to determine the feasibility of detecting aircraft trailing vortices using instrumentation on-board an aircraft. A front-end modified millimetric wave weather radar may allow vortex identification over a range of several kilometers for a sufficiently large target cross-section. A 10.6-micron coherent Doppler optical radar detects the presence of a trailing vortex over a range of several miles. A passive radiometric technique in the 8-14 micron range also shows considerable promise.

"EVALUATION OF THE FLOW DISTORTION AROUND THE CAMPBELL SCIENTIFIC CSAT3 SONIC ANEMOMETER RELATIVE TO INCIDENT WIND DIRECTION"

Journal of Atmospheric and Oceanic Technology, Vol. 26, March 2009, pp. 582-592.

In June 2002, a high-frequency air-sea momentum system was deployed in the surf zone for 3 days as part of an experiment to quantify air-sea momentum transfer when the wind and wave direction were at angles. The system obtained measurements in the nearshore via a high-resolution Campbell Scientific CSAT3 3D sonic anemometer and five high-frequency saltwater wave staffs. An advantage of the air-sea momentum system is that direct measurements of the atmospheric turbulent fluctuations can be obtained and applied to the calculation of momentum transfer at the air-sea interface. The Campbell Scientific CSAT3 sonic anemometer was post-calibrated under turbulent wind conditions to determine incident wind direction measurements influenced by the geometry of the instrument. Measurement results are compared to a pre-established benchmark, constant tow speed, and the mean wind speed, incident wind direction, and spectral density characteristics are evaluated to resolve specific instrument orientations in which the measurements are corrupted by the head and probe supports of the sonic anemometer.

Friedlander, S.

"ON VORTEX TUBE STRETCHING AND INSTABILITIES IN AN INVISCID FLUID"

Journal of Mathematical Fluid Mechanics, Vol. 4, No. 1, February 2002, pp. 30-40

We study instabilities that are present in two models that retain some of the dynamics of vortex tube stretching in the motion of a fluid in 3 dimensions. Both models are governed by a 2-dimensional PDE and are hence more tractable than the full 3-dimensional Euler equations. The first model is the so-called surface quasi-geostrophic equation. The second model is a class of 3-dimensional flows that are invariant with respect to one spatial coordinate. Both models appear in the context of a rapidly rotating fluid. Instabilities due to an effect analogous to vortex tube stretching are detected: these

instabilities are in the linearized equations in the first model and in the nonlinear equations in the second model. Such instabilities are absent, or weaker, in strictly 2-dimensional fluid motion.

"STABILITY AND TUBULENCE IN THE ATMOSPHERIC BOUNDARY LAYER: A COMPARISON OF REMOTE SENSING AND TOWER OBSERVATIONS"

Geophysical Research Letters, Vol. 39, 2012, pp. L03801-L03801-6.

When monitoring winds and atmospheric stability for wind energy applications, remote sensing instruments present some advantages to in-situ instrumentation such as larger vertical extent, in some cases easy installation and maintenance, measurements of vertical humidity profiles throughout the boundary layer, and no restrictions on prevailing wind direction. In this study, we compare remote sensing devices, Windcube lidar and microwave radiometer, to meteorological in-situ tower measurements to demonstrate the accuracy of these measurements and to assess the utility of the remote sensing instruments in overcoming tower limitations. We compare temperature and wind observations, as well as calculations of Brunt-Vaisala frequency and Richardson numbers for the instrument deployment period in May-June 2011 at the U.S. Department of Energy National Renewable Energy Laboratory's National Wind Technology Center near Boulder, Colorado. The study reveals that a lidar and radiometer measure wind and temperature with the same accuracy as tower instruments, while also providing advantages for monitoring stability and turbulence. We demonstrate that the atmospheric stability is determined more accurately when the liquid-water mixing ratio derived from the vertical humidity profile is considered under moist-adiabatic conditions.

Frink Jr., W. D.

"HOT-WIRE SURVEYS IN THE VORTEX WAKE DOWNSTREAM OF A THREE-PERCENT FIGHTER AIRCRAFT MODEL AT HIGH ANGLES OF ATTACK"

MS Thesis, Dec. 1990, Naval Postgraduate School, Monterey, CA.

A low-speed wind tunnel investigation was conducted to examine the vortex wake downstream of a three-percent scale model of the YF-17 lightweight fighter prototype at high angles of attack. The study was in support of NASA Ames Research Center's High Alpha Technology Program. Smoke flow visualization was used to locate the downstream vortex wake. Hot-wire surveys were taken through the vortex at two stations; one directly aft of the model and the other at a station three model lengths downstream of the model. The effect of adding a fence to the leading-edge extension was studied. Power spectra from the hot-wire were recorded for the survey station directly aft of the model. Results show that peak turbulent fluctuation at this station occurred at 25 degrees angle of attack, lateral turbulent fluctuation greatly diminished at the far downstream station, and the addition of the leading-edge extension fence shifted energy content of turbulence toward higher frequencies.

Friso, H. F., Richard, C., Visser, H. G., Vincent, T. and Bruno, D.

"PREDICTING ABNORMAL RUNWAY OCCUPANCY TIMES AND OBSERVING RELATED PRECURSORS"

Journal of Aerospace Information Systems, Vol. 15, No. 1, January 2018, pp. 10-21.

Accidents on the runway triggered the development and implementation of mitigation strategies. Therefore, the airline industry is moving toward proactive risk management, which also aims to identify and predict risk precursors and to mitigate risks before accidents occur. For certain predictions machine learning techniques can be used. Although many studies have explored and applied novel machine learning techniques on different radar and A-SMGCS data, the identification and prediction of abnormal runway occupancy times and the observation of related precursors are not well developed. In our previous papers, three existing methods were introduced, lasso, multi-layer perception, and neural networks, to predict the taxi-out time on the taxiway and the time to fly and true airspeed profile on final approach. This paper presents a new machine learning method where the existing machine learning techniques are combined for predicting the abnormal runway occupancy times of unique radar data patterns. Additionally, the regression tree method is used in this study to observe the key related precursors extracted from the top 10 features. Compared with existing methods, the new method no longer requires predefined criteria or domain knowledge. Tests were conducted using final approach radar data and A-SMGCS runway data consisting of 78,321 flights at Paris Charles de Gaulle airport and were benchmarked against 500,000 flights at Vienna airport.

"THE USE OF CIRCULATION CONTROL FOR FLIGHT CONTROL"

Circulation Control Workshop, Hampton, VA, March 2004, pp. 657-674

An experimental investigation into the application of circulation control on a 50-degree swept delta wing has been performed in a closed return wind tunnel at 25 m/s. This was then extended to a sting-mounted circulation control demonstrator with two control surfaces, in order to determine whether the technique could be used for roll control whilst maintaining high lift coefficient within the limits of pitch trim. A lift augmentation of approximately 20 was achieved with all configurations. Roll of the aircraft was possible with differential blowing of the circulation control systems.

"OBJECT-ORIENTED UNSTEADY VORTEX LATTICE METHOD FOR FLAPPING FLIGHT"

Journal of Aircraft, Vol. 41, No. 6, November-December 2004, pp. 1275-1290.

The unsteady vortex lattice method is used to model the oscillating plunging, pitching, twisting, and flapping motions of a finite-aspect-ratio wing. Its potential applications include design and analysis of small unmanned air vehicles and in the study of the high-frequency flapping flight of birds and other small flyers. The results are verified by theory and, in the plunging and pitching cases, by experimental data. The model includes free-wake relaxation, vortex stretching, and vortex dissipation effects and is

implemented using object-oriented computing techniques. The results show that the method is capable of accurately simulating many of the features of complex flapping flight.

"NUMERICAL INVESTIGATIONS OF THE COMPRESSIBLE FLOW AND THE ENERGY SEPARATION IN THE RANQUE-HILSCH VORTEX TUBE"

International Journal of Heat and Mass Transfer, Vol. 42, 1999, pp. 415-422.

In the Ranque-Hilsch vortex tube a compressible fluid (e.g., air) experiences an expansion process leading to separation into a cold and hot gas stream. The compressible flow and energy separation phenomena are simulated numerically by using the code system CFX. In order to calculate successfully the energy separation, the numerical model had to be extended by integrating relevant terms for the shear-stress-induced mechanical work. An axisymmetric model was developed, allowing a successful post-calculation of experimental results.

"OPTIMIZING MOTION CUEING FOR RESEARCH FLIGHT SIMULATION"

1st CEAS European Air and Space Conference, Berlin, Germany, CEAS-2007-330, September 2007, pp. 1305-1313

Research flight simulation conducted with the A330/340 Full-Flight Simulator located at Technical University Berlin exceeds the typical flight envelope of airline pilot training. For such simulator studies a motion cueing algorithm optimized for the research task should provide improved motion reproduction. As one of the potential applications the specific motion system requirements of wake vortex encounter simulation are analyzed. An optimized setting of the motion cueing algorithm is derived and implemented into the simulator motion system. To conclude, results of a piloted test campaign are presented, in which the effect of simulator motion on perceived severity of wake vortex encounters and pilot reaction were studied by comparing results for a motion cueing setup as used for pilot training, a setup optimized for wake vortex encounter simulation and wake encounters conducted without simulator motion.

Fuentes, O. U. V.

"ON THE TOPOLOGY OF VORTEX LINES AND TUBES"

J. Fluid Mechanics, Vol. 584, 2007, pp. 147-156.

This paper examines the widespread idea that vortex lines and tubes must either close on themselves or extend to the boundary of the fluid. A survey of the origins of this misconception, and of earlier attempts to set it right, is followed by an analysis of simple flows exhibiting vortex lines and tubes which do not fit those shapes. Two types of vortex lines are discussed: dense, which comprise open

lines of infinite length but confined in a finite region, and separatrix, which comprise lines that begin or finish within the fluid, at points where the vorticity is null. The presence of these vortex lines in a vortex tube affects its topology in the following ways: Vortex tubes formed by dense vortex lines have infinite length; they self-intersect an infinite number of times but do not close on themselves. Vortex tubes formed by separatrix vortex lines (and either closed or open vortex lines) are torn apart at the points where the vorticity is null. Vortex tubes exclusively composed of separatrix vortex lines begin or finish at points or surfaces within the fluid; in this particular situation, the vortex tube has zero strength.

Fuentes, O. V. and Arteaga, A. R.

"QUASI-STEADY LINKED VORTICES WITH CHAOTIC STREAMLINES"

Journal of Fluid Mechanics, Vol. 687, 2011, pp. 571-583.

This paper describes the motion and the flow geometry of two or more linked ring vortices in an otherwise quiescent, ideal fluid. The vortices are thin tubes of near-circular shape which lie on the surface of an immaterial torus of small aspect ratio. Since the vortices are assumed to be identical and evenly distributed on any meridional section of the torus, the flow evolution depends only on the number of vortices (n) and the torus aspect ratio (r_1/r_0 , where r_0 is the centerline radius and r_1 is the cross-section radius). Numerical simulations based on the Biot-Savart law showed that a small number of vortices ($n = 2, 3$) coiled on a thin torus (r_1/r_0 less than or equal to 0.16) progressed along and rotated around the symmetry axis of the torus in an almost uniform manner while each vortex approximately preserved its shape. In the comoving frame the velocity field always possesses two stagnation points. The transverse intersection, along $2n$ streamlines, of the stream tube emanating from the front stagnation point and the stream tube ending at the rear stagnation point creates a three-dimensional chaotic tangle. It was found that the volume of the chaotic region increases with increasing torus aspect ratio and decreasing number of vortices.

Fuhrmann, H. D. and Stewart, E. C.

"AN EVALUATION OF THE MEASUREMENT REQUIREMENTS FOR AN IN-SITU WAKE VORTEX DETECTION SYSTEM"

NASA TM-110218, May 1996, Langley Research Center, Hampton, VA

Results of a numerical simulation are presented to determine the feasibility of estimating the location and strength of a wake vortex from imperfect in-situ measurements. These estimates could be used to provide information to a pilot on how to avoid a hazardous wake vortex encounter. An iterative algorithm based on the method of secants was used to solve the four simultaneous equations describing the two-dimensional flow field around a pair of parallel counter-rotating vortices of equal and constant strength. The flow field information used by the algorithm could be derived from measurements from the flow angle sensors mounted on the wing tips of the detecting aircraft and an inertial navigation system. The study determined the propagated errors in the estimated location and

strength of the vortex which resulted from random errors added to theoretically perfect measurements. The results are summarized in a series of charts and a table which make it possible to estimate these propagated errors for many practical situations. The situations include several generator-detector-airplane combinations, different distances between the vortex and the detector airplane, as well as different levels of total measurement error.

"AN EXPERIMENTAL STUDY ON VORTEX BREAKDOWN IN A DIFFERENTIALLY-ROTATING CYLINDRICAL CONTAINER"

Experiments in Fluids, Vol. 36, 2004, pp. 399-407

The vortex breakdown phenomenon in a closed cylindrical container with a rotating end-wall disk was reproduced. Visualizations were performed to capture the prominent flow characteristics. The locations of the stagnation points of breakdown bubbles and the attendant global flow features were in excellent agreement with the preceding observations. Experiments were also carried out in a differentially-rotating cylindrical container in which the top end-wall rotates at a relatively high angular velocity and the bottom end-wall and the sidewall rotate at a low angular velocity. For a fixed cylinder aspect ratio, and for a given relative rotational Reynolds number based on the angular velocity difference the flow behavior is examined as the Reynolds number increases. For a co-rotation, the breakdown bubble is located closer to the bottom end-wall disk. However, for a counter-rotation, the bubble is seen closer to the top end-wall disk. For sufficiently large values the bubble ceases to exist for both cases.

Fukumoto, Y.

"THE THREE-DIMENSIONAL INSTABILITY OF A STRAINED VORTEX TUBE REVISITED"

J. Fluid Mech., Vol. 493, 2003, pp. 287-318.

We revisit the Moore-Saffman-Tsai-Widnall instability, a parametric resonance between left- and right-handed bending waves of infinitesimal amplitude, on the Rankine vortex strained by a weak pure shear flow. The results of Tsai and Widnall (1976) and Eloy and Le Dizès (2001), as generalized to all pairs of Kelvin waves whose azimuthal wavenumbers m are separated by 2, are simplified by providing an explicit solution of the linearized Euler equations for the disturbance flow field. Given the wavenumber k and the frequency ω of an intersection point of dispersion curves, the growth rate is expressible solely in terms of the modified Bessel functions, and so is the unstable wavenumber range. Every intersection leads to instability. Most of the intersections correspond to weak instability that vanishes in the short-wave limit, and dominant modes are restricted to particular intersections. For helical waves $m = \pm 1$, the growth rate of non-rotating waves is far larger than that of rotating waves. The wavenumber width of stationary instability bands broadens linearly in k , while that of rotating instability bands is bounded. The growth rate of the stationary instability takes, in the long-wavelength limit, the value of $E/2$ for the two-dimensional displacement instability, and, in the short-

wavelength limit, the value of $9E/16$ for the elliptical instability, being larger at large but finite values of k . Here E is the strength of shear near the core center. For resonance between higher azimuthal wavenumbers m and $m + 2$, the same limiting value is approached as k goes to infinity, along sequences of specific crossing points whose frequency rapidly converges to $m + 1$. This happens in two ways, from above for a fixed m and from below for m going to infinity. The energy of the Kelvin waves is calculated by invoking Cairns' formula. The instability result is compatible with Krein's theory for Hamiltonian spectra.

Fukumoto, Y. and Hattori, Y.

"CURVATURE INSTABILITY OF A VORTEX RING"

J. Fluid Mech., Vol. 526, 2005, pp. 77-115

A global stability analysis of Kelvin's vortex ring to three-dimensional disturbances of infinitesimal amplitude is made. The basic state is a steady asymptotic solution of the Euler equations, in powers of the ratio r of the core radius to the ring radius, for an axisymmetric vortex ring with vorticity proportional to the distance from the symmetric axis. The effect of ring curvature appears at first order, in the form of a dipole field, and a local straining field, which is a quadrupole field, follows at second order. The eigenvalue problem of the Euler equations, retaining the terms to first order, is solved in closed form, in terms of the Bessel and the modified Bessel functions. We show that the dipole field causes a parametric resonance instability between a pair of Kelvin waves whose azimuthal wavenumbers are separated by 1. The most unstable mode occurs in the short-wavelength limit, under the constraint that the radial and the azimuthal wavenumbers are of the same magnitude, and the limiting value of maximum growth rate coincides with the value $165/256r$ obtained by Hattori and Fukumoto (Phys. Fluids, vol. 15, 2003, p. 3151) by means of the geometric optics method. The instability mechanism is traced to stretching of disturbance vorticity in the toroidal direction. In the absence of viscosity, the dipole effect outweighs the straining field effect known as the Moore-Saffman-Tsai-Widnall instability. The viscosity acts to damp the former preferentially and these effects compete with each other.

Fukumoto, Y. and Hattori, Y.

"LINEAR AND NONLINEAR INSTABILITY OF A VORTEX RING"

In IUTAM Symposium on Elementary Vortices and Coherent Structures: Significance in Turbulence Dynamics, edited by S. Kida, Springer, The Netherlands, 2006, pp. 283-294.

A new linear instability mechanism of curvature origin is established for a vortex ring. The curvature effect reduces $O(2) \times SO(2)$ symmetry of a circular-cylindrical tube to $O(2)$, and fuels a pair of Kelvin waves whose azimuthal wavenumbers on the core are separated by one. For Kelvin's vortex ring, the growth rate and eigenfunctions are written out in closed form. In the inviscid case, the curvature effect dominates over the elliptically straining effect, but the former suffers from enhanced viscous damping. There are numerous excitable modes. As a first step toward an understanding of the route to a

matured stage, we derive equations for weakly nonlinear evolution of amplitudes of the curvature instability. One direct numerical simulation successfully captures the elliptical instability.

Fukumoto, Y. and Moffatt, H. K.

"MOTION OF A THIN VORTEX RING IN A VISCOUS FLUID: HIGHER-ORDER ASYMPTOTICS"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

The motion of an axisymmetric vortex ring of small cross-section in a viscous incompressible fluid is investigated using a large-Reynolds-number asymptotic theory. Tung and Ting and Saffman considered the effect of decaying core vorticity due to the action of viscosity. The vortex ring induces a local straining field on itself which deforms the core into an ellipse. The purpose of the present investigation is to elucidate the structure of strained core and its influence on the translation speed.

Fukumoto, Y. and Okulov, V. L.

"THE VELOCITY FIELD INDUCED BY A HELICAL VORTEX TUBE"

Physics of Fluids, Vol. 17, 2005, 107101-1 to 107101-19

The influence of finite-core thickness on the velocity field around a vortex tube is addressed. An asymptotic expansion of the Biot-Savart law is made to a higher order in a small parameter, the ratio of core radius to curvature radius, which consists of the velocity field due to lines of monopoles and dipoles arranged on the centerline of the tube. The former is associated with an infinitely thin core and is featured by the circulation alone. The distribution of vorticity in the core reflects on the strength of dipole. This result is applied to a helical vortex tube, and the induced velocity due to a helical filament of the dipoles is obtained in the form of the Kapteyn series, which augments Hardin's [Phys. Fluids 25, 1949 (1982)] solution for the monopoles. Using a singularity-separation technique, a substantial part of the series is represented in a closed form for both the mono- and the dipoles. It is found from numerical calculation that the smaller the helix pitch is, the larger the relative influence of the dipoles is as the cylinder wound by the helix is approached.

Fuller, C. E.

"A STUDY OF TURBULENCE MEASUREMENTS USING LASER DOPPLER SYSTEM"

NASA CR-119804, June 1971, Remtech Inc., Birmingham, AL

The object of the wing tip vortex test is to demonstrate the extent with which the Laser Doppler Velocimeter system can be used for the measurement of gas velocities with high spatial and temporal resolution. This test was planned to provide three-dimensional mean velocity data of the vortex pattern shed from a wing tip at an angle of attack. These measurements are being conducted at the MSFC 7inch x 7inch wind tunnel facility. The test plan and procedure as well as the measurements that

were made are included. In addition, data on several measurements of the system's operating parameters which are important to these tests are also given.

Fuller, C. E.

"WING TIP DOPPLER MEASUREMENTS WITH LASER DOPPLER SYSTEMS"

RTR-002-3, April 1973, Remtech Inc., Huntsville, AL

The vortex velocity field produced by a rectangular wing in a subsonic wind tunnel was measured using two laser Doppler velocimeter systems. One system made three-dimensional mean velocity measurements and the other made one-dimensional turbulence measurements. The systems and test procedures are described and the measurements are presented and comparisons made. The data defined a strong spiral motion in the vortex- formation process.

Funk, B. H. and Johnston, K. D.

"LASER NET - A SYSTEM FOR MONITORING WINGTIP VORTICES ON RUNWAYS"

NASA TM X-64525, June 1970, NASA Marshall Space Flight Center, Huntsville, AL

A laser schlieren method is proposed which potentially provides a means for monitoring the strength of vortex wakes on and near runways. The method could provide a gross, continuous assessment of the intensity of disturbances over airport runways and aircraft carriers. Preliminary measurements behind a wingtip mounted on the wall of a small subsonic wind tunnel indicate that wingtip vortices are readily detectable with this simple system.

Funk, R. B. and Komerath, N. M.

"ROTOR WAKE INTERACTION WITH A LIFTING SURFACE"

51st Annual Forum of the American Helicopter Society, May 1995, Ft. Worth, TX.

Vortex interaction with wings and control surfaces causes unsteady, three-dimensional flow separation phenomena which are only beginning to be understood. An NACA0021 wing interacting with the wake from a 2-bladed teetering rotor is used as a basic experimental configuration to study such phenomena. Video images of surface tufts and smoke in pulsed light sheets, laser velocimetry and surface pressure sensors are used to capture the primary features of the interaction. The interaction is found to be periodic except during the impingement of the vortices on the surface. Strong once-per-revolution pressure fluctuations are shown to result from the divergence of vortex trajectories, enhanced by surface interaction. Flow reversal is found upstream and under regions of vortex interaction on the wing upper surface, and massive steady separation is found on the lower surface. Vortex core flow stagnation on the surface under the advancing blade side appears to cause an apparent 'diffusion' of vorticity seen in vorticity contours constructed from velocity data. Strong, quasi-steady spanwise flow is caused downstream of vortex interaction. The separation line moves rapidly

over the surface. Integrated section pressure distributions are dominated by the blade passage signature, periodic at the blade frequency.

Funk, R. B., Fawcett, P. A. and Komerath, N. M.

"SCV MEASUREMENTS IN THE WAKE OF A ROTOR IN HOVER AND FORWARD FLIGHT"

AIAA Paper 93-3080, July 1993, Orlando, FL.

Progress in the capability to measure instantaneous velocity fields in complex flows and over large areas is discussed. The rotor wake is a complex flow field containing a wide range of velocity scales that exhibit a periodic variation with rotor azimuth. The measurement of instantaneous planar velocity fields over large areas in such flows is demonstrated using Spatial Correlation Velocimetry. A dual video camera system is used to obtain images over short intervals, with velocities computed using a fully numerical procedure. Results are presented for twelve azimuth positions in the wake of a 2-bladed teetering rotor of 0.457 m radius, at 1050 rpm in low-speed forward flight, with smoke in the flow illuminated using a pulsed laser sheet. Detection of a roll-up under the rotor hub is discussed. A second area of application is shown in the measurement of turbulence statistics in recirculating flows over large areas. The recirculating flow in a 4.88 m rotor hover test facility is measured piecewise. Ensemble-averaging of local mean and root-mean-square velocity components is presented, with incoherent light sheets created from quartz lamps. Problems encountered and possible solutions are also discussed.

"A TRAILING VORTEX MODEL AND ITS EFFECT ON A PENETRATING AIRCRAFT"

Proceedings of the National Aerospace Electronics Conf., IEEE, 1971, pp. 23-27

The high strength of the trailing vortex system produced by the new jumbo jet aircraft has renewed interest in the study of the vortex phenomenon and its effect on proximate aircraft operations. In the present study, the trailing vortex system produced by an aircraft in flight and penetration of the system by a second aircraft are modeled mathematically. The effect of turbulent mixing on the persistence of the intact trailing vortices is modeled by modifying the similar solution for a decaying laminar vortex. The correction is made by introducing an effective turbulent viscosity which is determined empirically. The vortex induced velocity is superimposed on the free stream velocity of a penetrating aircraft to determine a total velocity vector and angle of attack history. Separation times and distances required for safe operation in traffic pattern conditions are predicted using a gust load formula and maximum incremental load factors. Calculations were performed for several generator/penetrator aircraft combinations.

"PROCEDURAL FEASIBILITY OF REDUCED SPACING UNDER WAKE VORTEX AVOIDANCE SYSTEM OPERATION, WITH APPLICATIONS TO ATLANTA AND O'HARE"

FAA-EM-79-18, August 1979, Mitre Corp., McLean, VA.

A Wake Vortex Avoidance System (WVAS) may provide increased airport capacity by allowing for reduced aircraft separation standards on final approach under certain meteorological conditions. Three sets of reduced separation standards have been hypothesized to describe the operational characteristics of potential WVAS systems. Analyses develop several operational schemes which allow aircraft to transition to reduced separation standards when under WVAS coverage, while maintaining larger terminal area standards prior to intercepting that coverage. Specific applications of these schemes to Atlanta Hartsfield and Chicago O'Hare International Airports are also described. Other analyses investigate procedures for and dynamics of transitioning between different sets of separation standards. Capacity benefits corresponding to the utilization of the different sets of separation standards, under various operational procedures, are estimated for Chicago and Atlanta.

"NUMERICAL INVESTIGATION OF TURBULENT MIXING IN A JET/WAKE VORTEX INTERACTION"

AIAA Journal, Vol. 40, No. 2, 2002, pp. 276-284

A three-dimensional temporal numerical simulation of the interaction between a jet and a vortex wake is described to contribute to the understanding and modeling of engine jet dispersion of an aircraft in cruise condition. First, a comparison of the numerical results with a wind-tunnel experiment is presented. Experimental data comprise turbulent rates measured by a laser Doppler velocimeter and mean temperature fields delivered by thermocouples. The calculation is in quite good agreement with the experiment. Second, the passive scalar distribution (initially included in the jet) in the vortex wake is focused on. The turbulence induced by the jet flow field interacts with the vortex, resulting in large-scale structures generated outside the vortex core, whereas the region very close to the core keeps its laminar state. The passive scalar concentrates in the large-scale structures where azimuthal and axial (positive and negative) vortices are combined. The resulting scalar field distribution shows no scalar inside the vortex core.

"EQUATIONS FOR THE SINUOUS INSTABILITY GROWTH DOWNSTREAM AN AIRCRAFT"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 148-161

Equations have been derived governing variation of sinuous disturbances' amplitude in aircraft vortex wakes. The wake sinuous instability has been studied in response to the frequency of disturbing factors, ground vicinity and parameters of turbulent atmosphere.

Gaifullin, A. M.

"EQUATIONS OF PERTURBATION GROWTH IN AIRCRAFT WAKES"

Fluid Dynamics, Vol. 36, No. 3, 2001, pp. 448-457

Equations for the perturbation amplitude in the vortex wake of an aircraft with a high-aspect-ratio wing are derived. The effect of the perturbing factor frequency, the proximity of the ground, and the turbulent atmosphere characteristics on the wake evolution is investigated.

Gaifullin, A. M.

"EQUATIONS OF PERTURBATION GROWTH IN AIRCRAFT WAKES"

Fluid Dynamic, Vol. 36, No. 3, 2001, pp. 448-457.

Equations for the perturbation amplitude in the vortex wake of an aircraft with a high-aspect-ratio wing are derived. The effect of the perturbing factor frequency, the proximity of the ground, and the turbulent atmospheric characteristics on the wake evolution is investigated.

"EVOLUTION OF VORTEX WAKE NEAR THE EARTH'S SURFACE"

International Conference on the Methods of Aerophysical Research (ICMAR 2016), AIP Conference Proceedings, Vol. 1770, 2016, pp. 020019-1 to 020019-8.

The evolution of the vortex wake behind an aircraft near the Earth's surface is considered. The problem of diffusion of two discrete vortices near a solid surface is solved.

Gaifullin, A. M. and Soudakov, G. G.

"FROZEN FIELD AND QUASI-STEADY HYPOTHESIS IN THE VORTEX-AIRFOIL INTERACTION PROBLEM"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 132-137

A 'frozen' wake model and a quasi-steady approximation are often used in flight-dynamics and structural-strength studies. This paper is devoted to the evaluation of the accuracy of these models. For this purpose, a 2D problem on the interaction of a vortex cluster with an airfoil is solved. Four related problems were considered: full formulation, problem 'frozen' field model approximation with a vortex cluster, moving together, quasi-stationary approximation which includes the 'frozen' field model combined with the absence of time derivatives in pressure calculations and with the absence of the vortex sheet shedding from the airfoil trailing edge. Comparison of the models shows that the 'frozen' field model gives about 50% errors and quasi-stationary model gives about 100% errors but only in a

short period of time. This discrepancy is of great importance for elasticity analysis because of short period of vibration excitation.

Gaifullin, A. M. and Soudakov, G. G.

"DYNAMICS OF THE WAKE BEHIND AN AIRCRAFT"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 109-118

The paper deals with the problem of wake behavior behind an aircraft in a steady-state formulation. Taken as a wake model is the tangential velocity discontinuity surface. As the transverse wake size at sufficiently large distances from the aircraft is much greater than the streamwise one, an asymptotic approach is used. To first approximation, the well-known unsteady analogy is obtained which fails to describe such phenomena as Crow's instability and wake breakdown. Hence, in this paper the second and, partially, third approximations have been constructed of the solution to the wake dynamics problem. The equations therewith obtained for vortex sheet evolution contain the terms proportional to wake curvature that describe the mechanism of wake breakdown. Studied in detail are the problems on a single vortex filament and two vortex filaments with circulations different in sign. It turned out that besides trivial solutions to these problems, there exist steady-state solutions, exponentially growing along the longitudinal x-axis with the presence of oscillations in the cross-flow plane and without the oscillations as well as neutrally oscillating solutions. The trivial solution for two vortex filaments being unstable, the solutions obtained in this work can be considered as a limit to which the trivial solution goes. [In Russian.]

Gaifullin, A. M. and Soudakov, G. G.

"AIRCRAFT VORTEX WAKE DYNAMICS"

SAE Paper No. 965547, Los Angeles, CA, October 1996

The work deals with the problem on aircraft vortex wake behavior in steady-flow formulation. Further approximations of slender-body theory are constructed with the aid of asymptotic methods. The mathematical approach proposed performs to calculate the aircraft wake up to breakdown. The nontrivial analytic solutions for the problem of motion of one and two vortex filaments with circular cross-section are obtained.

Gaifullin, A. M. and Sviridenko, Y. N.

"DYNAMICS OF THE AIRCRAFT IN A VORTEX WAKE"

Heat and Mass Transfer and Hydrodynamics in Swirling Flows, published in IOP Journal of Physics: Conference Series, Vol. 980, 2018, pp. 012005-1 to 012005-6.

This paper considers the aerodynamics and the dynamics of an aircraft on various modes when the aircraft enters a strongly swirling flow. This is the case when an aircraft purposefully enters the jet-vortex wake of another aircraft during in-flight refueling, when an aircraft is flying in the trail of an aircraft carrier during landing, or when an aircraft accidentally enters other aircrafts' vortex wakes. These situations, according to pilots' evaluation, are the most dangerous and the most difficult modes for piloting. That is why their real time modelling on flight simulators has taken on particular importance. This article provides the algorithms and methodology of mathematical modelling of aerodynamic forces and moments which act upon an aircraft in vortex wakes.

Gaifullin, A. M. and Zoubtsov, A. V.

"ON DIFFUSION OF TWO VORTICES"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 102-112

A two-dimensional problem on the diffusion of two vortices with the intensities $\pm \Gamma$ and spacing $2l$ at the initial instant of time has been considered. The case of high Reynolds numbers $Re \gg 1$ has been investigated. It is shown that at $0 < T \ll Re$ ($T = t\Gamma / (l^2)$) the diffusion process becomes localized in the neighborhood of the vortices' centers. Vorticity distribution in these limited regions is non-axisymmetric in nature, which is responsible for the appearance in the external flow field ($r \sim l$) of unsteady potential disturbances from two multipoles of time-varying strength. The influence of these disturbances on the shape of the boundary of a cluster evolved in the course of the two vortices' self-induced motion has been studied. The vorticity distribution in the main flow region has been investigated. The diffusion process has been shown to be limited, to a first approximation, by a zone where streamlines are closed, whereas outside this zone, the azimuthal component of the velocity is zero.

Gaifullin, A. M. and Zubtsov, A. V.

"DIFFUSION OF TWO VORTICES"

Fluid Dynamics, Vol. 39, No. 1, 2004, pp. 112-127

The problem of the diffusion of two vortices with circulations of opposite sign is considered. An asymptotic solution of the problem is constructed for large Reynolds numbers. The vortex circulation dissipation mechanism is discussed. The results of the analytic investigation are compared with the results of numerical solution of the Navier-Stokes equations.

Gaifullin, A. M., Soudakov, G. G., Voyevodin, A. V. and Zakharov, S. B.

"COMPUTATION OF FLOW IN THE WAKE BEHIND A HIGH-ASPECT-RATIO WING"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 33-42

This work is devoted to studying the aircraft vortex wake using a zonal approach. The whole flow field is subdivided into several zones: the aircraft's neighborhood, near wake, far wake and turbulent core. For each zone, corresponding equations are solved. Numerical matching is performed on the zones' boundaries. In the turbulent core an algebraic turbulence model is used. These computational results agree well with data obtained by use of empirical formulas or experimentally.

Gaifullin, A. M., Voyevodin, A. V. and Zakharov, S. B.

"ZONAL METHOD OF AIRCRAFT WAKE CALCULATION"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 111-120

Basic factors are singled out that influence the structure of the vortex wake and its lifetime: spanwise circulation distribution, turbulent structure of the vortex core, air turbulence properties, vortex merging, circulation loss in the vortices, sinuous disturbances. Main modules of the software package ZONWAKE are described which allow calculation of the wake flow characteristics. Computed results of the B747-400 aircraft are presented.

Gaifullin, A. M., Voyevodin, A. V. and Zakharov, S. B.

"CALCULATION OF THE EVOLUTION OF THE NEAR WAKE BEHIND A HIGH-LIFT WING IN WIND-TUNNEL EXPERIMENT"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 34-38

A version of the ZONWAKE algorithm has been developed, which allows one to numerically investigate the evolution of the near wake behind a wing with high-lift devices, taking into consideration the wall interference of a rectangular cross-section wind tunnel. Computations of the vortex wake were performed in both unconstrained flow and in the presence of solid boundaries. A comparison was conducted between computed data and experimental results obtained in TsAGI's T-124 wind-tunnel.

"REAL TIME MATHEMATICAL MODELING OF THE AERODYNAMIC CHARACTERISTICS OF AN AIRCRAFT ENCOUNTERING VORTEX WAKES"

ICAS Paper 2010-10.3.3, September 2010, Nice, France.

The work describes formation and evolution of vortex street turbulence behind an aircraft in a turbulent atmosphere. It suggests the approach to creation of a mathematical model of aircraft aerodynamics in the in-flight refueling mode based on the use of artificial neural networks. Accuracy appraisal and response time of program modules of the flight simulator software assessment when simulating aerial refueling have been conducted. The main purpose of this work is to develop program modules of software of an aviation training device or a flight simulator when the aerial refueling is simulated. IL-78 is considered as an aerial tanker and IL-76 as a receiver aircraft. During the in-flight refueling the receiver aircraft is subjected to the nonhomogeneous field of velocities caused by the jet vortex wake of the aerial tanker, in which case additional aerodynamic forces and moments acting on the receiver do emerge. The paper developed a mathematical model of aerodynamic characteristics of aircraft in jet vortex wake based on the set of aircraft flow-around calculation programs and wake flows. This technique can be used to model a flight in case one aircraft inadvertently enters the other aircraft's wake.

Gaitonde, D. V.

"MEAN FLOWFIELD STRUCTURE OF A SUPERSONIC THREE-DIMENSIONAL BASE FLOW"

Journal of Aircraft, Vol. 47, No. 2, March-April 2010, pp. 368-382.

The mean flow field structure in the wake region of a circular cylinder at a 10 deg angle of attack in a Mach 2.5 flow is described. Results from the full three-dimensional Reynolds-averaged Navier-Stokes equations, supplemented with a compressibility-corrected two-equation turbulence model, are compared with extensive available experimental data. Mesh resolved results indicate that surface pressure trends on both the afterbody and the base are reproduced well, but quantitative differences of about 15 percent are observed in different regions. The main experimental observations of the shock pattern, surface oil flow on the afterbody and the base surfaces, velocity vector plots in the symmetry and lateral planes, and end-view flow images are reproduced to good accuracy. Based on this success, the computed solution is employed to generate a model for the mean flow. The main feature is a pair of longitudinal vortices separated by high-speed fluid entrained primarily from the leeward and lateral afterbody boundary layers and bounded from below by the windward afterbody layer. The mean vorticity distribution reveals a vortex core pair forming a horseshoe-like structure. The three-dimensional wave structure is elucidated and correlated with the streamline pattern.

"DETAIL OF MAIN/TAIL-ROTOR VORTEX INTERACTION ON ROTORCRAFT"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

The paper describes the work carried out at Glasgow University on orthogonal interaction of a rotor-tip vortex with a fixed blade mimicking the tail rotor. The vortex is generated from a single bladed rotor mounted in the contraction of the Glasgow Argyle wind tunnel. The pitch of the blade was varied using

a smooth cam such that it is pitched up as the blade approached the tunnel working section and pitched down as it departed. This resulted in a sequence of near orthogonal vortices travelling down the working section. They were true trailing vortices containing the associated axial flow component. The fixed blade was mounted offset to the center of the wind tunnel and was liberally instrumented with pressure transducers. The blade could be adjusted both vertically and in pitch. It is clear from the data that for the airfoil surface, on which the axial flow of the vortex is towards the airfoil, there is a pressure pulse resulting in a compression which, as the vortex convects across the chord, disappears and a suction wave develops. On the opposite side, where the axial flow is away from the airfoil, there is increased suction that is observed throughout the convective process. When these interactions were observed using particle image velocimetry, and the velocity vectors decomposed into the radial and tangential components, the immediate interaction appears to be the combination of a simple vortex and a source. The source being positive on the compression side and negative on the suction side. To assess how appropriate the aerodynamic modelling in the wind tunnel has been, the presentation will finally discuss the replacement of the fixed blade by an instrumented tail-rotor. That rotor will have fewer transducers and hence less fidelity. Nonetheless, similar temporal pressure data, from both the fixed and the rotating rotor, will indicate appropriate modelling of the interaction.

"LIDAR MEASUREMENTS AND VISUALISATION OF TURBULENCE AND WAKE DECAY LENGTH"

EWEA 2014 Annual Conference, Poster PO 175, March 2014, Barcelona, Spain.

Galion Lidar was used to measure the wake of a wind turbine to investigate wake decay length. The PARK wake model using a wake decay constant of 0.038 was compared with the measured data to assess its effectiveness for wake modelling. The data was filtered to periods where there was a single wake only. It was found that the PARK wake model generally predicts the recovery (i.e. over predicts wake loss) towards free stream inflow wind speed as measured by the Lidar at low wind speeds with better agreement in the high inflow wind speed bins. The PARK wake model shows best agreement with the Lidar data at high inflow wind speed and proves a good match for the 16-18 m/s inflow wind speed. In the 5 to 14 rotor diameter downstream distance PARK is seen to over predict wake losses across wind speed bins. After this distance the comparison with the Lidar data is less consistent and a wake scan with a longer focus point to capture this area in more detail would shed more light on the comparison between the model and the data.

"THREE-DIMENSIONAL INSTABILITY OF ISOLATED VORTICES"

Physics of Fluids, Vol. 15, No. 8, August 2003, pp. 2113-2126

We study the three-dimensional stability of the family of vortices introduced by Carton and McWilliams describing isolated vortices. For these vortices, the circulation vanishes outside their core over a distance depending on a single parameter, the steepness a . We proceed to the direct numerical

simulation of the linear impulse response to obtain both temporal and spatio-temporal instability results. In the temporal instability framework, growth rates are calculated as a function of the axial wavenumber k and the azimuthal wavenumber m . The stability analysis is performed at a Reynolds number of $Re=667$. It is shown that the most unstable mode is the axisymmetric mode $m = 0$, regardless of the steepness parameter in the investigated range. When the steepness a is increased the band of unstable azimuthal modes widens, i.e., larger m modes are destabilized. The study of the spatio-temporal spreading of the wave packet shows that the $m = 2$ mode is always the fastest traveling mode, for all studied values of the steepness parameter.

Gallaire, F. and Chomaz, J.-M.

"INSTABILITY MECHANISMS IN SWIRLING FLOWS"

Physics of Fluids, Vol. 15, No. 9, September 2003, pp. 2622-2639

We investigate the stability of the screened Rankine vortex with added plug flow where the azimuthal velocity decreases abruptly outside the core of the vortex. The jump in circulation is known to induce centrifugal and azimuthal Kelvin-Helmholtz instabilities. Their effect on the stability of the different azimuthal wave number m is discussed using physical considerations associated with asymptotic expansions and numerical computations of the dispersion relation. It is shown that the axial shear and centrifugal instability are active for all m , and that modes with m greater than or equal to 2 are also destabilized by azimuthal shear. In contrast, the bending modes $m = \text{plus/minus } 1$ are stabilized by a coupling with Kelvin waves in the core. Effects of rotation on the absolute/convective transition are also discussed. The absolute instability of positive helical modes is seen to be promoted by centrifugal instability and azimuthal shear.

Gallaire, F., Rott, S. and Chomaz, J.-M.

"EXPERIMENTAL STUDY OF A FREE AND FORCED SWIRLING JET"

Physics of Fluids, Vol. 16, No. 8, August 2004, pp. 2907-2917

The present study concerns the response of a swirling jet to various azimuthal modes and frequencies forced at the nozzle exit. The different unforced dynamical states are first described as a function of the swirl setting, determined from measured velocity fields in the longitudinal plane using particle image velocimetry. A second experimental technique, based on laser induced fluorescence, is described, which is more suited to the description of the low-amplitude response of the jet to the forcing. It is shown that the receptivity of the jet is very poor when the forcing is set to the naturally prevailing azimuthal mode ($m = 2$) and frequency. In contrast, a strong response is observed for both co-rotating and counter-rotating forced azimuthal modes ($m = \text{plus/minus } 2$, $m = \text{plus/minus } 3$) for frequencies about one order of magnitude larger than the frequency prevailing in the absence of forcing. Finally, the present actuator is seen to be ineffective in preventing the appearance of vortex breakdown itself.

Gallaire, F., Ruith, M., Meiburg, E., Chomaz, J.-M. and Huerre, P.

"SPIRAL VORTEX BREAKDOWN AS A GLOBAL MODE"

J. Fluid Mech., Vol. 549, 2006, pp. 71-80

The spiral form of vortex breakdown observed in the numerical simulations of Ruith et al. (J. Fluid Mech., vol. 486, 2003, p. 331) is interpreted as a nonlinear global mode originating at the convective/absolute instability transition point in the lee of the vortex breakdown bubble. The local absolute frequency at the transition station is shown to yield a satisfactory prediction of the precession frequency measured in the three-dimensional direct numerical simulations.

"EFFECT OF WAKE STRUCTURE ON BLADE-VORTEX INTERACTION PHENOMENA: ACOUSTIC PREDICTION AND VALIDATION"

Journal of Aircraft, Vol. 35, No. 2, March-April 1998, pp. 267-273.

The higher harmonic control aeroacoustic rotor test conducted at Duits-Nederlandse Wind Tunnel has made extensive measurements of the rotor aerodynamics, far-field acoustics, wake geometry, and the blade motion for powered descent flight conditions. These measurements have been used to validate and improve the prediction of blade-vortex interaction (BVI) noise. The improvements made to the BVI modeling after the evaluation of the test data are discussed. The effect of these improvements on the acoustic-pressure predictions is shown. These improvements include restructuring the wake, modifying the core size, incorporating the measured blade motion into the calculations, and attempting to improve the dynamic blade response. A comparison of four different implementations of the Ffowcs Williams and Hawkings equation is presented. A common set of aerodynamic input has been used for this comparison.

Gallman, J. M., Tung, C. and Low, S. L.

"THE EFFECTS OF VORTEX MODELING ON BLADE-VORTEX INTERACTION NOISE PREDICTION"

AIAA Paper No. 1995-0832, January 1995, Reno, NV.

The use of a blade vortex interaction noise prediction scheme, based on CAMRAD/JA, FPR and RAPP, quantifies the effects of errors and assumptions in the modeling of the helicopter's shed vortex on the acoustic predictions. CAMRAD/JA computes the wake geometry and inflow angles that are used in FPR to solve for the aerodynamic surface pressures. RAPP uses these surface pressures to predict the acoustic pressure. Both CAMRAD/JA and FPR utilizes the Biot-Savart Law to determine the influence of the vortical velocities on the blade loading and both codes use an algebraic vortex model for the solid body rotation of the vortex core. Large changes in the specification of the vortex core size do not change the in-plane wake geometry calculated by CAMRAD/JA and only slightly affect the out-of-plane wake geometry. However, the aerodynamic surface pressure calculated by FPR changes in both magnitude and character with small changes to the core size used by the FPR calculations. This in turn

affects the acoustic predictions. Shifting the CAMRAD/JA wake geometry away from the rotor plane by 1/4 chord produces drastic changes in the acoustic predictions indicating that the prediction of acoustic pressure is extremely sensitive to the miss distance between the vortex and the blade and that this distance must be calculated as accurately as possible for acceptable noise predictions. The inclusion or exclusion of a vortex in the FPR-RAPP calculation allows for the determination of the relative importance of that vortex as a BVI noise source. Being able to identify which vortex is responsible for the largest noise sources will lead to improved BVI noise reduction methods.

"EFFECT OF WAKE STRUCTURE ON BLADE-VORTEX INTERACTION PHENOMENA: ACOUSTIC PREDICTION AND VALIDATION"

AIAA Paper 1995-0022, June 1995, Munich, Germany.

During the Higher Harmonic Control Aeroacoustic Rotor Test, extensive measurements of the rotor aerodynamics, the far-field acoustics, the wake geometry, and the blade motion for powered, descent, flight conditions were made. These measurements have been used to validate and improve the prediction of blade-vortex interaction (BVI) noise. The improvements made to the BVI modeling after the evaluation of the test data are discussed. The effects of these improvements on the acoustic-pressure predictions are shown. These improvements include re-structuring the wake, modifying the core size, incorporating the measured blade motion into the calculations and attempting to improve the dynamic blade response. A comparison of four different implementations of the Ffowcs Williams and Hawkings equation is presented. A common set of aerodynamic input has been used for this comparison.

Gallo, W.

"WAKE TURBULENCE LITIGATION"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 48-1 - 48-7

All of the published wake-turbulence-encounter legal decisions have been analyzed and summarized to present a picture of the bottom line effect of the wake turbulence dangers. Eighteen such cases, which at least have alleged wake turbulence as the cause of an airplane crash, are listed and a brief set of circumstances or particulars are included to show a brief history of such litigation. Obviously, the mere allegation, as found in a lawsuit, brought by some lawyer, does not always translate into an actual wake turbulence encounter. Some courts have decided, that despite allegations and testimony by a so-called expert in the field, the subject accident although alleged to be a wake turbulence accident was not attributable to wake turbulence at all.

Gally, T.

"AERODYNAMIC EVALUATION OF WING TIP MOUNTED NACELLES"

AIAA Paper 2001-2482, Anaheim, CA, June 2001

A computational investigation of the impact of wing tip mounted engine nacelles was undertaken in order to quantify potential improvements in performance and reductions in wake vortex strengths as had been identified in previous wind tunnel tests by Patterson, et al. The results obtained indicated that the bulk of the performance gains are associated with the diameter of the wing tip body and not with the presence of axial flow in the tip vortex core. However, the tip vortex strength is reduced by such core flow and forced core blowing does enhance the viscous dissipation of the vortex. The possibility still exists to affect the tip vortex stability through blowing, but vortex breakdown was not observed in the computational analysis.

Galovic, B., Grozdanic, B. and Steiner, S.

"INFLUENCE OF WAKE-VORTEX TURBULENCE ON THE FLIGHT SAFETY"

Promet Traffic, Vol. 9, No. 1-2, 1997, pp. 1-14

With the growing air traffic intensity, at some airports we are more often faced with the fact that aircraft land or takeoff one after another. Since every aircraft leaves a turbulent vortex behind, which acts unexpectedly and is destabilizing for the aircraft flying into it, the flight safety for such repeated landings and takeoffs becomes questionable. Determining the minimum safety time interval between the repeated operations becomes imperative and a limiting factor for some airports with high traffic intensity. Unlike military flying, where crew is trained to fly in a group, in civil air traffic the crew is not trained for such flying and on top of it mostly operate on large aircraft, which produce very strong turbulent vortex. Additional sophisticated equipment in new modern aircraft improves navigation, communication and steering of the aircraft, but does not insure it from flying into an invisible turbulent vortex. This paper discusses the vortex generation, its nature and factors that influence its intensity and duration. The paper also deals with a model of calculating the probability of flying into a turbulent vortex regarding time interval of repeated operations, and influence of sophisticated equipment installed, on the stability and flight safety of an aircraft. Conclusion underlines the need to standardize the minimum safety time interval separation between the repeated operations, with the aim of improving flight safety.

"EUROPEAN WAKE VORTEX MITIGATION BENEFITS STUDY WORK PACKAGE 3 DELIVERABLE: HIGH LEVEL BENEFITS ANALYSIS AND SYSTEMIC ANALYSIS"

TRSD03/WP3, 2005, Eurocontrol.

PART A: This technical contribution to Work Package 3 consists of a high-level benefits study conducted for the airports brought forward from Work Package 1. Benefits (in terms of extra

movements) were estimated for 3 concepts - ATC-Wake, CREDOS, and Time-Based Spacing - and took advantage of the meteorological profiles produced in Work Package 2. PART B: This technical contribution to Work Package 3 consists of a high-level systems analysis describing the required modifications for the implementation of the WV mitigation concepts considered in this study on a generic ATM system. This analysis intends to serve as an input to develop the costs assessment required to obtain the Cost Benefit Analysis for the different target airports identified in Work Package 1.

Gan, L. and Nickels, T. B.

"AN EXPERIMENTAL STUDY OF TURBULENT VORTEX RINGS DURING THEIR EARLY DEVELOPMENT"

Journal of Fluid Mechanics, Vol. 649, 2010, pp. 467-496.

In this paper, the early development of turbulent vortex rings at two Reynolds numbers is studied using two-dimensional and stereoscopic particle image velocimetry (PIV). In the late 1980s, a similarity theory of turbulent vortex rings was proposed and this theory was tested primarily using Doppler velocimetry. However, because of limitations of the experimental technique, the tests were inconclusive and important assumptions could not be checked. Because single-point measurements were used, vortex ring structures could only be inferred using a complex signal analysis technique. In this study, the PIV technique provides spatial measurements of the full field of the cross-section of a ring from which a more rigorous investigation of the similarity theory is possible. Because the region over which the similarity theory appears to hold starts at about 2.5 orifice diameters downstream, this study focusses on the early development region from this point to 8 diameters downstream. Finally, Reynolds stresses and turbulence production contours are presented. The effects of ring dispersion on the measurements is also studied and quantified.

Gan, L., Dawson, J. R. and Nickels, T. B.

"ON THE DRAG OF TURBULENT VORTEX RINGS"

Journal of Fluid Mechanics, Vol. 709, 2012, pp. 85-105.

In this paper the pressure field during the early development of turbulent vortex rings at two Reynolds numbers is determined using temporally resolved two-dimensional and stereoscopic particle image velocimetry. The pressure gradient terms are obtained by solving the incompressible Euler equation so that the drag coefficients of the vortex rings can be evaluated. Maxworthy and Glezer and Coles each developed models to describe the long-term physics of turbulent vortex rings: the former developed a semi-empirical model which permits loss of impulse via the shedding of vorticity into the wake whereas the latter developed a similarity model based on invariance of the hydrodynamic impulse. Maxworthy's model implies that a significant correction to the similarity solution is required to account for the drag on the vortex ring bubble. We show that during the early development of the turbulent vortex rings the drag is very small and the similarity scaling can basically be retained.

"AN EXPERIMENTAL STUDY OF A TURBULENT VORTEX RING: A THREE-DIMENSIONAL REPRESENTATION"

Experimental Fluids, Vol. 51, 2011, pp. 1493-1507.

This paper presents a reconstruction of the three-dimensional velocity field of a turbulent vortex ring by means of Taylor's hypothesis. Stereoscopic PIV is used to acquire three velocity component information on a plane. The accuracy of the Taylor's hypothesis for this particular flow pattern is first discussed, and the three-dimensional velocity and vorticity information are then presented. This study also introduces an azimuthally averaging method to give a mean structure in cylindrical coordinates from a single realization and from which turbulent stresses and production can be estimated. The azimuthally averaged quantities are then compared with the ensemble-averaged results from the previous planar (two-dimensional and stereoscopic) PIV experiments.

"IDENTIFICATION OF AIRCRAFT BY THEIR UNIQUE TURBULENT WAKE SIGNATURE: EXPERIMENTAL VALIDATION"

AIAA Paper No. 2012-0066, January 2012, Nashville, Tennessee.

Earlier work on the theoretical foundation for the identification of aircraft by their unique turbulent wake signature is experimentally validated. A brief review of this theoretical foundation will be discussed wherein the drag coefficient can be used to estimate either a Reynolds Stress distribution or (indirectly) a model of the velocity profile of the turbulent wake. A previously unpublished sensitivity study on the conditions of application of the method is included. This sensitivity reviews the robustness of the method to differentiate between aircraft across a much wider range of cruise and payload conditions than those previously published as well as a few corners where the method could potentially have difficulty differentiating between aircraft. Experimentally, initially the Reynolds stress distribution downstream of a circular cylinder is determined using Particle Image Velocimetry (PIV) in the University of Dayton low speed wind tunnel and those results compared to the predicted Reynolds Stress distribution calculated from the drag coefficient obtained through direct force measurement. Subsequently, the Reynolds stress distribution downstream of a moderate aspect ratio wing obtained through PIV is similarly compared to a predicted Reynolds Stress distribution derived through the drag coefficient obtained from direct force measurement. Finally, a small remote-control twin engine aircraft is tested with wind-milling propellers and its drag measured from a force balance is used to generate the expected Reynolds stress distribution. This distribution is then compared to the Reynolds stress distribution obtained from PIV downstream of the model where the wake had not yet achieved a self-preserved state. This prevented a complete demonstration of practical feasibility of the technique; however, several key underlying assumptions of the method are validated.

"ZONAL DETACHED EDDY SIMULATION OF A CIVIL AIRCRAFT WITH A DEFLECTED SPOILER"

AIAA Journal, Vol. 51, No. 3, March 2013, pp. 697-706.

This paper presents the simulation of a wing/body configuration with a deflected spoiler using the Zonal Detached Eddy Simulation approach in an emergency dive scenario at the Reynolds number based on the wing chord $Re=5,000,000$. The objective is to assess the reliability of this numerical method in the framework of the creation of aerodynamic data models in off-design conditions. The mesh is built using the Chimera technique (or overset grids) to gather multiblock, structured, near-wall grids and Cartesian off-body grids. The results are compared to wind tunnel data and show the dramatic increase of accuracy provided by the zonal detached eddy simulation approach in the spoiler area compared to a standard steady Reynolds-averaged Navier-Stokes simulation using the Spalart-Allmaras model. Furthermore, the zonal detached eddy simulation gives insights on the unsteady properties of the turbulent structures downstream of the spoiler, which is of major importance in the aerodynamic design process of an aircraft related to tail buffet.

Gandhi, N. T.

"AUTOMATIC DEPENDENT SURVEILLANCE-BROADCAST ENABLED, WAKE VORTEX MITIGATION USING COCKPIT DISPLAY"

MS Thesis, December 2012, Ohio University, Athens, OH.

Wake turbulence has the potential to cause accidents during the landing phase of flight. This thesis work documents the development and testing of a prototype cockpit display to help pilots avoid this wake turbulence using ADS-B technology. Several landing profiles of the wake generating aircraft and the trailing aircraft were created using computer simulations to generate the synthetic data. A tracking algorithm was developed to compute the altitude of the leading aircraft to be displayed in the altitude strip of the cockpit display. This algorithm will search for all the points of flight data of a leading aircraft, within a predefined region near a trailing aircraft. This flight data is projected on a primary or multifunction display to create an imaginary scenario and tested for data acquisition and transmission from one aircraft to another. The parameters and the number of bits that are necessary to transmit these data via the ADS-B for avoiding the wake turbulence, especially in the case of busy airports are documented. As a final step, necessary hardware was installed in two GA (General Aviation) aircraft and a flight test was performed. The flight-tested prototype successfully provided the pilot of the trailing aircraft with intuitive information on a multifunction display to avoid wake turbulence.

"UNSTEADY AERODYNAMICS OF ROTORCRAFT IN GROUND EFFECT"

AIAA Paper 2004-2431, June 2004, Portland, OR.

The aerodynamic characteristics of rotorcraft flight close to the ground are studied. Flow visualization was done to identify the flow structure in ground effect, and compare it with the out of ground effect flow structure. Hotwire measurements were done to quantify time scales of fluctuations. Six

component force measurements were done to measure the loads at various advance ratios and yaw angles.

Gangwani, S. T.

"DETERMINATION OF ROTOR WAKE INDUCED EMPENNAGE AIRLOADS"

American Helicopter Society Northeast Region National Specialists' Meeting on Helicopter Vibration Technology for the Jet Smooth Ride, November 1981, Hartford, CT.

An efficient time-domain method has been developed to determine the unsteady vibratory air-loads produced by the interaction of the main rotor wake with the helicopter empennage. An analysis technique has been followed wherein a rotor wake program is used to determine the main rotor wake position and the strength of blade tip vortices that are located near the empennage surfaces. A nonlinear lifting surface analysis is utilized to predict the aerodynamic loads on the empennage surfaces in the presence of these concentrated vortices. This nonlinear analysis has been formulated so as to include pertinent effects such as the suction effects of the interacting vortices and the effects of shed vorticity behind the empennage surfaces. The problem is solved in a stepwise manner (time-domain); that is, a period corresponding to one blade passage is divided into many time intervals and unsteady air-loads are computed at each step. The output of the analysis consists of chordwise and spanwise air-load distributions on the empennage surfaces at each time step. These air-load distributions are converted into the harmonic air-loads that are applied to the tail boom of the helicopter for use in vibration analysis. The results of a limited correlation study involving the application of the present computer analysis to a full-scale helicopter stabilizer indicate a reasonably good correlation between analytical predictions and the flight test data.

"A QUANTITATIVE ANALYSIS OF VISCOUS AND LIFT-INDUCED DRAG COMPONENTS FROM DETAILED WAKE MEASUREMENTS BEHIND A HALF-SPAN MODEL"

NLR-TP-2002-320, June 2000, National Aerospace Laboratory, Cambridge, UK

In the Low-Speed Wind Tunnel of DNW detailed wake surveys were made behind an aircraft half-span model (ALVAST) using a rake with 5-hole probes. Different model configurations were considered including a body with wing, a body with wing and a Through Flow Nacelle and a body with wing and a low-powered Counter Rotating Ultra-high-bypass Fan. The lift and drag coefficients calculated from the measured velocities and pressures in the wake are compared with the force coefficients measured with a force balance. The spanwise distributions of lift, viscous drag and induced drag are presented.

"NUMERICAL STUDY OF A HOVERING HELICOPTER ROTOR BLADE IN GROUND EFFECT"

AIAA Paper 2019-1099, January 2019, San Diego, CA.

This paper focuses on the numerical simulation of a 3-D hovering helicopter rotor blade in ground effect in transonic regime. The study consists of two parts. The first part involves the study of blade pressure distribution, lift on blade sections and rotor thrust performance. Along the span wise direction near the blade tip, local Mach number becomes close to 1 and shock is captured numerically. The numerical results are validated against the experimental data for the hovering rotor blade. When rotor blade is close to the ground, the change in blade pressure distribution is studied. The second part involves mainly the properties of the wake when rotor blade is close to the ground. It includes the trajectory and strength of the wake.

"PARAMETER-RETRIEVAL OF DRY-AIR WAKE VORTICES WITH A SCANNING DOPPLER LIDAR"

Optics Express, Vol. 28, No. 13, June 2018, pp. 16377-16392.

A wake vortex is a form of irregular airflow generated by a flying aircraft, which can cause a severe hazard for aviation. To quantify the hazard of a wake after fully roll-up and before rebound, this paper proposes an algorithm to retrieve its characteristic parameters (circulation, vortex-core positions, and vortex-core radii) with a scanning Doppler Lidar. In the algorithm, a governing equation related to the Doppler velocities and characteristic parameters is established based on the aerosols' weak inertia, from which the target parameters are solved with an optimization method. During the process, the distortion of Doppler velocity caused by the scanning of the Lidar beam is adjusted by the Doppler acceleration to achieve better estimations of the target characteristic parameters. Good performance of the algorithm has been verified by simulation and field detection data.

"AN EXPERIMENTAL SURVEY OF A WING-TIP VORTEX IN A CONTRACTED FLOW"

AIAA Paper No. 2010-4616, June 2010, Chicago, Illinois.

Vortex stretching is a phenomenon vital to many areas of aerodynamic study. Circumstances arise where the dynamics of evolving vortices can significantly influence surrounding flow fields. Some of these circumstances include wing tip vortex persistence related to formation flight, the dynamics of leading-edge vortices in delta wing flight, vortex interactions with buildings, and complex rotorcraft wake flow fields. In these cases, vortex interaction can have beneficial or detrimental effects. The evolution of wing-tip vortices in wake flow fields has been well studied through experiment. Typically, the major concern of these studies involved the viscous decay of wing-tip vortices with applications to close-proximity flight. This experiment sought to detail the evolution of a wing-tip vortex shed into a favorable pressure gradient. Cross sectional velocities were measured at sequential locations in a mild contraction in the Cal Poly 3 x 4 ft low-speed wind tunnel to examine the circumferential velocity and vorticity evolutions of the vortex in the streamwise direction. Afterwards, these experimental results

were compared with previous experiments as well as an approximate analytical solution to a vortex in stretched flow.

"ACCURATE PREDICTIONS OF ROTOR HOVER PERFORMANCE AT LOW AND HIGH DISC LOADINGS"

Journal of Aircraft, Vol. 55, No. 1, January-February 2018, pp. 89-110.

This paper presents evidence on the ability of modern computational fluid dynamics methods to accurately predict hover performance of rotors with modest computer resources. The paper uses two well-studied blades, the S-76 main rotor blade and the XV-15 tiltrotor blade. The results are compared with experiments and show that the performance is well predicted. In addition, the employed computational fluid dynamics method was able to capture the effects of the tip Mach number, tip shape, blade aeroelasticity, and flow transition on the performance of the blade as well as on the wake structure and the rotor acoustics.

Garcia, A. J. and Barakos, G. N.

"NUMERICAL SIMULATIONS ON THE ERICA TILTROTOR"

Aerospace Science and Technology, Vol. 64, May 2017, pp. 171-191.

This paper presents aerodynamic calculations of the model-scale ERICA tiltrotor with high-fidelity computational fluid dynamics. The aim of this work is to assess the capability of the present CFD method in predicting air-loads on the tiltrotor at different flight configurations. In this regard, three representative flight configurations of the ERICA were selected, corresponding to airplane, transition corridor, and helicopter modes, covering most modes of tiltrotor flight. The rotor blades were fully resolved and the use of a uniform and non-uniform actuator disk was also put forward to quantify the effect of the rotor on the fuselage loads. A fundamental investigation of the effect of the aerodynamic interference between the rotor and wing of the tiltwing aircraft is also shown. The employed CFD method was able to capture the aerodynamics of the different configurations and the overall agreement obtained with the experimental data demonstrates the capability of the present CFD method in accurately predict tiltrotor flows.

"CONFIDENCE INTERVALS IN THE DETERMINATION OF TURBULENCE PARAMETERS"

Experiments in Fluids, Vol. 40, 2006, pp. 514-522.

This paper quantifies uncertainty in turbulence parameters using the moving block bootstrap technique (MBB). This technique provides a good approximation of confidence intervals of turbulence parameters such as time and length scales of turbulent flow, convective velocities and dissipation of turbulent kinetic energy which cannot be estimated based on the available standard methodology

because of their computational complexity and reliance on correlation structure in the signal. The validation consisted of a comparison between uncertainty estimates of various parameters from MBB and those from analytical and experimental data.

Garcia, D. L. and Katz, J.

"TRAPPED-VORTEX IN GROUND EFFECT"

AIAA Paper No. 2002-3307, St. Louis, MO, June 2002

The effects of vortices trapped between a flat plate and a ground plane were studied in a wind tunnel experiment. The flat plate was mounted parallel to the ground to represent the lower surface of a generic road vehicle. Rectangular vortex generators mounted onto the plate were used to generate streamwise vortices between the plate and the ground plane. The main variables investigated were the ground clearance and vortex generator orientation, both influencing the trapped vortex strength. The experimental data indicates that considerable aerodynamic loads can be created with such vortex generators, particularly for small ground clearance values (even at zero plate incidence).

"SPECTRAL CHARACTERISTICS OF VORTEX BREAKDOWN FLOWFIELDS"

Phys. Fluids, Vol. 22, No. 11, November 1979, pp. 2053-2064

Laser-Doppler anemometer measurements upstream and in the wakes of vortex breakdowns of bubble and spiral types are described. Spectral analysis of the data indicates prominent oscillations in the wakes at less than 10 Hz. These oscillations correspond closely to theoretical predictions of the linearly most unstable normal modes of the time-averaged mean flow profiles. The oscillations are more energetic, and vortex core expansions are greater for flows with a bubble form of vortex breakdown, which is therefore regarded as the stronger form of breakdown.

Garmann, D. J. and Visbal, M. R.

"TRANSIENT ENCOUNTERS OF A NACA0012 WING WITH A STREAMWISE-ORIENTED VORTEX"

AIAA Paper 2015-3073, June 2015, Dallas, TX.

A high-fidelity numerical study has been conducted to examine the unsteady interactions resulting from a finite wing maneuvering into a streamwise-oriented vortex as a representative problem of wake encounters. A NACA0012 wing at an angle of 4 degrees and operating at a Reynolds number of $Re = 200000$ is dynamically maneuvered into the path of a stationary vortex, and the transient encounter is analyzed for three side-slip velocities corresponding to 10, 20, and 40 percent of the free stream. The wing is shown to traverse a range of flow regimes, including instances of vortex pairing of the tip and incident vortices that lead to mutual induction and attenuation of the pair, tip vortex suppression as the impingement passes inboard of the wingtip, and induced separation that precipitates an abrupt transition at the leading edge. The overall flow structure is mostly consistent among the wing speeds examined, indicating an almost quasi-stationary response with relative vortex position. However, a notable lag is observed in the development of a spiraling instability in the incident vortex just upstream of the wing. With slower encounter speeds, the vortex core exhibits a pronounced spiraling undulation that persists farther upstream earlier in the motion. The advanced development is attributed to prolonged exposure to the adverse pressure gradient from stagnation on the underside of the wing that decelerates the core axial flow below known stability bounds of the vortex. Additionally, a dynamic loading effect is identified prior to the vortex crossing inboard of the wingtip, whereby the incident structure's relative position at peak loading shifts outboard with increased wing speed. The peak magnitudes of lift, pitching moment, and rolling moment coefficients are also shown to scale proportionally with the wing's side-slip speed as they are predicated upon an enhanced tip vortex development. In all cases as the wing approaches the vortex, an upstream progression of separation, transition, and reattachment over the leading-edge leads, which forward tilts the force vector and reduces the drag. Once the vortex is brought inboard, however, the drag saturates, and the other quantities exhibit a nearly quasi-stationary response with vortex position as the wingtip unloads.

Garmann, D. J. and Visbal, M. R.

"INVESTIGATION OF THE UNSTEADY TIP VORTEX STRUCTURE ON A NACA0012 WING AT FIXED INCIDENCE"

AIAA Paper 2017-1002, January 2017, Grapevine, TX.

High-fidelity implicit large-eddy simulation is used to investigate the dynamics of wingtip vortices formed on an aspect-ratio-four NACA0012, rounded-tip wing at $Re = 200,000$ for incidence of α greater than or equal to 4 and less than or equal to 16. At its initial separation and inception, the tip vortex core exhibits a strengthening favorable pressure gradient with increased angle of attack that promotes acceleration of its axial flow to values higher than the free-stream speed for α greater than or equal to 8 degrees, or jet-like vortices. Approaching the trailing edge, however, the core is subjected to an adverse pressure gradient that decelerates the core flow before entering the wake. The extent and strength of this adverse region grows with increased incidence, but it does not reach a sufficient level to stagnate the core flow and cause breakdown for the conditions examined. The nature of the vortex (wake- or jet-like) is determined through this pressure gradient above the wing and does not appear to be associated with wake interactions. Analysis of the instantaneous and time-mean flow also reveals the formation, separation, and entrainment of shear-layer substructures within the tip vortex feeding sheet are stationary features, i.e. fixed in space and time. Interactions with the wake,

however, are highly unsteady as wake vortices shed from the wing's trailing edge are entrained into the vortex periphery.

Garmann, D. J. and Visbal, M. R.

"FURTHER INVESTIGATIONS OF THE TIP VORTEX ON AN OSCILLATING NACA0012 WING"

AIAA Paper 2016-4343, June 2016, Washington, DC.

The unsteady character of the wingtip vortex formed on a low-amplitude/high-frequency heaving wing is examined using high-fidelity numerical simulation. The wing of aspect ratio $AR = 6$ has a NACA0012 airfoil section and a rounded tip, and it operates at a Reynolds number of $Re = 200,000$, free-stream Mach number of 0.1, and fixed incidence of 8 degrees. Three plunging motions are considered with amplitudes of $A/c = 0.02$ or 0.03 and reduced frequencies of $k = (\pi)fc/U = 1.05$ or 2.00 . The chosen kinematics provide cases of mild, moderate, and extreme excursions in effective angle of attack that induce significant unsteadiness in the tip vortex but also avoid wing stall. The overall flow structure is characterized by a similar separation, transition, and reattachment process, albeit with varying levels of intensity and time scales. The tip vortex formation is distinguished by an initially laminar feeding sheet that separates from the underside of the wingtip and reattaches on the upper surface. As it continues to roll up towards the tip, a secondary separation ensues at advanced chordwise stations. As the wing plunges downward, this separation progresses forward towards the leading edge, which also leads to the inception of spiraling sub-structures in the feeding sheet that are entrained into the tip vortex periphery and are stretched longitudinally. Higher frequency and amplitude promote a more compact tip vortex core as the structure separates from a more upstream position. The location of separation balanced with the variation in adverse streamwise pressure gradient magnified within the tip vortex core, precipitate alternating moments of axial velocity wake- and jet-like profiles that persist well into the near-wake, where axial velocity fluctuations on the order of 60 percent of the free-stream speed are observed. Additionally, the near-field evolution of the tip vortex is augmented by a motion-induced wandering that becomes increasingly pronounced with more aggressive kinematics. Significant and growing vertical excursion are found with downstream location that far exceeded the initial offsets of the imposed wing motion. All cases develop spanwise excursions in the vortex trajectory leading to an induced orbital motion. The higher frequencies and amplitudes also promote dramatic tilting of the trajectory relative to its initial vertical motion. This unintended wandering may have serious implications for reliable vortex tracking based on wing position alone.

Garmann, D. J. and Visbal, M. R.

"ANALYSIS OF TIP VORTEX NEAR-WAKE EVOLUTION FOR STATIONARY AND OSCILLATING WINGS"

AIAA Journal, Vol. 55, No. 8, August 2017, pp. 2686-2702.

A numerical study is conducted to characterize the tip vortex unsteady evolution on a rounded-tip NACA0012 wing of aspect ratio $AR = 6$ operating at a Reynolds number of $Re = 200,000$ and an incidence of 8 deg. Stationary and plunging wing configurations are examined as representative

problems of aircraft wandering, wing vibration, or structural compliance that may all drastically affect the nature of the tip vortex and have important consequences in applications of formation flight, for instance. The high-frequency ($k = 2.09$), low-amplitude ($A = \pm 0.02c$) heaving motion of the wing promotes significant three-dimensionality of the overall flow structure with substantial variations in the tip vortex structure, including shear-layer substructure formation through enhanced separation and stretching, and alternating wake-like and jet-like behavior of its axial flow that leads to transitory enlargement or contraction of its core. The initial low-amplitude vertical displacement of the vortex grows dramatically as the structure advects into the wake, and a significant self-induced orbital motion results, which could be detrimental for downstream aerodynamic surfaces or for reliable vortex tracking in real-world applications. The dynamic state of the vortex as it leaves the wing is also shown to persist well into the wake.

Garmann, D. J. and Visbal, M. R.

"INTERACTIONS OF A TRAILING VORTEX WITH A DOWNSTREAM NACA0012 WING"

AIAA Paper 2017-3319, June 2017, Denver, CO.

A high-fidelity numerical study has been conducted to investigate the unsteady interactions of a trailing vortex impinging upon a downstream wing. Two NACA0012, rounded-tip wings of aspect ratio $AR = 4$ and Reynolds number $Re = 200,000$ are effectively simulated in tandem as a representative problem of formation flight or blade/vortex interactions. The unsteady velocity fluctuations and dynamic wandering of the lead wing's tip vortex are modeled and prescribed at the inflow of the subsequent follower wing simulations. The chosen model provides an extremely favorable match of the time-mean and turbulent nature of the vortex, while also supplying a simple mechanism for the unsteady characterization of tip vortices. The dynamic behavior of the modeled vortex as it convects and subsequently interacts with the downstream wing is also examined. This is in an effort to extend the findings of previous studies with analytically-defined incident vortices to more realistic and relevant conditions. Similar types of interactions are found here, including vortex-induced variations in effective angle of attack on the downstream wing that lead to upstream propagation of separation, transition, and reattachment inboard of impingement, and enhanced attached flow near the tip. The vortex evolves into a spiraling structure upstream of the wing that alternately deflects to the upper and lower surfaces. The buffeting behavior appears as a time-mean bifurcation of the incident structure with discrete vortices passing to either side of the wing. One distinguishing feature here, however, is that the incident vortex exhibits a definitive spiral-type breakdown preceding its impact on the wing, which differs slightly from the helical instability in lieu of flow reversal encountered in previous investigations. The predominant commonality of the flow topology with previous studies of various Reynolds numbers and with drastically different incident structures indicates the robust nature of these types of interactions, which is promising for future study. Vortex-induced upwash also led to a lift-to-drag ratio increase of 63% over the baseline wing alone, but the enhancement was also accompanied by more than twice the force and moment root-mean-squared fluctuations.

Garmann, D. J. and Visbal, M. R.

"UNSTEADY EVOLUTION OF THE TIP VORTEX ON A STATIONARY AND OSCILLATING NACA0012 WING"

AIAA Paper 2016-0328, January 2016, San Diego, CA.

A numerical study is conducted to characterize the unsteady evolution of a tip vortex formed on a NACA0012 wing with an aspect ratio of $AR = 6$ and rounded tip that is operating at a Reynolds number $Re = 200,000$ and incidence of 8° . Stationary and plunging wing configurations are examined as representative problems of aircraft wandering, wing vibration, or structural compliance that may all drastically affect the nature of the tip vortex and have important consequences in applications of formation flight, to name one example. The high-frequency ($k = 2.09$), low-amplitude ($A = \pm 0.02c$) heaving motion of the wing promotes significant three-dimensionality of the overall flow structure with substantial variations in the tip vortex structure, including shear layer substructure formation through enhanced separation and stretching, alternating wake- and jet-like behavior of its axial flow that leads to transitory enlargement or contraction of its core. The initial low-amplitude vertical displacement of the vortex grows dramatically as the structure advects into the wake, and a significant self-induced orbital motion also results, which could be detrimental for downstream aerodynamic surfaces or for reliable vortex tracking in real-world applications. The state of the vortex as it leaves the wing is also shown to persist well into the wake.

Garmann, D. J. and Visbal, M. R.

"INTERACTION OF A STREAMWISE-ORIENTED VORTEX WITH A WING"

AIAA Paper 2014-1282, January 2014, National Harbor, MD.

This work examines the interaction of a streamwise-oriented vortex impinging upon a wing for applications in formation flight. An analytically defined vortex superimposed on a free-stream is convected toward an aspect-ratio-six wing oriented at an angle of 4° and Reynolds number of $Re = 20,000$ in order to characterize the unsteady loading and induced vortex separation. Several spanwise positions of the vortex are analyzed and three distinct flow regions are found. When the vortex is positioned outboard of, but in close proximity to the wingtip, it pairs with the tip vortex to form a dipole that propels itself away from the plate due to its self-induced velocity and diffuses slowly. When the incoming vortex is aligned with the wingtip, the incident and tip vortex feeding sheets interact quite strongly and become entrained in the circulation of the opposite structure, which diminishes the coherence of both vortices into the wake. Finally, when the incident vortex is positioned inboard of the wingtip, the vortex bifurcates in the time-mean sense with portions convecting below and above the wing. The increased effective angle of attack inboard of impingement enhances the three-dimensional recirculation region created by the separated boundary layer off the leading edge which draws fluid from the incident vortex inboard and diminishes its impact on the outboard section of the wing. The slight but remaining downwash present outboard of impingement reduces the effective angle of attack in that region resulting in a small separation bubble on either side of the wing in the time-mean solution effectively unloading the tip outboard of impingement. All incident vortex positions provide substantial increases in the wing's lift-to-drag ratio; however, significant sustained

rolling moments also result. As the vortex is brought inboard, the rolling moment diminishes and eventually switches sign, indicating that small changes in vortex position can cause dramatic moment variations, which will require dynamic and responsive control systems.

Garmann, D. J. and Visbal, M. R.

"UNSTEADY INTERACTIONS OF A WANDERING STREAMWISE-ORIENTED VORTEX WITH A WING"

AIAA Paper 2014-2105, June 2014, Atlanta, GA.

The unsteady interaction of wandering streamwise-oriented vortex impinging upon a finite wing are examined using high-fidelity numerical simulation. The incident vortex is prescribed analytically upstream of an aspect-ratio-six wing and is defined with a sinusoidal variation in its spanwise position. Two wandering amplitudes are considered, $0.25c$ and $0.5c$, oscillating around a mean location measure $0.25c$ inboard of the wingtip at a normalized frequency of $f_c/(U \text{ sub infinity}) = 0.2$. The imposed lateral motion of the vortex spatially evolves as it approaches the wing by inclining relative to its initial horizontal trajectory and also diminishing in amplitude. Just ahead of the wing, both wandering amplitudes are reduced by 36 percent, and the horizontal trajectory inclined by nearly 38 and 53 degrees, respectively, for the initial wandering amplitudes of $0.5c$ and $0.25c$. This streamwise development of the incident vortex path has implications on the subsequent interaction with the wing, as the wing's streamwise position relative to the vortex self-induced motion dictates how the surface will be impacted. The vertical offset of the vortex core was also shown to drive an eventual pinch-off and alternating attachment to the upper and lower surfaces, which then evolved into a horseshoe-like structure before coalescing into a ring vortex and convecting into the wake. This contrasts with the pinch-off experienced by a stationary vortex impacting a wing, which is driven by a spiraling instability in the vortex core induced by the upstream influence of the wing that reorients the vortex ahead of the leading edge. The wandering vortices examined here exhibited no signs of the same spiraling undulation. This finding prevents conclusions about the flow structure engendered by a stationary vortex impingement from being generated in the more dynamic wandering vortex interaction. Despite the differing pinch-off mechanisms, the unsteady loading experienced by the wing is shown to fall within the bounds of the time-mean loading of the stationary impinging vortices.

Garner, H. C.

"THE EVALUATION OF DOWNWASH AT LARGE SPANWISE DISTANCES FROM A VORTEX LATTICE"

R&M 2808, Dec. 1950, Aeronautical Research Council, Great Britain

This note explains an improved numerical method of evaluating the contributions to the downwash at moderate or large spanwise distances from a vortex lattice. By allowing freedom of choice of the chordwise positions of the discrete vortices of the lattice, it is possible to select three definite chordwise positions and strengths of vortices at each of these positions dependent on the chordwise pressure distribution, so as to determine the downwash with good accuracy for three particular

pressure distributions proportional to $\cot(1/2 \theta)$, $\sin(\theta)$ and $\sin(2 \theta)$. The corresponding chordwise loading factors have also been evaluated for deflected flaps.

Garnet, M. and Altman, A.

"IDENTIFICATION OF ANY AIRCRAFT BY ITS UNIQUE TURBULENT WAKE SIGNATURE"

J. Aircraft, Vol. 46, No. 1, Jan.-Feb. 2009, pp. 263-268

The theoretical groundwork for the detection of any aircraft from its unique turbulent wake signature will be discussed, and practical methods to implement this theoretical result will be recommended. During the mid-1990's, NASA conducted research on the detection of atmospheric turbulence using light detection and ranging equipment. This light detection and ranging technology was able to detect turbulent disturbances by the Doppler shift in the frequency of laser-emitted energy that is scattered from atmospheric aerosols. Using this technology, the detection of turbulent disturbances physically created by the passage of aircraft through the atmosphere can be developed. In a military application, light detection and ranging turbulent detection would be able to spot the unconcealable turbulent disturbances caused by aircraft, thereby defeating current stealth technology. In addition, research suggests that turbulent wake generators (i.e., aircraft) have unique turbulent energy signatures. Using the principles of turbulent self-preservation, models can be created to predict both the Reynolds stress and momentum-defect signatures of aircraft as a function of their altitude and airspeed.

Garnier, F. and Laverdant, A.

"EXHAUST JET MIXING AND CONDENSATION EFFECTS IN THE NEAR FIELD OF AIRCRAFT WAKES"

Aerospace Science and Technology, Vol. 3, Issue 5, July 1999, pp. 271-280

To investigate the process of contrail formation, an integral model and a two-dimensional direct numerical simulation have been used to analyze the mixing and entrainment processes of the engine exhaust through their interaction with the vortex wake of various aircraft. The objective of this study is to evaluate the partial vapor pressure of water and temperature in the near field of subsonic and supersonic aircraft. Results are presented involving the saturation calculation by post-processing solution fields which provide a qualitative indicator of the condensation process. After testing the numerical algorithm with some success, this study was performed for three transport subsonic aircraft: A-330, B-737 and DC-9; for the twin-engine ATTAS of DLR and for the Anglo-French supersonic Concorde. For subsonic aircraft, in the early wake, the distance where saturation is reached depends only upon the engine jet characteristics. The engine jet location with respect to the vortex axis has an important influence on the mixing rate and on the saturation evolution. For the supersonic aircraft, a low saturation ratio has been shown along the plume centerline. The wing-tip vortices contribute largely to increase the mixing and dispersion of the exhaust plume. Consequently, the water saturation profiles are clearly changed by the vortical structure. Effects of the aerodynamic parameters are analyzed and discussed.

"MODELING EXHAUST JET DILUTION IN AIRCRAFT WAKES: APPLICATION TO THE CONTRAIL FORMATION"

ICAS Paper No. 98-2.10.1, Sept. 1998, Melbourne, Australia.

To investigate the process of contrail formation, an integral model and a two-dimensional direct numerical simulation have been performed to analyze the mixing and entrainment processes of the engine exhaust through their interaction with the vortex wake of various aircraft. The objective of this study is to evaluate the partial vapor pressure of water and temperature in the near field of subsonic and supersonic aircraft. Results are presented involving the relative humidity calculation by post-processing solution fields and provide a qualitative indicator of the condensation process. After testing the numerical algorithm with some success, this study was performed for three transport subsonic aircraft: A-330, B-737 and DC-9; for twin-engine ATTAS of DLR and for the Anglo-French supersonic Concorde. For subsonic aircraft, in the early wake, the distance where the saturation is reached depends only upon the engine jet characteristics. For the supersonic aircraft, a low relative humidity has been shown in the plume centerline. However, the wing-tip vortices contribute largely to increase the mixing and dispersion of the exhaust plume. Consequently, the persistence or evaporation processes is clearly changed by the vortical structure. Effects of aerodynamic parameters are analyzed and discussed.

"ENGINE EMISSION ALTERATION IN THE NEAR FIELD OF AN AIRCRAFT"

Atmospheric Environment, Vol. 31, No. 12, 1997, pp. 1767-1781

The objective of this paper, which constitutes a part of the AERONOX project, is the investigation of the potential transformation of the active species emitted from aircraft into reservoir species. The analysis is based on modeling of transformations of the near-field region, 1 km behind a Boeing 767 and a Boeing 747 aircraft. The processes considered are, firstly the dynamics of the jet flow and the jet-wing tip vortices interaction and secondly the potential chemical transformations of species such as NO, NO₂, HNO₂, HNO₃ and H₂SO₄. The wake dynamical processes are performed by using the 3D turbulent Navier-Stokes equations. Chemistry is calculated using a box model including the photochemical and heterogeneous reactions. In the jet flow, calculations have been performed for two engines CFM 56 and RB 211. Temperature fields and dilution profiles are compared. In the wake, the influence of the vortical motion on the inboard and outboard jet engines is shown. The chemical calculations show that there is a rapid disappearance of OH and HO₂ at the very beginning of the plume and simultaneous growth of HNO₂ and HNO₃. All the main chemical transformations are made in the hot jet flow. In the limits of the calculations, there is no significant chemical transformations during the first kilometer behind the Boeing 767, except for OH, HO₂ and CH₂O₂ whose concentrations appear highly dependent on the local exhaust NO_x concentration.

"MODELLING EXHAUST PLUME MIXING IN THE NEAR FIELD OF AN AIRCRAFT"

Ann. Geophysicae, Vol. 15, 1997, pp. 1468-1477

A simplified approach has been applied to analyze the mixing and entrainment processes of the engine exhaust through their interaction with the vortex wake of an aircraft. Our investigation is focused on the near field, extending from the exit nozzle until about 30 s after the wake is generated, in the vortex phase. This study was performed by using an integral model and a numerical simulation for two large civil aircraft: a two-engine Airbus 330 and a four-engine Boeing 747. The influence of the wing-tip vortices on the dilution ratio (defined as a tracer concentration) shown. The mixing process is also affected by the buoyancy effect, but only after the jet regime, when the trapping in the vortex core has occurred. In the early wake, the engine jet location (i.e. inboard or outboard engine jet) has an important influence on the mixing rate. The plume streamlines inside the vortices are subject to distortion and stretching, and the role of the descent of the vortices on the maximum tracer concentration is discussed. Qualitative comparison with contrail photograph shows similar features. Finally, tracer concentration of inboard engine centerline of B-747 are compared with other theoretical analyses and measured data.

"NUMERICAL SIMULATION OF LARGE-SCALE STRUCTURES IN EXHAUST JET/WAKE VORTEX MERGING"

AIAA Paper No. 2001-1039, Reno, NV, January 2001

This paper reports on a 3D temporal numerical simulation of the interaction between a jet flow and a trailing vortex. The simulation was performed from an experimental database of the vortex wake generated by a rectangular wing NACA0012 equipped with two jets beneath the airfoil. In this work, we focus on the 3D vorticity and scalar (initially included in the jet) fields in the vortex wake. The turbulence induced by the jet flow field interacts with the vortex, resulting in the large-scale structure generation outside the vortex core whereas the region very close to the core keeps its laminar state. The scalar field is subject to distortion and stretching inside the azimuthal vorticity tubes. The scalar concentration provides a reliable signature of where the helical instability occurs outside the vortex core. Later, the counter rotating vortices undergo a connection and consequently lose coherence in a very short time. The resulting scalar field concentrates then in small-scale eddies.

"ENGINE JET ENTRAINMENT IN THE NEAR FIELD OF AN AIRCRAFT"

International Colloquium CAO on Impact of Aircraft Emissions upon the Atmosphere, October 1996, Clamart, France.

A simplified approach has been applied to analyze the mixing and entrainment processes of the engine exhaust through their interaction with the vortex wake of an aircraft. Our investigation is

focused on the near field, extending from the exit nozzle to the beginning of the vortex phase (i.e. to about 20 seconds after the wake is generated). This study is performed by using an integral model and a numerical simulation for a two-engine large civil aircraft. The properties of the wing-tip vortices on the calculation of the dilution ratio (defined as a tracer concentration) have been shown. The mixing process is also affected by the buoyancy effect, but only after the jet regime, when the trapping in the vortex core has occurred. Qualitative comparison with contrail photography shows similar features. Finally, the distortion and stretching of the plume streamlines inside the vortices can be observed, and the role of the descent of the vortices on the maximum tracer concentration has been discussed.

"ABBREVIATED FULL-SCALE FLIGHT TEST INVESTIGATION OF THE LOCKHEED L1011 TRAILING VORTEX SYSTEM USING TOWER FLY-BY TECHNIQUE"

Report FAA-AFS-I-76-1, June 1972, FAA NAFEC, Atlantic City, NJ.

A brief flight test program was performed at the National Aviation Facilities Experimental Center (NAFEC) to investigate the time-history characteristics of the vortex system of a Lockheed L1011 airplane in terminal area-type operations using a 140-foot-high instrumented tower. Vortex rotational flow velocities were measured by hot-film anemometers, vortex flow visualization -- as outlined by tower-mounted smoke grenades -- was documented, and meteorological data was recorded. In addition, data on aircraft track, performance, and configuration were gathered. The test results show that: (1) the L1011 vortex system was more persistent and intense than that of other heavy jet transport (300,000 lb) aircraft tested by NAFEC, but did not persist for more than 2 minutes; (2) vortex dissipation was due primarily to vortex breakdown (bursting); (3) vortex core diameters were on the average about 5, 4 and 2 feet in diameter for the landing, approach, and takeoff configurations, respectively; (4) peak recorded tangential velocities were 126, 135, and 224 feet per second for these same respective configurations; (5) vortex lateral movement in-ground effect was approximately $(\pi/6.6)b$, above ground level; and (6) average vortex descent velocities approached 6 feet per second out of ground effect.

Garodz, L. J.

"INVESTIGATION OF THE RELATIVELY LONG TIME-HISTORY CHARACTERISTICS OF THE CV-880 AIRPLANE IN TERMINAL AREA-TYPE FLIGHT OPERATIONS"

FAA Data Report, Project 504-303-03X, November 1970, NAFEC, Atlantic City, NJ

The CV-880 vortex characteristics were investigated using the tower fly-by and aircraft-mounted vortex flow visualization techniques. Tests were performed in takeoff, landing and holding (clean) configurations. General results were (1) vortex characteristics; i.e., intensity, persistence, and movement followed the same pattern with regard to aircraft configuration effects as noted and reported on previously for other aircraft; (2) vortex lateral movement in ground effect was about 47 feet AGL which approximates $(\pi/8)b$ for the CV-880; (3) the automatic 8-degree spoiler deflection on

the top of the wing combined with landing flap deflection of 55 degrees appeared to assist in producing low V -theta and in accelerating vortex dissipation; (4) an ambient wind velocity of 3 to 7 mph appears to be most conducive to vortex persistence within the first 100 feet above ground for takeoff and landing configurations; (5) vortices changed from an orderly to a random, turbulent-type flow in less than 2 minutes with some degree of flap deflection; and (6) CV-880 vortices for the conditions of these tests, were considered to have dissipated to insignificant velocities in less than 2,500 feet lateral travel under crosswind conditions.

Garodz, L. J.

"INVESTIGATION OF JET TRANSPORT AIRCRAFT VORTEX SYSTEMS DESCENDING INTO AND GENERATED IN GROUND EFFECT"

FAA Data Report, Project 504-303-03X, November 1970, NAFEC, Atlantic City, NJ.

Flight tests were performed with B-707, B-727, DC-9 and CV-880 to investigate the characteristics of vortex systems generated within ground effect and those generated out of but descending into ground effect. The tower fly-by technique was used. Aircraft passed upwind of the tower in takeoff, holding and landing configuration with the latter on a 2.75-degree glide-slope at 20-, 40-, 60-, 80-and 100-foot altitudes above ground level (AGL). General results were (1) vortices generated by aircraft with some degree of flap deflection tended to become unstable and degenerate to discontinuous, segmented-type vortices or a random-type motion in about 90 seconds; (2) a pulsating axial flow appears to signal the onset of vortex core disintegration; (3) for identical ages, there appears to be a drop-off in vortex tangential velocities as they are generated closer to the ground; (4) airflow sensors which were spaced at 10-foot intervals on the 100-foot tower were too far apart; and (5) with the exception of the DC-9/B-727 aircraft, flap deflection had a significant effect on V (max, vortex structure and life-span. As with previous tests, DC-9/B-727 vortex characteristics appeared to be independent of aircraft configuration and produced the highest V -theta, about 200 feet per second for the B-727.

Garodz, L. J.

"FEDERAL AVIATION ADMINISTRATION FULL-SCALE AIRCRAFT VORTEX WAKE TURBULENCE FLIGHT TEST INVESTIGATIONS: PAST, PRESENT, FUTURE"

AIAA Paper No. 1971-0097, New York, NY, 197.

This is a brief summary/status report on flight test programs which are designed to gather quantitative data on aircraft vortex characteristics for air traffic control application. Aircraft tested to date include the Sikorsky S-58 helicopter; the Boeing 747, 727 and 707; the Douglas DC8-63, DC8-33 and DC9-10; the Lockheed C5A, C-141; and the Convair CV-880 aircraft. Future vortex investigation flight tests will include the Douglas DC-10, Lockheed L1011 and the Concorde aircraft. Test techniques discussed are the aircraft tower fly-bys, vortex penetrations with suitably instrumented probe aircraft and vortex probing with an airborne rake-type airflow measurement system suspended from a second aircraft.

Garodz, L. J.

"MEASUREMENTS OF BOEING 747, LOCKHEED C5A AND OTHER AIRCRAFT VORTEX WAKE CHARACTERISTICS BY TOWER FLY-BY TECHNIQUES"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 265-285.

Flight tests have been conducted by the FAA at both the ESSA/AEC facility, Idaho Falls, Idaho, and the NAFEC, Atlantic City, New Jersey, during the period 18 February 1970 through 3 August 1970 to gather quantitative data on aircraft vortex wake characteristics using the tower fly-by technique. Aircraft tested included the Boeing 747, 707-300, and 727-100; the Douglas DC-8-63F, DC-8-33, and DC-9-10; the Lockheed C5A; the Convair 880; and the Learjet 24. A 200-foot and a 100-foot tower was used at the ESSA and NAFEC test sites, respectively. Vortex flow velocities were obtained using hot-film/hot-wire sensors.

Garodz, L. J.

"MEASUREMENTS OF THE VORTEX WAKE CHARACTERISTICS OF THE BOEING 747, LOCKHEED C5A AND OTHER AIRCRAFT"

FAA Data Report, Project 177-621-03X, April 1970, NAFEC, Atlantic City, N.

Flight tests were conducted at the Environmental Services Sciences Agency (ESSA) Site, Idaho Falls, Idaho, to investigate the vortices of the Boeing 747, 707, 727, Douglas DC-8 and DC-9, and the Lockheed C5A using the tower fly-by technique and a 200-foot tower. Flow visualization was provided by smoke grenades on the tower. In addition, CORVUS smoke oil was used on the B-747 and B-707 for vortex marking. Three-dimensional airflow measurement hot-wire sensors were mounted at 25-foot intervals up the tower. Atmospheric measurements were performed by ESSA. These tests revealed that (1) vortex core diameters are much smaller (almost an order of magnitude) than certain existing theories predicted; (2) vortex characteristics are significantly affected by air plane configuration, except for the clean wing B-727/DC-9. For the former, the vortex tangential velocities decreased with an increase in flap deflection. For the latter, the tangential velocities were independent of airplane configuration. V_{max} was about 140 ft/sec for the B-747/707/C5A in clean/low flap setting configuration and decreased to 60-100 ft/sec for the landing configuration, full flaps; (3) the B-727 vortices produced a distinct artillery shell-type whine as they passed overhead; (4) the primary vortex dissipation mode appeared to be bursting; (5) the vortices persisted for less than 2 minutes regardless of aircraft and configuration.

Garodz, L. J.

"HELICOPTER FLIGHT TESTS -- WAKE STUDIES AND ENCOUNTERS"

DOT/FAA/CT-81/206, March 1982, FAA, Atlantic City Airport, NJ.

The report describes a proposed program for a full-scale flight test investigation of helicopter vortex wake and downwash flow fields and helicopter response to an aircraft trailing vortex.

Garodz, L. J. and Clawson, K. L.

"VORTEX WAKE CHARACTERISTICS OF B757-200 AND B767-200 AIRCRAFT USING THE TOWER FLYBY TECHNIQUE"

ERL ARL-199, Vol. 1 and 2, January 1993, NOAA Air Resources Lab., Idaho Falls, ID

The number of large wing-mounted twin-engine jet transport aircraft in operation in the National Airspace System (NAS) has significantly increased over the past few years. Very little is known about the vortex wake characteristics of these aircraft, particularly in takeoff and landing configurations. Since aircraft classification and Air Traffic Control (ATC) separation criteria in terminal area flight operations are based primarily on the aircraft vortex wake hazard, the FAA undertook a flight test program in the fall of 1990 to investigate the vortex wakes of the Boeing 757-200 and 767-200. The tests were conducted at the NOAA vortex test facility near Idaho Falls, Idaho. This report presents the results of the flight tests using the tower flyby technique. Included are characterizations of vortex wakes as a function of aircraft configuration and performance, and ambient atmospheric conditions. Very high vortex tangential velocities were created by the B757 aircraft, with the most intense vortex measured at 326 feet per second (fps). Vortex velocities generated by the B757 were approximately 50% higher than those of the B767 at similar vortex ages younger than 60 seconds. The oldest vortices generated by the B757 were much younger than those generated by the B767, and were 84 and 135 s, respectively. The most intense vortices were generated under stable or near-neutral atmospheric conditions. Richardson Number, air temperature gradient, and wind speed were good general indicators of the Vmax-vortex age envelope. The 3-degree glide slope did not produce vortices that were statistically significantly greater in intensity.

Garodz, L. J. and Clawson, K. L.

"VORTEX CHARACTERISTICS OF C5A/B, C141B AND C130E AIRCRAFT APPLICABLE TO ATC TERMINAL FLIGHT OPERATIONS TOWER FLY-BY DATA"

NOAA Tech Memorandum ERL ARL-190, August 1991, Air Resources Lab., Silver Spring, MD.

During the spring of 1987, NOAA conducted a full-scale flight test program to investigate the vortex wake characteristics of the 3 primary USAF Military Airlift Command jet transport aircraft, namely, the Lockheed C5A/B Galaxy, the C141B Starlifter, and the C130B Hercules. The tower fly-by technique was employed for vortex data acquisition purposes. The FAA subsequently commissioned NOAA to reexamine the data with the objective of extending the existing knowledge of vortex behavior in terminal area flight operations. The FAA was particularly interested in the application of the data to Air Traffic Control separation standards. This report describes the results of that effort. Of significance in the reexamination of the USAF data was the length of vortex persistence even under somewhat turbulent or unstable atmospheric conditions. Although no vortex ages older than 2 minutes were

observed in the anemometer data, visual observations of vortex-entrained smoke indicated that C5A/B vortices persisted for as long as 3 minutes. Correlation of the Richardson Number with vortex persistence indicated the difficulty of using this atmospheric turbulence as an indicator of vortex decay. The effect of the high wing configuration of all three aircraft and the T-tail configuration of two of the aircraft on trailing vortex system characteristics is also discussed.

Garodz, L. J. and Miller, N. J.

"INVESTIGATION OF THE VORTEX WAKE CHARACTERISTICS OF JET TRANSPORTS DURING CLIMBOUT AND TURNING FLIGHT"

FAA AEQ-75-1, May 1975, NAFEC, Atlantic City, NJ

The characteristics of the trailing vortices of several large propeller and jet transport aircraft have been investigated by the National Aviation Facilities Experimental Center (NAFEC), Atlantic City, N.J. This investigation centered around jet transport vortex persistence and movement during noise abatement-type departure operations at the Los Angeles International Airport and how approaching aircraft could avoid these vortices, however, it is concluded that the results and conclusions would be applicable to similar operations at other airports. The study is primarily based upon full-scale flight tests of vortex characteristics and their effect on encountering aircraft, conducted by NAFEC, NASA, Boeing, and the Royal Aircraft Establishment (RAE). Special flight tests for vortex investigations of the B-727 during noise abatement climb-outs, straightaway and turning flight, in takeoff and clean configuration are included. Vortex-generating aircraft included C5A, B-747, B-707, B-727, DC-7, CV-880 and Lincoln; vortex probe aircraft included CV-990, B-737, Learjet 23, DC-9 and Devon. A vortex avoidance zone was developed which has an active life of 2 minutes when below 5,000 feet above ground level and 2.6 minutes when higher than 5,000 feet above ground level.

Garodz, L. J. and Schutz, C. M.

"ANALYSIS OF LOW ATMOSPHERIC DENSITY WAKE TURBULENCE CHARACTERISTICS FOR JET TRANSPORT CATEGORY AIRCRAFT"

FAA Data Report, Project 177-621-04X, February 1968, NAFEC, Atlantic City, NJ.

The characteristics of the trailing vortices of several large jet transport aircraft operating at high altitudes at enroute speeds over the ocean were investigated by vortex flow visualization and penetration techniques. Flight tests were conducted from 29,000 to 38,000 feet. Vortex generators were a Lockheed C141, CV-880, Boeing C-135. Vortex penetrators included a C141, CV-880, Boeing C-135 and two specially instrumented Lockheed T-33 aircraft, one from National Aeronautical Establishment, Canada, and the other from NASA-Langley Research Center. Contrails were the primary means of vortex flow visualization except for the CV-880 wherein dumped dyed fuel was used. Separation distances between generator and penetrator ranged from 1,000 feet up to 8 nautical miles. It was found that (1) the contrails when they existed did indeed mark the trailing vortices for these model aircraft; (2) vortex turbulence induced on the probe aircraft ranged from moderate to severe; (3)

discrete vortices in the form of toroids, with high energy content, were observed and felt by the probe aircraft; and (4) compressor stall was experienced on three of the four C141 engines, and the fourth flamed out during an encounter at 1 nautical mile separation.

Garodz, L. J., Barber, M. R. and Kurkowski, R. L.

"FLIGHT TEST INVESTIGATION OF THE VORTEX WAKE CHARACTERISTICS BEHIND A BOEING 727 DURING TWO-SEGMENT AND NORMAL ILS APPROACHES"

FAA-NA-75-151, October 1975, FAA National Aviation Facilities Experimental Center, Atlantic City, NJ

A series of flight tests were performed to evaluate the vortex wake characteristics of a Boeing 727 (B727-200) aircraft during conventional and two-segment ILS approaches. Twelve flights of the B727, equipped with smoke generators for vortex marking, were flown wherein its vortex wake was intentionally encountered by a Lear Jet model 23 (LR-23) or a Piper Twin Comanche (PA-30); and its vortex location during landing approach was measured using a system of photo-theodolites. The tests showed that at a given separation distance there were no readily apparent differences in the upsets resulting from deliberate vortex encounters during the two types of approaches. Timed mappings of the position of the landing configuration vortices showed that they tended to descend approximately 91 meters (300 feet) below the flight path of the B727. The flaps of the B727 have a dominant effect on the character of the trailed wake vortex. The clean wing produces a strong, concentrated vortex. As the flaps are lowered, the vortex system becomes more diffuse. Pilot opinion and roll acceleration data indicate that 4.5 nautical miles would be a minimum separation distance at which roll control could be maintained during parallel encounters of the B727's landing configuration wake by small aircraft. This minimum separation distance is generally in scale with results determined from previous tests of other aircraft using the same roll control criteria.

Garodz, L. J., Hanley, W. J. and Miller, N. J.

"ABBREVIATED INVESTIGATION OF THE LOCKHEED L1011 AIRPLANE VORTEX WAKE CHARACTERISTICS IN TERMINAL AREA-TYPE OPERATIONS"

FAA Data Report, Project 214-741-04X, July 1972, NAFEC, Atlantic City, NJ

A brief flight test investigation was performed at the National Aviation Facilities Experimental Center (NAFEC) to investigate the time-history characteristics of the vortex system of the Lockheed L1011 Tri-Star jet transport airplane in terminal area-type operations using a 140-foot-high instrumented tower. Vortex rotational flow velocities were measured by hot-film anemometers, vortex flow visualization as outlined by tower-mounted smoke grenades was documented and meteorological data was recorded. Although only 19 tower fly-by passes were made, the test results showed that (1) the L1011 vortex system was more persistent and intense than other heavy jet transport (greater than 300,000 lbs.) aircraft tested by NAFEC but did not persist for more than 2 minutes; (2) vortex dissipation was primarily due to vortex instability (bursting); vortex core diameters were on the average of 5, 4 and 2 feet in diameter for the landing, approach and takeoff configurations, respectively; (4) peak-recorded

tangential velocities were 126, 135, and 224 feet per second for these same respective configurations; (5) a logarithmic model appeared to best describe the radial distribution of tangential velocities; (6) the upwind vortex was more intense and persistent than the downwind vortex for crosswind tests; (7) vortex lateral movement in ground effect was about $(\pi/6.6)b$ above ground level; and (8) average vortex descent velocities approached 6 feet per second out of ground effect.

Garodz, L. J., Hanley, W. J. and Miller, N. J.

"ABBREVIATED INVESTIGATION OF THE DOUGLAS DC-10 AIRPLANE VORTEX WAKE CHARACTERISTICS IN TERMINAL AREA-TYPE OPERATIONS"

FAA Data Report, Project 214-741-04X, August 1972, NAFEC, Atlantic City, NJ

The Douglas DC-10 Series 10 vortex characteristics were investigated using the tower fly-by technique. NAFEC's 140-foot-high vortex test tower was used. Hot-film airflow sensors at 1-foot intervals on the tower were used for tangential velocity measurements and smoke grenades for flow visualization. Wind velocity/direction and temperature were measured at 5 points on the tower. Twenty tower fly-bys were conducted in takeoff, approach, and landing configurations. Results indicated that (1) DC-10 vortex characteristics were similar to another wide-bodied jet, the L1011 which was previously tested; (2) multiple vortices were noted in the recorded data; (3) visually, vortex flow visualization revealed that the vortices underwent an instability mode and dissipated, primarily by bursting, in less than 2 minutes; (4) vortex tangential velocities of up to 192 feet per second were recorded (takeoff configuration); and (5) core diameters were relatively small - about 8 to 10 feet.

Garodz, L. J., Lawrence, D. M. and Miller, N. J.

"THE MEASUREMENT OF THE BOEING 747 TRAILING VORTEX SYSTEM USING THE TOWER FLY-BY TECHNIQUE"

FAA-RD-73-156, June 1974, NAFEC, Atlantic City, NJ

The characteristics of the trailing vortex system of the Boeing 747 airplane have been investigated by the National Aviation Facilities Experimental Center (NAFEC), Atlantic City, N.J., during a series of flight tests conducted in September and October 1972. This investigation is part of a long-term program, started in February 1970 with flight tests conducted by NAFEC at the Atomic Energy Commission site at Idaho Falls, Idaho, devoted to the study of the overall wake turbulence problem. The present tests were conducted using improved flow measurement and meteorological instrumentation, permitting greater resolution than had been possible in earlier testing. Principal findings were that the peak tangential velocity decays as the reciprocal of the square root of the time elapsed since vortex generation; that the peak velocity is unaffected by the throttling back of the adjacent outboard engine; and that the lateral transport velocities correlate quite well with theory. Vortex descent rates did not correlate with theory, being up to three times greater than theoretical values.

Garodz, L. J., Lawrence, D. M. and Miller, N. J.

"THE MEASUREMENT OF THE BOEING 727 TRAILING VORTEX SYSTEM USING THE TOWER FLY-BY TECHNIQUE"

FAA-RD-74-90, August 1974, NAFEC, Atlantic City, NJ

The results are presented of a series of low altitude (100-300 feet above ground level) flight tests performed at the National Aviation Facilities Experimental Center (NAFEC), Atlantic City, New Jersey, in which the trailing vortices of the Boeing 727 airplane were investigated, using a 140-foot tower instrumented with air velocity, direction, temperature, and humidity sensors. Flow visualization was also employed, using colored smoke streams and film records made. The airplane was tracked by the NAFEC Phototheodolite Facility. The data presented consists of plots of vortex tangential velocity distribution, peak tangential velocity as a function of time, airplane configuration, windspeed, and airplane altitude in proximity to the tower, vortex descent rates, lateral transport velocities, and specimen time histories of the velocities measured by individual sensors.

Garodz, L. J., Lawrence, D. M. and Miller, N. J.

"THE MEASUREMENT OF THE BOEING 707 TRAILING VORTEX SYSTEM USING THE TOWER FLY-BY TECHNIQUE"

FAA-RD-75-15, March 1975, NAFEC, Atlantic City, NJ

The results are presented for a series of low altitude (160-240 feet above ground level) flight tests performed at the National Aviation Facilities Experimental Center (NAFEC), Atlantic City, New Jersey, in which the trailing vortices of the Boeing 707 airplane were investigated using a 140-foot tower instrumented with airspeed, velocity, direction, temperature, and humidity sensors. Flow visualization was employed and motion picture records made. The airplane was tracked by the NAFEC Phototheodolite Facility.

Garodz, L. J., Lawrence, D. M. and Miller, N. J.

"MEASUREMENT OF THE TRAILING VORTEX SYSTEMS OF LARGE TRANSPORT AIRCRAFT USING TOWER FLY-BY AND FLOW VISUALIZATION (SUMMARY, COMPARISON AND APPLICATION)"

FAA RD-75-127, May 1975, NAFEC, Atlantic City, NJ.

Full-scale flight test investigations have been made of the characteristics, persistence and movement of the trailing vortices generated by propeller and jet transport aircraft. The tests were performed by NAFEC, Atlantic City, N.J., during the period 1970-1973 using tower fly-by and vortex flow visualization. The results are summarized and comparisons made of the vortices of the Douglas DC-10, DC-9, and DC-7; Boeing 747, 727 and 707; Lockheed C5A, C141, and L1011; and the Convair 880 aircraft. Vortex mathematical models and decay mechanisms are discussed and their effects (upset potential) on encountering aircraft are investigated for possible air traffic control application.

Garodz, L. J., Lawrence, D. M. and Miller, N. J.

"THE MEASUREMENT OF THE MCDONNELL-DOUGLAS DC-9 TRAILING VORTEX SYSTEM USING THE TOWER FLY-BY TECHNIQUE"

FAA-RD-74-173, November 1974, NAFEC, Atlantic City, NJ

The results are presented of a series of low-altitude (approximately 200 feet above ground level) flight tests performed at NAFEC, Atlantic City, N.J., in which the trailing vortices of the McDonnell-Douglas DC-9 airplane were investigated, using a 140-foot instrumented tower. Flow visualization (colored smoke streams) was employed and film records made. The airplane was tracked by the NAFEC phototheodolite facility. Data presented consists of plots of vortex tangential velocity distribution, peak velocity as a function of time, airplane configuration and wind speed, vortex descent rates, and lateral transport rates. Principal findings were that (1) within the time period 30-100 seconds after vortex generation, the peak velocities within the vortices were bounded by the function $V_{\theta} = 396 \exp(-.0347t)$, with a half-life of 20 seconds; (2) vortex cores were uniformly small (1-2 feet) in both configurations tested (takeoff and landing), and little or no growth with time was found; (3) vortex lateral transport velocities correlated well with the crosswind measured at 140 feet; and (4) the presence of a temperature inversion markedly retarded the vortex descent rates. The highest peak recorded tangential velocity was 120-130 feet per second, found to occur in both configurations tested.

Garodz, L. J., Miller, N. J. and Lawrence, D. M.

"THE MEASUREMENT OF THE DC-7 TRAILING VORTEX SYSTEM USING THE TOWER FLY-BY TECHNIQUE"

FAA-RD-73-141, November 1973, NAFEC, Atlantic City, NJ

This report describes the technique and presents the results of a series of full-scale flight tests performed at NAFEC in September 1971, in which the wing trailing vortices of the Douglas DC-7 airplane were investigated by flying the airplane at low altitude, upwind of, and in close proximity to a 140-foot instrumented tower. Tower instrumentation consisted of hot-film anemometers located at 4-foot intervals and wind velocity and direction sensors. Vortex air flow visualization was by use of colored smoke. The aircraft was tracked by the National Aviation Facilities Experimental Center's Phototheodolite Facility. The data consists of tangential velocity distribution plots, peak recorded velocity as a function of time, airplane configuration and wind; vortex vertical and lateral transport velocities, and specimen time histories of the velocities recorded at individual sensors. The principal findings were: (1) Peak absolute velocity, associated with the vortex core decays exponentially; (2) Vertical transport velocities of the vortices do not correlate well with those predicted by potential flow theory; (3) Lateral transport velocities correlate fairly well with values obtained from theory; and (4) The resolution possible with 4-foot spacing of the hot-wire anemometer is insufficient to precisely define vortex core size of the subject airplane.

"THE INFLUENCE OF HIGH-SPEED SPIV DATA PROCESSING PARAMETERS ON AIRCRAFT WING VORTEX WAKE ASSESSMENT"

31st Congress of the International Council of the Aeronautical Sciences (ICAS 2018), September 2018, Belo Horizonte, Brazil.

This paper uses Stereoscopic Particle Image Velocimetry (SPIV) data from the near wake of a detailed sub-scale 1/2 model of a representative transport aircraft wing with leading and trailing edge high lift systems and outboard aileron representation, to analyze the influence of data-sampling period and frequency on the magnitude and position of the vortices resolved within the wake. The paper also evaluates the extent of vortex 'wander' at various stages of development within the near wake and offers guidance for optimum time-averaging strategy when investigating complex longitudinal vortex interaction studies in similar flow fields.

Garten, J. F.

"AN INVESTIGATION OF THE EFFECTS OF ENVIRONMENTAL STRATIFICATION AND SHEAR ON THE EVOLUTION OF VERTICALLY-PROPOGATING VORTEX PAIRS"

Ph.D. Thesis, 1997, Univ. of Colorado, Boulder, CO

The trailing vortices which roll up behind an aircraft and descend downwards through the atmosphere can pose considerable danger to other nearby aircraft. There is therefore longstanding practical interest in how counter-rotating vortex pairs evolve under a variety of ambient conditions. The effects of stratification, mean shear, and turbulence on the evolution are of particular interest, as their dynamical consequences can result in a wide range of possibilities, from a vortex pair rapidly dissipating to coherent structure emerging and surviving for very long periods. The results of direct numerical simulations of vortex pairs evolving under a variety of ambient conditions are presented and analyzed here. It is shown that weak stratification can lead to acceleration of a laminar vortex pair, while strong stratification can result in a vortex pair not propagating a significant vertical distance before being dissipated while exciting a complex collection of internal waves. The high numerical resolution requirements of these direct numerical simulations make it impossible to include realistic turbulent effects; however, weakly imposed perturbations within the initial flow field of a vortex pair are found to lead to instability processes which significantly alter the evolution. A mean shear of uniform vorticity is found to result in the rotation of the vortex pair, and this rotation initiates an instability process which can potentially lead to the eventual emergence of a solitary vortex. The results of preliminary direct numerical simulations of fully three-dimensional vortex pairs are also discussed, and they indicate that three-dimensional processes such as the Crow instability and vortex ring formation occur on long enough time scales that some of the previously discussed two-dimensional effects (due to ambient stratification and/or mean shear) may in part or whole persist.

"DYNAMICS OF COUNTER-ROTATING VORTEX PAIRS IN STRATIFIED AND SHEARED ENVIRONMENTS"

J. Fluid Mech., Vol. 361, 1998, pp. 189-236

The evolution of a vertically propagating vortex pair in stratified and sheared environments is studied with a two-dimensional numerical model. We consider a range of Froude (Fr) and Richardson (Ri) numbers, and a limited number of Reynolds numbers (Re). We find that stratification causes the formation of counter-sign vorticity around each of the original vortices through baroclinic production. At higher Fr , this wake vorticity advects the primary vortices closer together, decreasing their separation distance and increasing their vertical propagation speed, as predicted by Crow (1974) and Scorer & Davenport (1970). For these higher values of Fr , the wake vorticity also participates in an instability of the primary vortex pair, with the direction of propagation of the pair oscillating about the vertical. We term this instability the vortex head instability to distinguish it from the jet instabilities to which the wake itself is also susceptible. At lower Fr , internal gravity wave radiation dominates, and the intensity and spatial coherence of each vortex is rapidly reduced. When a mean horizontal flow having constant shear is present in an unstratified fluid, we find that the vortices eventually rotate about one another with the same rotational sense as the background shear flow, as predicted in Lissaman et al. (1973). When stratification is also present, we find that the distribution of baroclinically generated wake vorticity is asymmetric, which sometimes leads to the emergence of a solitary vortex with the same sign as the background shear vorticity (depending on the values of Fr , Ri , and Re). Our limited survey of parameter space indicates that a solitary vortex emerges more rapidly for smaller values of Ri , smaller values of Fr , and/or larger values of Re .

"THE EFFECTS OF AMBIENT STRATIFICATION ON THE CROW INSTABILITY AND SUBSEQUENT VORTEX RECONNECTION"

Proceedings of Third International Workshop on Vortex Flows and Related Numerical Methods, ESAIM, Vol. 7, 1999, pp. 151-160

Discussed are the results of direct numerical simulations of three-dimensional anti-parallel vortex pairs evolving in ambient stratification for a range of Reynolds and Froude numbers. These results have relevance to both the study of aircraft trailing vortices, which can pose considerable hazard to following aircraft, and the general topic of vortex reconnection, an important process in fully-developed turbulence and other complex flows.

Garten, J. F., Werne, J., Fritts, D. C. and Arendt, S.

"DIRECT NUMERICAL SIMULATIONS OF THE CROW INSTABILITY AND SUBSEQUENT VORTEX RECONNECTION IN A STRATIFIED FLUID"

Journal of Fluid Mechanics, Vol. 426, January 2001, pp. 1-45.

The evolution of a vertically propagating three-dimensional vortex pair in ambient stratification is studied with a three-dimensional numerical model. We consider a range of Reynolds (Re) and Froude (Fr) numbers, and initialize the vortex pair in a configuration that promotes growth of the Crow instability (Crow 1970). The growth rate of the instability is Re dependent, and we present a method for extending Crow's model to predict this dependence. We also find that relatively strong ambient stratification (Fr less than or equal to 2) further alters the growth of the instability via advection by baroclinically produced vorticity. For all of our cases with Fr greater than or equal to 1 (including our unstratified cases where Fr goes to infinity), the instability leads to vortex reconnection and formation of a vortex ring. A larger Re delays the commencement of the reconnection, but it proceeds more rapidly once it does commence. We compute a reconnection time scale (t), and find that $t \sim 1/Re$, in agreement with a model formulated by Shelley et al. (1993). We also discuss a deformative/diffusive effect (related to yet distinct from the curvature reversal effect discussed by Melander and Hussain 1989) which prevents complete reconnection. Ambient stratification (in the range Fr greater than or equal to 1) accelerates the reconnection and reduces t by an amount roughly proportional to $1/Fr$. For some Fr , stratification effects overwhelm the deformation effect, and complete reconnection results.

"DEMONSTRATION OF RAPID-SCAN TWO-DIMENSIONAL LASER VELOCIMETRY IN THE LANGLEY VORTEX RESEARCH FACILITY FOR RESEARCH IN AERIAL APPLICATIONS"

NASA TM 74081, August 1977, NASA Langley Research Center, Hampton, VA

Tests were conducted to demonstrate a rapid scan two-dimensional laser velocimeter (LV) measurement technique for aerial applications research. The LV system is capable of simultaneously measuring both vertical and axial flow velocity components in a near or far field vortex system. Velocity profiles were successfully measured in the wake vortex of a representative agricultural aircraft model, with the vortex system rapidly transporting in ground effect. Results indicate that the laser velocimetry technique can provide quantitative information of wake vortex characteristics in ground effect.

Gartrell, L. R. and Rhodes, D. B.

"A SCANNING LASER-VELOCIMETER TECHNIQUE FOR MEASURING TWO-DIMENSIONAL WAKE-VORTEX VELOCITY DISTRIBUTIONS"

NASA TM-1661, May 1980, NASA Langley Research Center, Hampton, VA

A rapid scanning two-dimensional laser velocimeter (LV) has been used to measure simultaneously the vortex vertical and axial velocity distributions in the Langley Vortex Research Facility. This system utilized a two-dimensional Bragg cell for removing flow direction ambiguity by translating the optical frequency for each velocity component, which was separated by band-pass filters. A rotational scan mechanism provided an incremental rapid scan to compensate for the large displacement of the vortex with time. The data were processed with a digital counter and an on-line minicomputer. Vaporized

kerosene (0.5 micron to 5-micron particle sizes) was used for flow visualization and LV scattering centers. The overall measured mean-velocity uncertainty is less than 2 percent. These measurements were obtained from ensemble averaging of individual realizations.

Gasich, W. E.

"THE DOWNWASH DISTRIBUTION BEHIND A WING WITH AN ANGLE OF ATTACK DISCONTINUITY AT SUPERSONIC SPEEDS"

Aeronautical Engineer Thesis, June 1948, California Institute of Technology, Pasadena, CA.

Investigation of the downwash field behind a wing with an angle of attack discontinuity at supersonic speeds by use of linearized conical flow theory has shown the downwash to be of finite magnitude at all points in and behind the plane of the wing. The downwash at more than five chord lengths behind the wing was found to asymptotically approach the value of downwash calculated in the Trefftz plane. Behind the wing and in the span that is determined by the intersection of the Mach cones from the leading edge with the trailing edge, an inexplicable action of the downwash was found to exist. It was found that at the trailing edge the downwash was a 100 percent of that on the wing surface. At two chord lengths, the downwash was 83 percent. Upon moving aft, it was found that the downwash increased in magnitude and that at 10 chord lengths, it asymptotically approached the value at the Trefftz plane, namely 100 percent again. By considering an idealized missile configuration, it was found that roll-reversal was possible. The possibility of reversal was found to be almost entirely dependent upon the location of the control lifting surfaces with respect to one another. A brief reference to the sidewash field was made, since the values of sidewash were a natural outgrowth of the solution of the downwash field in the Trefftz plane. An elementary consideration of the sidewash field also showed a contribution to an induced rolling moment that tends to produce roll reversal.

"EXPERIMENTAL INVESTIGATION INTO ARTICULATED WINGLET EFFECTS ON FLYING WING SURFACE PRESSURE AERODYNAMICS"

Journal of Aircraft, Vol. 47, No. 5, September-October 2010, pp. 1811-1815.

The use of articulated winglets on a baseline swept wing configuration to influence the surface pressure aerodynamics of a model flying wing has been experimentally investigated in this Note. From the surface pressure data taken from the upper wing and winglet surfaces, there is a substantial influence of winglet dihedral position on the main wing surface pressure. The ability of this concept to adjust and tailor this aerodynamic loading toward the main wing tip may provide useful application to second-order performance and efficiency enhancements such as gust load alleviation.

"EXPERIMENTAL INVESTIGATION OF BISTABLE WINGLETS TO ENHANCE WING LIFT TAKEOFF CAPABILITY"

Journal of Aircraft, Vol. 46, No. 2, March-April 2009, pp. 647-655.

An experimental investigation into the use of a bistable winglet to enhance the lift characteristics of a wing transitioning from lower to higher subsonic flow speeds is presented in this paper. The concept centers around the use of a specifically designed composite winglet, manufactured with an unsymmetric layup, which, when increasingly loaded, snaps between two stable states. Initially, during low-speed operation, the winglet is fixed in one stable state that is specifically designed to be cambered, thus enhancing the lift capability of the wing. At higher dynamic pressures, the winglet snaps to a configuration more intuitive and conventional to current winglet design. Results presented in this paper show the concept to be viable at enhancing the lift produced by a swept wing as aerodynamic loading increases before snap-through. During snap-through, however, the absence of any method of controlling the snap-through process generated significant dynamic loading that was transmitted, unhindered, throughout the entire test rig.

Gausz, T.

"BLADE VORTEX INTERACTION PROBLEM AT HELICOPTER ROTORS"

Conf. on Modelling Fluid Flow (CMFF'03), 12th International Conf. on Fluid Flow Technologies, Sept. 2003, Budapest, Hungary.

The helicopter rotor blade excites a vortex system, which consists of bound, trailed and shed vortices. The trailed and shed vortices roll up to the blade tip vortex. This strong tip vortex has a remarkable induced velocity field, which can cause pregnant changes in the aerodynamic loads of the rotor blade. This tip vortex moves together with the ambient air masses. Arises a 'Blade Vortex Interaction' (BVI) problem when this tip vortex moves closely to a rotor blade. To get physically real induced velocity field a real vortex model with finite core must be applied.

"ANTENNA ARRAYS FOR RF-MEMS BASED 77 GHZ ON-BOARD WAKE VORTEX DETECTION SENSOR"

2nd International ITG Conf. on Antennas, INICA '07, March 2007, pp. 217-221

In this paper the first generation of transmit and receive antennas for an on-board wake vortex detection front end module at 76.5 GHz is presented. The antennas are realized with serially fed patch antenna arrays connected in parallel by a corporate feed network. The use of RF-MEMS phase shifters between the feed network and the 2D patch antenna arrays will, in a future integration step, allow for steering the receive antenna beam in discrete steps in the horizontal plane. The principle of operation of the front-end module and the design of both antennas are described. Simulated and measured results are presented to validate the design.

"THE EVOLUTION OF MICROPHYSICAL AND OPTICAL PROPERTIES OF AN A380 CONTRAIL IN THE VORTEX PHASE"

Atmospheric Chemistry and Physics, Vol. 12, 2012, pp. 6629-6643.

A contrail from a large-body A380 aircraft at cruise in the humid upper troposphere has been probed with in-situ instruments onboard the DLR research aircraft Falcon. The contrail was sampled during 700 s measurement time at contrail ages of about 1-4 min. The contrail was in the vortex regime during which the primary wake vortices were sinking 270 m below the A380 flight level while the secondary wake remained above. Contrail properties were sampled separately in the primary wake at 90 and 115 s contrail age and nearly continuously in the secondary wake at contrail ages from 70 s to 220 s. The scattering phase functions of the contrail particles were measured with a polar nephelometer. The asymmetry parameter derived from these data is used to distinguish between quasi-spherical and aspherical ice particles. In the primary wake, quasi-spherical ice particles were found with concentrations up to 160 per cubic cm, mean effective diameter D of 3.7 microns, maximum extinction of 7.0 inverse km, and ice water content (IWC) of 3 mg per cubic m at slightly ice-subsaturated conditions. The secondary and primary wakes were separated by an almost particle-free wake vortex gap. The secondary wake contained clearly aspherical contrail ice particles with mean D of 4.8 microns, mean (maximum) concentration, extinction, and IWC of 80 (350) per cubic cm, 1.6 (5.0) inverse km, and 2.5 (10) mg per cubic m, respectively, at conditions apparently above ice-saturation. The asymmetry parameter in the secondary wake decreased with contrail age from 0.87 to 0.80 on average indicating a preferential aspherical ice crystal growth. A retrieval of ice particle habit and size with an inversion code shows that the number fraction of aspherical ice crystals increased from 2 percent initially to 56 percent at 4 min contrail age. The observed crystal size and habit differences in the primary and secondary wakes of an up to 4 min old contrail are of interest for understanding ice crystal growth in contrails and their climate impact. Aspherical contrail ice particles cause less radiative forcing than spherical ones.

"ANALYSIS OF A WAKE TURBULENCE HAZARD IN USAF OPERATIONS (T-39 ACCIDENT)"

AFFDL-TM-75-19-FGC, January 1975, Air Force Flight Dynamics Lab; Wright-Patterson Air Force Base, OH. (for official use only)

Analyses related to the investigation of a T-39 accident are presented which appeared caused by an encounter with the wake of a DC-10. Wake propagation and dynamic encounter numerical simulations are compared to the pilots' statements and other relevant facts. The necessary existence of an inversion layer which could prevent the rapid descent of the DC-10 wake is also noted.

"EFFECT OF FRACTAL ENDPLATES ON THE WINGTIP VORTEX"

AIAA Paper 2018-1796, January 2018, Kissimmee, FL.

An experimental investigation was performed on the effect of fractal endplates on the wingtip vortex of a NACA 0012 semi span wing at a Reynolds number of 200,000. The endplates were obtained by introducing three different fractal patterns. Constant temperature anemometry and stereoscopic particle image velocimetry were employed to assess both the local flow properties as well as the spatial organization of the wingtip vortex. The results show that the introduction of a fractal endplate strongly affects both the geometry and the turbulence features of the vortex. In particular, it is found that the fractal geometry weakens the vortex by spreading the turbulent kinetic energy over a broader range of frequencies. We relate this loss of coherence to a faster dissipation of the vortex, thus paving the way to the employment of fractal endplates to reduce the hazard associated to such flow features.

"INTEGRATING UNMANNED AIRCRAFT EFFICIENTLY INTO HUB AIRPORT APPROACH PROCEDURES"

NAVIGATION: Journal of the Institute of Navigation, Vol. 60, No. 3, Fall 2013, pp. 235-247.

Future Aircraft Surveillance Application (ASA) systems for situational awareness applications (e.g., conflict detection and resolution, final approach and runway occupancy awareness, and airport surface situational awareness methods), airborne spacing applications, airborne separation applications, and self-separation applications will benefit from the introduction of Automatic Dependent Surveillance-Broadcast (ADS-B). An alternative ADS-B implementation, which transmits measurements from the Global Navigation Satellite System (GNSS) instead of aircraft state vectors and performance parameters in the current implementation, has been proposed previously to improve surveillance performance. This paper summarizes the proposed methodology, discusses its threat models and integrity aspects, and presents the initial flight test results of this alternative ADS-B implementation, along with a performance analysis.

"HEAT TRANSFER ENHANCEMENT BY DELTA-WING VORTEX GENERATORS ON A FLAT PLATE: VORTEX INTERACTIONS WITH THE BOUNDARY LAYER"

Experimental Thermal and Fluid Science, Vol. 14, 1997, pp. 231-242.

New data are presented that demonstrate a 50 to 60 percent enhancement of average heat and mass transfer for flow over a flat plate at low Reynolds numbers, using delta-wing vortex generators. The mechanisms responsible for the enhancement are determined, and a single parameter for estimating their effect is established. Using a straightforward method for evaluating this parameter from flow visualization data, optimal delta-wing geometries were found for Reynolds numbers of 600, 800, and 1000 based on wing-chord length. The results were also used to develop a clearer understanding of the interactions between the vortex and boundary layer. When a high-circulation vortex is placed near the edge of the boundary layer, it effectively thins the boundary layer; the vortex advects free-stream fluid into the temperature or species boundary layer. Vortices should be generated in a common inflow arrangement so that induced velocities keep the vortices near the boundary layer.

"INVESTIGATION OF THE DOWNWASH ENVIRONMENT GENERATED BY V/STOL AIRCRAFT OPERATING IN GROUND EFFECT"

Technical Report 68-52, July 1968, Dynasciences Corp., Blue Bell, PA.

Analytical methods are developed for determining the downwash environment generated by multirotor/propeller V/STOL aircraft configurations operating in ground proximity. These methods are utilized to compute rotor flow field and contaminant dust cloud characteristics (including particle density and size distributions) for the H-21, XC-142, X-22A, X-19A, and XV-5A aircraft. The effects of the contaminated atmosphere on pilot's visibility, ground equipment, and personnel are also determined for these aircraft. The theoretically predicted results are generally in good agreement with the limited test data. Additional full-scale test data are required to verify further the assumptions inherent in the theory.

George, R. and Yang, J.

"A SURVEY FOR METHODS OF DETECTING AIRCRAFT VORTICES"

ASME Paper DETC2012-70632, August 2012, Chicago, IL.

Wake vortices produced by the lifting surfaces of large aircraft can have catastrophic effects on aircraft that follow too close behind. Many incidents have been blamed on wingtip vortices in the past several decades. Therefore, vortex detection is important for enhancing airport productivity by allowing adoptive spacing and for increasing the safety of all aircraft operating around the airport by alerting controllers that hazardous conditions may exist near the runways. Many methods have been developed for detecting wake vortices. However, there is a lack of a literature review to summarize all the methods and compare their advantages and drawbacks. Thus, the purpose of this paper is to review these technologies and to summarize their strengths and weaknesses. There are two main methods available in the literature: active and passive detection methods. Active detection methods include LIDAR (LIGHT Detection and Ranging), RADAR (Radio Detection and Ranging), and SODAR (Sonic Detection and Ranging). Passive detection methods include microphone systems, opto-acoustic systems, and ultrasonic detection of circulation. Although vortex detection methods are available, due to military and scientific usage, many researchers are still investigating new methods that are more effective.

"WAKE VORTICES GENERATED BY AN AIRCRAFT FUSELAGE: COMPARISON OF WIND TUNNEL MEASUREMENTS ON THE TAK MODEL WITH RANS AND RANS-LES SIMULATION"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

The first objective of the present study is to identify the proper influence of the fuselage to the global wake of a complete aircraft. The second objective is to investigate the ability of different numerical approaches to properly compute the near-field wake. The selected geometry is a generic 4-engines civil aircraft, the TAK model of TUM, where windtunnel hot-wire measurements have been performed. On the one hand, the DLR realized RANS simulations using the TAU code. On the other hand, Cenaero performed RANS simulations using the Spalart-Allmaras model and unsteady RANS-LES computations by way of the standard DES model. The vorticity field in a plane located just behind the fuselage tail is studied; the different approaches capture successfully the three main wake vortices. The present investigation showed that for this low-Mach application, the spatial discretization has a larger influence on the solution quality than the turbulence modelling approach. Furthermore, for the angle of attack and the geometry considered, the DES approach produced a steady wake: in experiments, unsteady turbulent structures are present but they are far smaller in size than the large scales of the flow, so that the meshes used in DES were too coarse to capture those small fluctuations.

Georges, L., Bricteux, L., Duponcheel, M., Geuzaine, P. and Winckelmans, G.

"LES OF WAKE VORTICES IN GROUND EFFECT WITHOUT AND WITH WIND, AND ALSO COMPARING DIFFERENT MULTISCALE SUBGRID MODELS"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008.

Cenaero and the UCL performed LES calculations of a two-vortex system in ground effect. A two-vortex system placed close to the ground generated boundary layers at the ground due to the no slip condition. These boundary layers are subject to an adverse pressure gradient that finally leads to their separation. A secondary counter-rotating vortex system is then generated that interacts strongly with the primary one. In fact, the secondary vortices are first orbiting around the primary vortices and are prone to short-wavelength instabilities that grow quickly in time. Finally, these three-dimensional instabilities are trapped by the primary vortices so that a strong interaction occurs between both vortex systems, eventually leading to a complex turbulent flow. The first objective of the present study was to investigate the influence of the Reynolds number by increasing it to 20000, a Reynolds number that is expected to be high enough to be representative of very high Reynolds number configurations. This work was done using wall-resolved LES on a 33-million node non-uniform cartesian mesh and a fourth-order accurate finite differences incompressible flow solver. The second objective of the study was to investigate the influence of the atmospheric conditions. Keeping the Reynolds number unchanged, this was done by superimposing three-dimensional time-dependent turbulent winds to the initial vortex pair.

"LES OF TWO-VORTEX SYSTEM IN GROUND EFFECT (LONGITUDINALLY UNIFORM WAKES)"

AST4-CT-2005-012238, CENAERO, Charleroi, Belgium, October 2006

This document reports about the large eddy simulation (LES) of a two-vortex system in ground effect, at a Reynolds of 20000. Two 'wall-resolved' LES, using different sub-grid scale (SGS) models, have been performed. The results will show the importance of the SGS modeling on the vortex system evolution. First, a LES with a Smagorinsky model supplemented by a Piomelli damping function in the near-wall region is selected; the main reason being that this model is rather standard. Secondly, an advanced modeling strategy, based on an approach with flow scales discrimination, is investigated. This better method prevents the over-diffusive behavior of the classical Smagorinsky model in the vortex cores.

Georges, T. M.

"ACOUSTIC RAY PATHS THROUGH A MODEL VORTEX WITH A VISCOUS CORE"

Journal of the Acoustical Society, Vol. 51, No. 1, January 1972, pp. 206-209

Angular deflection and the formation of a line caustic are examined for acoustic waves passing through a cylindrical vortex with a viscous core. Ray paths are displayed in normalized form and appear to be applicable to the aircraft-wake problem as well as to long-distance sound propagation through synoptic weather features.

Gerhardt, H. A.

"WINGTIP VORTEX DEVICE FOR INDUCED DRAG REDUCTION AND VORTEX CANCELLATION"

US Patent 5,934,612, August 1999.

The present invention is a wingtip vortex device for induced drag reduction and vortex cancellation. The wingtip vortex device is an aerodynamic drag reduction system installed at the wingtips of an aircraft. The wingtip vortex device comprises an impeller located ahead of the wingtip chord, a wind turbine device located behind the wingtip chord, and an intermediate gear device for coupling the impeller with the wind turbine and/or for generating power. Thus, the wingtip vortex device is self-contained as the impeller is powered by the vortex-driven turbine. As a result, induced drag is reduced without requiring an external power source such as the aircraft propulsion system.

"NEAR WAKE BEHIND AN AIRFOIL WITH LEADING-EDGE FLOW CONTROL"

Journal of Aircraft, Vol. 42, No. 2, March-April 2005, pp. 561-568

The effect of leading-edge cylinder rotation on the near wake behind a NACA 0015 airfoil was investigated. The results show that 1) depending on the magnitude of the rotation speed, the structure of the vortical wake could be substantially modified and a variety of vortex-shedding modes (e.g., the regular Karman vortex-shedding mode and also its combination with a single vortex pairing in each half of vortex-shedding cycle, the nearly parallel vortex-shedding mode, and the locally and globally stable modes), in addition to the expected delay in the boundary-layer flow separation, were observed; 2) the

location of inception of the Karman-type vortex-shedding mode moved upstream with increasing cylinder rotation; 3) the frequency of the vortex shedding, or the number of shed vortices, decreased with increasing cylinder rotation; 4) the vortex strength was found to decrease with the cylinder rotation and was weaker than that of a baseline airfoil; and 5) the longitudinal spacing of the shed vortices was found to be a strong function of the cylinder rotation while the lateral spacing a weaker function. Moreover, the presence of a leading-edge rotating cylinder with no rotation rendered no noticeable increase in the wake width and drag. However, with an increase in cylinder rotation the separation of the boundary layer was delayed, and the wake width and deficit were reduced.

Gerontakos, P. and Lee, T.

"EFFECTS OF WINGLET DIHEDRAL ON A TIP VORTEX"

Journal of Aircraft, Vol. 43, No. 1, January-February 2006, pp. 117-124

The effect of winglet dihedral on the near-field tip vortex flow structure behind a swept and tapered NACA 0015 wing was investigated at $Re = 1.81 \times 100,000$. The winglet dihedral led to a significantly reduced (increased) peak tangential velocity and vorticity (core radius) compared to a baseline wing. The values of core circulation (core axial velocity) could be below or above the baseline-wing value, depending on the winglet angle, and exhibited a local maximum (minimum) at winglet dihedral = 0 deg. The inner region of the tip vortex flow exhibited a self-similar behavior for a wing with and with no winglet. The lift-induced drag was always reduced by the addition of a winglet. The negative dihedral was more effective in reducing the lift-induced drag compared to the corresponding winglet of positive dihedral. A large discrepancy in the lift-induced drag was, however, observed between the wake integral method and the classical lifting-line theory.

Gerontakos, P. and Lee, T.

"EFFECTS OF WINGLET DIHEDRAL ON A TIP VORTEX"

Journal of Aircraft, Vol. 43, No. 1, January - February 2006, pp. 117-124

The effect of winglet dihedral on the near-field tip vortex flow structure behind a swept and tapered NACA 0015 wing was investigated at $Re = 1.81 \times 100,000$. The winglet dihedral led to a significantly reduced (increased) peak tangential velocity and vorticity (core radius) compared to a baseline wing. The values of core circulation (core axial velocity) could be below or above the baseline-wing value, depending on the winglet angle, and exhibited a local maximum (minimum) at winglet dihedral = 0 deg. The inner region of the tip vortex flow exhibited a self-similar behavior for a wing with and with no winglet. The lift-induced drag was always reduced by the addition of a winglet. The negative dihedral was more effective in reducing the lift-induced drag compared to the corresponding winglet of positive dihedral. A large discrepancy in the lift-induced drag was, however, observed between the wake integral method and the classical lifting-line theory.

"NEAR-FIELD TIP VORTEX BEHIND A SWEPT WING MODEL"

Experiments in Fluids, Vol. 40, 2006, pp. 141-155

The near-field flow structure of a tip vortex behind a sweptback and tapered NACA 0015 wing was investigated and compared with a rectangular wing at the same lift force and $Re = 181,000$. The tangential velocity decreased with the downstream distance while increased with the airfoil incidence. The core radius was about 3% of the root chord regardless of the downstream distance and angle of attack less than 8 deg. The core axial velocity was always wake-like. The core circulation and total circulation of the tip vortex remained nearly constant up to $x = 3.5 \times$ root chord and had a ratio of 0.63. The total circulation of the tip vortex accounted for only about 40% of the bound root circulation. For a rectangular wing, the axial flow exhibited islands of wake- and jet-like velocity distributions with Core circulation/Total circulation = 0.75 and Total circulation/Bound root circulation = 0.70. For the sweptback and tapered wing tested, the inner region of the tip vortex flow exhibited a self-similar behavior for x greater than or equal to the root chord. The lift force computed from the spanwise circulation distributions agreed well with the force-balance data. A large difference in the lift-induced drag was, however, observed between the wake integral method and the inviscid lifting-line theory.

"ACTIVE TRAILING-EDGE FLAP CONTROL OF OSCILLATING-WING TIP VORTEX"

AIAA Journal, Vol. 44, No. 11, November 2006, pp. 2746-2754

The tip vortex generated by an oscillating NACA 0015 wing with a moveable trailing-edge flap was investigated at $Re = 1.65 \times 100,000$ by using a miniature triple hot-wire probe. Both positive and negative flap deflections, actuated at different start times, were tested. The negative flap motion was found to be most effective in displacing the vortex position with earlier actuation leading to larger vertical vortex displacements. Negative flap deflections strengthened the vortex, moved the centroid further outboard, decreased the peak vorticity, and increased the vortex size. The positive trailing-edge flap motion, however, resulted in a more concentrated tip vortex of reduced vortex strength located further inboard. The lift-induced drag was decreased (increased) for positive (negative) trailing-edge flap, compared to a baseline wing.

"ATMOSPHERIC IMPACT ON WAKE VORTEX DEVELOPMENT"

European Congress on Computational Methods in Applied Sciences and Engineering ECCOMAS 2004, Jyväskylä, Finland, July 2004

A robust wake vortex warning system needs to predict the decay and transport of aircraft vortices along the glide path. Besides a validated, real-time wake vortex transport and decay model, such a system requires highly resolved forecast and measurement data of meteorological quantities as vertical

profiles of wind, turbulence kinetic energy, eddy dissipation rate, and temperature. To this end, wake vortex forecasting and measuring campaigns have been accomplished. The objective was to test the components of the weather and wake vortex monitoring and prediction system as the local weather forecast model NOWVIV, the wake transport and decay model P2P, the lidar as a wake detecting and characterizing tool. NOWVIV predicts the profiles of wind, virtual potential temperature, and turbulent kinetic energy around the airfield for 24 hours. These profiles served as input for the wake transport and decay model P2P. P2P predicts probabilistic wake vortex behavior as a function of aircraft and environmental parameters in real time. Probabilistic components account for deviations from deterministic vortex behavior inherently caused by the stochastic nature of turbulence and vortex instabilities as well as uncertainties of environmental and aircraft parameters.

Gerz, T.

"TRAILING WAKE VORTICES IN THE ATMOSPHERE"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

The lecture focuses on the evolution of wake vortices in typical atmospheric environments. Most prominent weather factors for wake transport and decay are the runway-crossing wind, turbulence, wind shear, thermal stratification, and contact with ground. The impact of weather on the wake evolution is illustrated with examples of wake vortices in a convectively driven (i.e. thermally unstable) atmospheric boundary layer, in thermally stable and quiet air, and in wind shear flows (low-level jets). The most important finding is that the circulation decays in two phases, the slow turbulent diffusion phase (inherent to the vortices themselves) followed by a phase of rapid decay (triggered by atmospheric disturbances). At the onset of rapid decay, the second vorticity, which is produced by baroclinic forces or enhanced by stretching of turbulent eddies, is strong enough to exchange vorticity between the 2 main vortices. The wake vortex prediction and measurement campaign WakeOP in April and June 2001 at Oberpfaffenhofen, Germany, is introduced where, to the first time, a fully equipped wake vortex prediction and monitoring system has been employed. During the over-flights of a DLR research aircraft its vortices have been traced with three continuous-wave Doppler lidars to obtain correct trajectories and circulation values.

Gerz, T.

"WAKE VORTEX PREDICTION AND OBSERVATION: TOWARDS AN OPERATIONAL SYSTEM"

Proceedings 3rd ONERA-DLR Aerospace Symposium, Paris, France, June 2001, pp. S1-3/1-10

New wake-vortex related staggering procedures for approaching aircraft are sought which reduce the current separations and thereby relax airport capacity shortages but do not lower today's safety levels. Reduced aircraft separation distances seem feasible under most meteorological conditions, whilst keeping or even increasing the safety level. The paper summarizes the impact of the atmosphere on the wake vortex behavior and decay. It describes requirements of reduced separation systems and notes the properties of the systems which are currently under development or run under test

conditions. The wake forecasting and measuring campaign WakeOP is introduced which has been accomplished recently. During that campaign the trajectories and decay of the wake vortices of a particular aircraft flying with prescribed configurations have been predicted and measured under various meteorological conditions.

Gerz, T.

"WAKE VORTEX PREDICTION AND OBSERVATION IN THE ATMOSPHERE"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

DLR launched the project 'Wirbelschleppe' (German for wake vortex) to reduce the capacity bottlenecks at airports caused by wake vortex problems. The key feature of this development is a system that makes it possible to predict and observe aircraft wake vortices along the glideslopes of airports. Reduced aircraft separation distances seem feasible under most meteorological conditions, whilst keeping or even increasing the safety level. The starting point for this work is a precise understanding of the laws under which these vortices are created and decay. Numeric simulations of the flow fields behind aircraft show that wake vortices behave in different ways. How long they remain in the air and where they drift to depend on atmospheric conditions as well as the condition of the ground. Therefore, an effective prevention system will have to consist of two elements: a short-term, weather and wake forecast is necessary for the time and place of landing. In addition, the system will need to monitor the weather and the wakes and recognize particularly dangerous situations. This kind of concept would make it possible to adapt the landing distances to the weather conditions. The paper presents results from the recent wake forecasting and measuring campaign WakeOP. During that campaign the trajectories and decay of the wake vortices of a particular aircraft flying with prescribed configurations have been predicted and measured under various meteorological conditions. High resolution weather forecasting and wake predictions are operationally possible in real-time.

"DECAY CHARACTERISTICS OF SINGLE AND DOUBLE WAKE-VORTEX PAIRS IN DIFFERENT ATMOSPHERIC FLOW REALISATIONS"

ICAS 2006, Sept. 2006, Hamburg, Germany.

This study analyses the decay characteristics of aircraft wake vortices as observed in real atmospheric environments. It further assesses the capability and robustness of different wake topologies to trigger quick vortex decays in the atmosphere which, in turn, might alleviate the impact upon encountering aircraft. The analysis focuses on single and double vortex pairs and is based on data from lidar and numerical large-eddy simulations.

Gerz, T. and Ehret, T.

"WAKE DYNAMICS AND EXHAUST DISTRIBUTION BEHIND CRUISING AIRCRAFT"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 35-1 to 35-12

By means of a vortex-filament technique and large-eddy simulations dynamics are discussed which control the distribution of the exhaust of a subsonic aircraft under cruising conditions from the nozzle exit to the distance where the trailing vortex pair starts to collapse into turbulence. Emphasis is first put on the method; second on the initial roll-up process and the phenomenon of 'non-entrainment' of exhaust into the vortex cores. Third, the role of turbulence on the onset of the wingtip-vortex decay is considered; thereby it is distinguished between background atmospheric turbulence and turbulence stemming from the boundary-layer around the aircraft.

Gerz, T. and Ehret, T.

"WINGTIP VORTICES AND EXHAUST JETS DURING THE JET REGIME OF AIRCRAFT WAKES"

Aerospace Science and Tech., Vol. 1, No. 7, January 1997, pp. 463-474

By means of a vortex-filament technique and large-eddy simulations, the dynamics during the jet regime of the wake of a subsonic aircraft cruising in a stably stratified and turbulent atmosphere is simulated. Such issues as the roll-up process of the vortex sheet around the wings into the wingtip vortices, the effect of the vortices upon the deformation and displacement of the exhaust jets, and the resulting distribution of the exhaust, are addressed. It is found that the roll-up process already significantly displaces the exhaust jets. The evolving wingtip vortices attract the exhaust and collect it around the vortex cores. This entrainment is further controlled by the buoyancy force of the hot exhaust, whereas the body of the aircraft, as a source of circulation disturbance, has no significant influence. Histories of temperature and species concentration can be used to determine the duration of the jet regime which, for a cruising B-747 aircraft lasts for 20 +/- 2 s. During that time the temperature of the trapped exhaust decays to the ambient value, and then rises again. Likewise, the exhaust concentration drops to 0.03 percent of its initial value but then stays constant during the vortex regime. Throughout the jet regime, the species are inhomogeneously mixed around the vortex cores with half-moon shaped local maxima.

"THE WAKE VORTEX PREDICTION AND MONITORING SYSTEM WSVBS, DESIGN AND PERFORMANCE AT FRANKFURT AIRPORT"

ODAS 2008 9th Onera-DLR Aerospace Symposium, Oct. 2008, Chatillon, France, pp. 1-19.

The design and performance of the Wake Vortex Prediction and Monitoring System WSVBS are described. The WSVBS has been developed to tactically increase airport capacity for approach and landing on closely-spaced parallel runways. It is thought to dynamically adjust aircraft separations dependent on weather conditions and the resulting wake vortex behavior without compromising

safety. Dedicated meteorological instrumentation and short-term numerical terminal weather prediction provide the input to the prediction of wake-vortex behavior and respective safety areas. As a safety net a LIDAR monitors the correctness of WSVBS predictions in the most critical gates at low altitude. The WSVBS is integrated in the arrival manager AMAN of DLR. Within 66 days of performance test at Frankfurt airport it was found that the system ran stable and the predicted minimum separation times were correct. The capacity improving concepts of operation could have been used in 75% of the time. From fast-time simulations the eventual capacity gain for Frankfurt was estimated to be 3% considering the real traffic mix and operational constraints in the period of one month.

"WINGTIP VORTICES, TURBULENCE, AND THE DISTRIBUTION OF EMISSIONS"

AIAA Journal, Vol. 37, No. 10, 1999, pp. 1270-127.

By means of large-eddy simulations the decay of wingtip vortices and the distribution of the turbine exhaust under the influence of turbulence in a stratified atmosphere is discussed. It is distinguished between atmospheric turbulence and a random turbulent flow originating from the boundary-layer around the aircraft. The ambient turbulence is weak, anisotropic, and decaying with sizes of the most energetic eddies at the order of the separation between the two wingtip vortices. The boundary-layer turbulence is wrapped around the vortices with the maximum intensity at the core diameter. The atmospheric eddies disturb the parallel vortex tubes by advection. Once distorted at that scale, the vortex- induced velocities amplify the disturbance according to Crow's instability. The vortex tubes break up after about 1.5 minutes and form rings; the continuous trail of exhaust is reorganized in a row of single puffs. Without any atmospheric turbulence, the wake does not experience a sinusoidal instability but the parallel vortex tubes approach and start to dissolve after 2 minutes when they touch. The dissolution is triggered by the small-scale turbulent friction owing to the boundary-layer turbulence of the aircraft. The exhaust trail remains aligned along the flight track. The numerical data are compared to in-situ measurements.

Gerz, T. and Holzaepfel, F.

"WINGTIP VORTICES, TURBULENCE, AND THE DISTRIBUTION OF EMISSIONS"

AIAA Paper No. 1998-2856, June 1998, Albuquerque, NM.

By means of large-eddy simulations the decay of wingtip vortices and the distribution of the turbine exhaust under the influence of turbulence in a stratified atmosphere is discussed. It is distinguished between atmospheric turbulence and a random turbulent flow originating from the boundary-layer around the aircraft. The ambient turbulence is weak, anisotropic, and decaying with sizes of the most energetic eddies at the order of the separation between the two wingtip vortices. The boundary-layer turbulence is wrapped around the vortices with the maximum intensity at the core diameter. The atmospheric eddies disturb the parallel vortex tubes by advection. "AIRCRAFT WAKE VORTICES IN THE ATMOSPHERE"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 169-184

By means of large-eddy simulations dynamics are discussed which control the decay of the wake vortices of a subsonic aircraft under cruising conditions. The period between 1 second and several minutes of wake age is considered. The method is briefly introduced. Emphasis is put on the effect of turbulence on the decay process of the wingtip vortices; thereby it is distinguished between background atmospheric turbulence and turbulence stemming from the boundary layer of the aircraft. Some results of wake vortices measured during flight campaigns as well as results of large-eddy simulations of the convective atmospheric boundary layer are presented.

Gerz, T. and Holzaepfel, F.

"LES OF WAKE VORTICES IN A STRATIFIED AND TURBULENT ATMOSPHERE"

Proceedings of the International Wake Vortices Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 69-72

Results of large-eddy simulations (LES) of the wake flow induced by a large-bodied aircraft flying through a stably stratified and turbulent atmosphere are presented. Details of the dynamics in the Jet, Vortex, and Dispersion regimes are outlined and analyzed. In a stratified and weakly turbulent atmosphere, as typical at cruising altitudes, the organized wingtip vortices collapse in the period between 1.5 and 3 minutes. The vortices live about 3 minutes when small-scale intense turbulent friction from the boundary-layer turbulence of the aircraft erodes them slowly. The vortices start to break up after 1.5 minutes already when weak atmospheric eddies of the size of the wing span trigger a large-scale oscillatory (Crow) instability. More intense atmospheric turbulence, typical for the lowest 2 km of the atmosphere, destroys the vortices even earlier by direct interaction between the eddies and the vortices. For weak to moderate stratification the baroclinic torque at the vortex boundaries detains mass, thus leading to a decreasing distance between the vortex centers which, in turn, accelerates the flow. For strong stratification it is observed that the vortices first decelerate and then vigorously accelerate their descent.

"INFLUENCE OF ATMOSPHERIC TURBULENCE ON THE DEVELOPMENT OF AN IDEALIZED AIRPLANE WAKE: NUMERICAL STUDIES"

Impact of Emissions from Aircraft and Spacecraft Upon the Atmosphere, edited by U. Schumann and D. Wurzel, DLR-Mitteilung 94-06, Deutsche Forschungs- und Versuchsanstalt für Luft- und Raumfahrt, Köln, Germany, 1994, pp. 309-314

The effect of a turbulent, sheared, and stably stratified atmosphere on the wake behind a cruising aircraft is studied by means of Direct Numerical Simulation. An early and a late evolutionary stage of the wake are considered. In the early stage, the flow consists of a developed pair of trailing vortices of the Rankine type; the late stage is after collapse of the organized vortex pair leaving a patch of enhanced turbulence behind in the otherwise calm atmosphere. As a preliminary result it is found that atmospheric turbulence mixes efficiently (within seconds) at scales smaller than the vortex-core diameter. Consequently, the in-core pressure increases and trapped substances are released.

"THE DLR PROJECT WETTER AND FLIEGEN (WEATHER AND FLYING)"

Forschungsbericht 2012-02, 2012, DLR Research Centers Oberpfaffenhofen, Braunschweig, Göttingen and Hamburg, Germany.

This report compiles major results of the 4-year DLR Project Wetter and Fliegen. Contributing DLR institutes and facilities were the Institutes of Atmospheric Physics, Flight Systems, Flight Guidance, Robotics and Mechatronics, Aerodynamics and Flow Technology, Air Transportation Systems as well as DLR Flight Experiments and Systemhaus Technik. The aim was to contribute to safety and efficiency of tomorrow's air transportation by developing weather and wake vortex expert systems along with operational concepts for the air traffic management and control at airports and researching new sensors and delivering automated flight control and innovative flight crew information technologies for the aircraft. Deeper insights were gained into wake vortex physics, the consequences for wake-encountering aircraft and separation prediction, as well as the detection, tracking and prediction of adverse weather phenomena like thunderstorms and snow and icing conditions. New operational concepts for air traffic control and tools for flight systems have been developed and the expert systems have been assessed from a technological and economical perspective. Prototype systems have been matured towards different levels of technological readiness and have been tested and evaluated with human-in-the-loop simulations and in field campaigns in real environments. Building on these achievements the work will be continued in the forthcoming DLR Project Weather Optimized Air Traffic.

"TRANSPORT AND EFFECTIVE DIFFUSION OF AIRCRAFT EMISSIONS"

Journal of Geophysical Research D: Atmospheres, Vol. 103, Issue D20, 1998, pp. 25905-25913

The transport and effective diffusion of exhaust are analyzed in the wake flow of a large-bodied aircraft which flies through a stably stratified, sheared, and turbulent atmosphere. The analysis is based on data sets from large-eddy simulations of the wake in the atmosphere. Diffusion and dilution measures are obtained from a chemically inert species concentration. Most of the exhaust is concentrated and isolated in the two wing tip vortices (the 'primary wake'). However, as the vortices sink through a stably stratified atmosphere, a baroclinic torque develops between the vortices and the surrounding flow and detrains about 10 to 30% of the exhaust mass from the vortices into the ambient air (the well mixed 'secondary wake'). Consequently, the entrainment rates computed for the primary and secondary wakes differ by orders of magnitude. In the period between 1.5 and 3 min the vortices collapse into aircraft turbulence. The trapped emissions of the primary wake are now released and diffused by ambient turbulence and shear. After about 5 min the exhaust concentration has been diluted by 0.00002 and 0.00004 compared to the value at the nozzle exit for the primary and secondary wakes, respectively, and covers areas of about 50,000 m squared and 20,000 m squared. Under flow conditions typically found at cruising heights the emissions are diluted to background concentrations within 2 and 12 hours for wind shear between 0.002 and 0.01/s. The spatial plume extension does not exceed the lower mesoscale range (20 km horizontally and 0.3 km vertically). Good to excellent agreement is achieved between the numerical results and in situ measured data.

"ATMOSPHERIC IMPACT ON WAKE VORTEX DEVELOPMENT"

European Congress on Computational Methods in Applied Sciences and Engineering, ECCOMAS 2004, edited by Neittaanm, Rossi, Korotov, Odate, Periaux and Knorzer, July 2004, Jyvaskyla, Finland.

Wake turbulence is one of the main reasons for capacity problems at busy airports. Solutions for new aircraft staggering procedures are sought which relax the current separations but do not lower today's safety levels. It is hoped that wake vortex warning systems will contribute to such a solution. For setting up a wake vortex warning system, the knowledge of wake vortex behavior under varying meteorological conditions achieves utmost significance. This paper will illustrate the impact of atmospheric parameters on the transport and decay of trailing wake vortices shed by commercial aircraft. Moreover, the architecture and design of a wake vortex prediction and monitoring system for busy airports will be outlined. Finally, two wake-vortex measurement and prediction campaigns will be described where the major components of that system have been tested successfully.

"EUROPEAN PREDICTION AND MEASUREMENT CAMPAIGNS OF WAKE VORTICES AND METEOROLOGICAL PARAMETERS: DATASETS, QUALITY ASSESSMENT AND ACHIEVEMENTS"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

This talk highlighted the major outcomes of recent wake vortex campaigns in terms of forecasted and observed meteorological conditions and their impact on predicted and measured wake vortex transport and decay. The necessity of probabilistic approaches will be pronounced. The potential to reduce aircraft separations with the given quality of prediction and observation data and methods will be discussed.

Gerz, T., Holzaepfel, F. and Darracq, D.

"COMMERCIAL AIRCRAFT WAKE VORTICES"

Progress in Aerospace Sciences, Vol. 38, 2002, pp. 181-208

The paper discusses the problem of aircraft wake vortices. It presents a consolidated European view on the status of knowledge of the nature and characteristics of aircraft wakes and of technical and operational procedures of minimizing and predicting the vortex strength and avoiding wake encounters. Methodological aspects of data evaluation and interpretation, like the description of wake ages, the characterization of wake vortices, and the proper evaluation of wake data from measurement and simulation, are addressed in the first part. In the second part, an inventory of our knowledge is given on vortex characterization and control, prediction and monitoring of vortex decay, vortex detection and warning, vortex encounter models, and wake vortex safety assessment. Each section is concluded by a list of questions and required actions which may help to guide further research activities.

Gerz, T., Holzaepfel, F. and Stephan, A.

"AIRCRAFT WAKE VORTICES IN THE ATMOSPHERIC BOUNDARY LAYER"

18th Conference on Aviation, Range, and Aerospace Meteorology, January 2017, Seattle, WA.

This paper introduces wall-resolved large eddy simulations to investigate the behavior of wake vortices in ground proximity at a variety of wind conditions. The six considered strengths of wind, ranging between 0.5 and 4 times the initial wake vortex descent speed, w , include practically and theoretically significant wind speeds. A crosswind of $0.5w$ may lead to windward stall posing a potential hazard to subsequently landing aircraft, whereas theoretical considerations predict that at $4w$ the rebound of the luff vortex is completely suppressed. The same range of wind speeds is also used to investigate the effects of headwind and diagonal wind to discriminate between effects of environmental turbulence increasing with wind speed and the direction of the wind shear. It is shown that vortex ascent, descent, rebound and decay characteristics are controlled by (i) the interaction of the vortices with secondary vorticity detaching from the ground, (ii) the redistribution of vorticity of the boundary layer which is altering the path of the primary vortices by mutual velocity induction, and (iii) the interaction of the vortices with the environmental turbulence.

"RESEARCH TOWARDS A WAKE-VORTEX ADVISORY SYSTEM FOR OPTIMAL AIRCRAFT SPACING"

C. R. Physique, Vol. 6, 2005, pp. 501-523

Wake turbulence is a major concern for busy airports since it limits capacity. Solutions for new aircraft staggering procedures are sought which relax the current separations but keep safety on a high level. Systems which advise air-traffic control on wake-vortex behavior under present and expected weather conditions will, hopefully, contribute to such a solution. Knowledge on transport and decay of wake vortices in the atmosphere is presented. Concepts and designs of wake-vortex advisory systems in Europe and the USA are outlined. European wake-vortex measurement and prediction campaigns are described where the components of such systems have been tested successfully.

"POSSIBLE CAPACITY GAINS FOR A GENERIC AIRPORT USING DLR'S WAKE VORTEX PREDICTION AND MONITORING SYSTEM"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

We will present results of various studies on possible capacity gains for a generic and for Frankfurt airport when using a WVPMS (wake vortex predicting and monitoring system). We developed a WVPMS within DLR's project Wirbelschleppe and the EU-project ATC-Wake. Data from the measurement and forecasting campaigns in C-Wake (WakeOP, WakeTOUL) and AWIATOR as well as from the Memphis and Dallas-Fort Worth campaigns in the USA have been utilized to demonstrate the impact of forecasted and observed meteorological properties on minimum safe aircraft separations. It is shown that prediction and measurement of the runway-crossing component of the horizontal wind vector bears a robust potential to apply minimum aircraft separations at a generic single-runway airport. Moreover, for Frankfurt airport a preliminary study on the potential for reduced separations on single and parallel runways is presented. The results are based on four days of weather data predicted by NOWVIV, vortex evolution predicted by P2P (i.e., the forecasting part of the WVPMS) and simplifying assumptions for aircraft adherence to the glide path and potentially hazardous areas around vortex centers. We will close our presentation by illuminating the skills of local weather forecasting techniques today and tomorrow and their impact on improved wake vortex predictions as well as on an increase in punctuality of air transportation in general.

"THE WAKE VORTEX PREDICTION AND MONITORING SYSTEM WSVBS PART II: PERFORMANCE AND ATC INTEGRATION AT FRANKFURT AIRPORT"

Air Traffic Control Quarterly, Vol. 17, No. 4, 2009, pp. 323-346.

The performance and the ATC test integration of DLR's wake vortex advisory system, WSVBS, for the dependent parallel runways 25L and 25R at Frankfurt Airport are described. WSVBS has components to

forecast and monitor the local weather and to predict and monitor wake transport and decay along the glide paths. Integration with the DLR's arrival manager AMAN has also been demonstrated. Every 10 minutes the WSVBS delivers minimum safe aircraft separation times for the next hour, which are translated into operational modes for runways 25L/R aiming at tactically improving capacity to reduce delays. During a performance test described herein the system was stable and the predicted minimum separation times were confirmed by measurements. Capacity-improving wake-vortex separation concepts of operation could have been applied used in 75% of the time and continuously applied for at least several tens of minutes. From fast-time simulations the (strategic) capacity gain for Frankfurt was estimated to be 3%, considering the real traffic mix and operational constraints.

Gerz, T., Holzaepfel, F., Gerling, W., Scharnweber, A., Frech, M., Kober, K., Dengler, K. and Rahm, S.

"THE WAKE VORTEX PREDICTION AND MONITORING SYSTEM WSVBS PART II: PERFORMANCE AND ATC INTEGRATION AT FRANKFURT AIRPORT"

Air Traffic Control Quarterly, Vol. 17, No. 4, pp. 323-346.

The performance and the ATC test integration of DLR's wake vortex advisory system, WSVBS, for the dependent parallel runways 25L and 25R at Frankfurt Airport are described. WSVBS has components to forecast and monitor the local weather and to predict and monitor wake transport and decay along the glide paths. Integration with the DLR's arrival manager AMAN has also been demonstrated. Every 10 minutes the WSVBS delivers minimum safe aircraft separation times for the next hour, which are translated into operational modes for runways 25L/R aiming at tactically improving capacity to reduce delays. During a performance test described herein the system was stable and the predicted minimum separation times were confirmed by measurements. "AIRCRAFT WAKE VORTICES IN THE ATMOSPHERE"

Industrial and Environmental Applications of Direct and Large-Eddy Simulation, Lecture Notes in Physics, Vol. 529, Springer Verlag, 1999, pp. 83-92.

The studies summarized here were motivated by the need to gain information (i) about the impact of aircraft emissions upon the atmosphere and the climate and (ii) about optimized separation distances between aircraft landing at an airport for possibly increasing its capacity. To this end, large-eddy simulations have been performed to learn about the behavior of vortex wakes shed by cruising aircraft in the free atmosphere and in the atmospheric boundary layer close to the ground.

Gesich, W. E.

"THE DOWNWASH DISTRIBUTION BEHIND A WING WITH AN ANGLE OF ATTACK DISCONTINUITY AT SUPERSONIC SPEEDS"

Degree of Aeronautical Engineer, June 1948, California Institute of Technology, Pasadena, CA.

Investigation of the downwash field behind a wing with an angle of attack discontinuity at supersonic speeds by use of linearized conical flow theory has shown the downwash to be of finite magnitude at all points in and behind the plane of the wing. The downwash at more than five chord lengths behind the wing was found to asymptotically approach the value of downwash calculated in the Trefftz plane. Behind the wing and within the span that is determined by the intersection of the Mach cones from the leading edge with the trailing edge, an inexplicable action of the downwash was found to exist. It was found that at the trailing edge the downwash was a 100 percent of that on the wing surface. At two chord lengths, the downwash was 83 percent. Upon moving aft, it was found that the downwash increased in magnitude and that at 10 chord lengths, it asymptotically approached the value at the Trefftz plane, namely 100 percent again. By considering an idealized missile configuration, it was found that roll reversal was possible. The possibility of reversal was found to be almost entirely dependent upon the location of the control lifting surfaces with respect to one another..

"AIRCRAFT WAKE TURBULENCE MINIMIZATION BY AERODYNAMIC MEANS"

Sixth Conference on Aerospace and Aeronautical Meteorology, American Meteorology Society, 1974

The paper reviews NASA's efforts on wake vortex turbulence minimization by aerodynamic design or retrofit modifications to large transport aircraft. Theoretical and experimental (ground-based and flight) results are presented which show that the adverse effects of a vortex wake produced by a large aircraft on a small following aircraft can be reduced significantly.

Geurts, B. J. and Kuczaj, A. K.

"WAKE-VORTEX DECAY IN EXTERNAL TURBULENCE"

ERCOFTAC Workshop, Direct and Large Eddy Simulation VII, September 2008, Trieste, Italy, pp. 513-518.

In this paper we considered the role of external turbulence in the decay of two counter-rotating vortices. At sufficiently high turbulence levels the decay of kinetic energy was found to be strongly increased. Particularly, the large scales are considerably reduced, hence constituting an interesting option for future aircraft separation under sufficiently lively meteorological conditions. The prediction of the vortical decay with LES based on regularization modeling was shown to yield accurate capturing of the velocity skewness and the Taylor Reynolds number. The parametric study documenting the precise influence of external turbulence on vortical decay at realistic Reynolds numbers is subject of ongoing research.

"RNAV (GPS) TOTAL SYSTEM ERROR MODELS FOR USE IN WAKE ENCOUNTER RISK ANALYSIS OF DEPENDENT PAIRED APPROACHES TO CLOSELY-SPACED PARALLEL RUNWAYS"

DOT-VNTSC-FAA-14-05, February 2014, Volpe National Transportation Systems Center, Cambridge, MA.

The purpose of this memorandum is to provide recommended Total System Error (TSE) models for aircraft using RNAV (GPS) guidance when analyzing the wake encounter risk of proposed simultaneous dependent ('paired') approach operations to Closely Spaced Parallel Runways (CSPR, defined as having centerline spacing less than 2,500 feet). RNAV (GPS) is being evaluated as a source of guidance to aircraft approaching one or both runways of specific CSPR pairs, in lieu of or in addition to ILS guidance, for possible inclusion in future changes to FAA Order 7110.308 and/or in future orders authorizing Wake Turbulence Mitigation for Arrivals -- Procedure-based (WTMA-P).

"A STATISTICAL ANALYSIS OF THE AIRCRAFT LANDING PROCESS"

Journal of Industrial and Systems Engineering, Vol. 3, No. 3, 2009, pp. 152-169.

Managing operations of the aircraft approach process and analyzing runway landing capacity, utilization and related risks require detailed insight into the stochastic characteristics of the process. These characteristics can be represented by probability distributions. The focus of this study is analyzing landings on a runway operating independent of other runways making it as a single runway. We provide statistical analysis of the final approach and runway occupancy time at Detroit airport at peak traffic periods on one of its major landing runways. Many weeks of aircraft track record data collected by a multilateration surveillance system is analyzed. We explain some characteristics and short comings of the database, and extract samples of the random variables of interest (i.e. aircraft time and distance separation, runway occupancy time, simultaneous runway occupancy, and aircraft speed). We estimate probability distributions of these variables under both instrument and visual flight rules. Although the focus here is on one runway at a large airport, probability distributions of these random variables for the landings on similar single or independent runways (with similar physical design, operating systems and landing guidance instruments) shall be alike.

Gharakhani, A.

"A LAGRANGIAN VORTEX METHOD FOR GRID-FREE DYNAMIC LES"

AIAA Paper 2005-4625, June 2005, Toronto, Canada.

A vorticity-based method for the Large Eddy Simulation (LES) of inhomogeneous turbulent incompressible flow is presented. To this end, the dynamics of the resolved vorticity field are accounted for via a grid-free Lagrangian Vortex Element Method. Turbulence is modeled using a Lagrangian dynamic Smagorinsky Sub-Grid-Scale (SGS) model. The latter is a grid-free, particle-based adaptation of the Lagrangian dynamic model that was originally developed for the primitive variable formulation of the Navier-Stokes equations, and applied successfully to grid-based simulations of inhomogeneous turbulent flow. In this paper, the formulations and basic concepts associated with incorporating the dynamic LES model in the Vortex Element Method are outlined. In addition, the salient features of the grid-free model are demonstrated using preliminary results from the very early stages of jet flow into a quiescent environment at Reynolds number 4,000 based on the jet diameter and inlet velocity.

Gharakhani, A. and Stock, M. J.

"3-D VORTEX SIMULATION OF FLOW OVER A CIRCULAR DISK AT AN ANGLE OF ATTACK"

AIAA Paper 2005-4624, June 2005, Toronto, Canada.

A Lagrangian Vortex Method for grid free simulation of unsteady incompressible laminar flow over 3-D geometries is developed. To this end, the fluid velocity is discretized using singular vortex particles and its inviscid transport predicted in a Lagrangian frame of reference using smooth velocity and velocity gradients. Diffusion is accounted for via the application of a Vorticity Redistribution Method, which facilitates automatic insertion of new vortex particles as vorticity spreads out due to diffusion. The object boundaries are discretized with triangular panels, and the wall velocity boundary conditions

imposed by solving a Petrov-Galerkin discretization of the Fredholm boundary integral equation of the second kind for the vector-valued sheets at the wall. A parallel adaptive oct-tree code is used to accelerate the velocity (and gradient) evaluations due to the vortex particles and panels. This paper describes the developed algorithm briefly and presents results from the simulation of impulsively started flow over a circular discoid, with thickness equal to a tenth of its diameter and positioned at a 30-degree angle of attack. The Reynolds number based on the freestream velocity and the discoid diameter is 1,000 for this problem.

"INTERFERENCE EFFECTS OF A LARGE WING ON THE PERFORMANCE OF A TRAILING WING"

Journal of King Saud University, Vol. 7, 1995, pp. 77-92.

Interference of trailing vortices from a flapped large leading wing on a flapped small trailing wing is experimentally investigated. The effect of such wake turbulence is investigated through wind tunnel measurements of lift and drag forces and the pitching moment on the trailing wing. The threat of wake vortices was manifested in substantial reduction in the lift performance. Such reduction of lift was magnified as the leading wing flap angle increased, but without affecting the slope of the lift coefficient curves. The resulting shift of those curves resulted in delayed separation on the trailing wing to higher angles of attack. Within the domain of parameters used in the study, the trailing wing stall angle has roughly doubled when a large wing equipped with a 30-degree flap was placed in the leading position. The drag force had been reduced as the leading wing flap angle was increased. However, the trailing wing stability had not been harassed by such hazard.

"THE WAKE OF A SMALL-SCALE ROTOR IN FORWARD FLIGHT USING FLOW VISUALIZATION"

Journal of the American Helicopter Society, Vol. 40, No. 3, July 1995, pp. 52-65.

An experimental investigation was conducted in the 14- by 22-Foot Subsonic Tunnel at NASA Langley Research Center to quantify the rotor wake behind a scale model helicopter rotor in forward flight at one thrust level. The rotor system used in the present test consisted of a four-bladed, fully articulated hub and utilized blades of rectangular planform with a NACA-0012 airfoil section. A laser light sheet, seeded with propylene glycol smoke, was used to visualize the flow in planes parallel and perpendicular to the freestream flow. Quantitative measurements of vortex location, vertical skew angle, and vortex particle void radius were obtained for vortices in the flow; convective velocities were obtained for blade tip vortices. Comparisons were made between the experimental results and the wake geometry generated by computational predictions. The results of these comparisons show that the interaction between wake vortex structures is an important consideration for correctly predicting the wake geometry.

Ghee, T. A., Berry, J. D., Zorri, A. J. and Elliott, J. W.

"WAKE GEOMETRY MEASUREMENTS AND ANALYTICAL CALCULATIONS ON A SMALL-SCALE ROTOR MODEL"

NASA TP-3584, August 1996, NASA Langley Research Center, Hampton, VA

An experimental investigation was conducted in the Langley 14- by 22-Foot Subsonic Tunnel to quantify the rotor wake behind a scale model helicopter rotor in forward level flight at one thrust level. The rotor system in this test consisted of a four-bladed fully articulated hub with blades of rectangular planform and an NACA 0012 airfoil section. A laser light sheet, seeded with propylene glycol smoke, was used to visualize the vortex geometry in the flow in planes parallel and perpendicular to the free-stream flow. Quantitative measurements of wake geometric properties, such as vortex location, vertical skew angle, and vortex particle void radius, were obtained as well as convective velocities for blade tip vortices. Comparisons were made between experimental data and four computational method predictions of experimental tip vortex locations, vortex vertical skew angles, and wake geometries. The results of these comparisons highlight difficulties of accurate wake geometry predictions.

"STUDY OF TIP-VORTEX FORMATION USING LARGE-EDDY SIMULATION"

AIAA Paper No. 2005-1280, Reno, NV, January 2005

The formation of the tip-vortex from a rectangular NACA 2415 wing-tip at a chord Reynolds number of 10000 has been simulated. The simulations employ a parallelized compressible large-eddy simulation solver that has been developed to simulate wing and rotor tip-flows. The solver employs an immersed-boundary technique in conjunction with a curvilinear structured grid and the dynamic model is used to model the subgrid-scale stress terms. A detailed discussion of the tip-vortex formation and evolution in the near wake is presented.

Ghias, R., Mittal, R., Dong, H. and Lund, T. S.

"LARGE-EDDY SIMULATION OF THE TIP FLOW OF A ROTOR IN HOVER"

AIAA Paper No. 2004-2432, Portland, OR, June-July 2004

An efficient and flexible parallel version of a Large-Eddy Simulation (LES) solver has been developed to simulate the compressible tip-flow of a rotor in hover. The solver employs an immersed-boundary technique in conjunction with a curvilinear structured grid and the dynamic model is used to model the sub-grid scale (SGS) stress terms. The solver also employs a hybrid implicit-explicit time-discretization scheme wherein the diagonal viscous terms are treated implicitly and all other terms including the convective terms and cross-terms are treated explicitly using a low-storage third-order Runge-Kutta

scheme. A mixed second-order central-difference-QUICK scheme has been used which allows us to precisely control the numerical damping. Preliminary results from non-rotating tip-flow are presented.

"FLYING WING TRAILING VORTICES, REDUCING A TECHNOLOGICAL HAZARD"

Third LACCEI International Latin American and Caribbean Conference for Engineering and Technology, June 2005, Cartagena, Columbia.

The flying wing is being studied as one of the future promising concepts that could alleviate some problems of the air transportation system, for exhibiting better aerodynamics and reduction of fuel burn, pollution and noise than conventional aircraft; and for flying in unused flight levels. Hence, this configuration is receiving a great deal of attention from various perspectives: performance and control; passenger acceptance and evacuation; airport compatibility; etc. This paper addresses the problem of trailing vortices shed from the flying wing. All airplanes, in any part of the flight, produce an intense wake mainly characterized by a pair of counter-rotating vortices, originated at the wing tips. The wake thus formed is very severe, with induced velocities higher than those found in natural atmospheric turbulence, although it decays further downstream. This phenomenon obliges to maintain certain safety distances in take-off and landing maneuvers which, in its turn, imply a time-lag between subsequent operations imposing a limit on the number of movements per runway. For various reasons, in-flight encounters are rare. The present paper provides estimations of core size, induced velocities and other relevant features of the wake of the flying wing, and shows that it is far less hazardous than that of conventional aircraft of the same size.

Ghigliazza, H. H., Martinez-Val, R., Perez, E. and Smrcek, L.

"WAKE OF TRANSPORT OF FLYING WINGS"

Journal of Aircraft, Vol. 44, No. 2, March-April 2007, pp. 558-562

Flying wings are among the most promising concepts regarding the ever-increasing air traffic demand. They could help in improving economic efficiency and would be environmentally friendly, both in terms of emissions and noise. This paper addresses the problem of trailing vortices shed from the flying wing, arranged as a pair of counter-rotating vortex tubes as in conventional aircraft. The turbulence produced by the wake obliges airports to maintain certain time and distance separation between aircraft in takeoff and landing maneuvers, imposing a limit on the number of movements per runway. With the help of a simple model, the present paper provides preliminary estimations of circulation, core size, induced velocities, and other relevant features of the wake of transport flying wings and shows that it is less hazardous than that of conventional aircraft of similar size.

"AN EXPERIMENTAL INVESTIGATION OF WING-TIP VORTEX DECAY IN TURBULENCE"

Physics of Fluids, Vol. 29, 2017, pp. 037108-1 to 037108-10.

Particle image velocimetry measurements were conducted for a wing-tip vortex decaying in free-stream turbulence. The vortex exhibited stochastic collapse with free-stream turbulence present, with the breakdown initiating earlier for higher levels of turbulence. An increased rate of decay of the vortex tangential velocity was also observed, increasing with increasing free-stream turbulence. The decay of the vortex tangential velocity without the free-stream turbulence was well represented by viscous diffusion, resulting in an increase in the core radius and decrease in the peak tangential velocity. With the addition of free-stream turbulence, the rate of decay of the peak tangential velocity of the vortex increases, whereas the rate of increase of core radius remains unchanged. The circulation of the vortex decayed in time when immersed in free-stream turbulence, whereas it remained approximately constant when free-stream turbulence was not present. This decay in circulation was found to be almost entirely due to a decrease in circulation of the vortex core, caused by the relative decrease in the peak tangential velocity without a corresponding increase in the core radius. The scaling of the radial profiles of velocity and circulation was also examined, and it was found that, regardless of the free-stream condition, the core was scaled by the peak tangential velocity and core radius. The region outside the core did not scale with these quantities, and an alternative scaling for circulation is proposed which results in improved collapse of the profiles.

"NUMERICAL SIMULATION OF WAKE FLOWFIELD BEHIND THE C-130H CARGO RAMP"

AIAA Paper 2016-4182, June 2016, Washington, DC.

This effort reports the development of a systems engineering capability at the U.S. Army Natick Soldier Research, Development, and Engineering Center through virtual prototyping of airdrop systems based on high performance computing. Simulation results are presented for a C-130H aircraft configured to perform cargo airdrop operations. Flight operations with either the troop door or cargo door open lead to strong vortical flow structures and unsteady flows which can adversely affect airdrop operations and parachute deployments. The turbulent flow associated with the spiral-shaped slipstream formed behind a rotating propeller, prop wash, may also disturb airdrop operations. Thus, the simulation models of this work consider propeller effects by replacing them with actuator disks. Grid and time sensitivity studies are performed for each geometry to ensure numerical simulations are accurate for the separated and vortical flows. The results reveal that complex wake structures are formed behind the C-130 with the cargo door open. In particular, the wake contains two asymmetric counter-rotating vortices formed near the rear edges of cargo storage. The flow separates along these edges because of the sharp turn that flow makes as it enters inside cargo storage. The separated flow then rolls up into two vortices. These vortices move outward and upward and then pass very near the lower surface of the horizontal tail. These vortical flows will therefore cause significant unsteady air loads on the tail and thus aircraft. The wake effects are larger behind the upper cargo storage section and are minimum at the lower positions. Finally, the results show that as the grid becomes more refined behind the cargo storage, the localized wake structures and unsteady effects are better captured by the flow solver.

Ghoreyshi, M., Bergeron, K. and Lofthouse, A. J.

"NUMERICAL SIMULATION OF WAKE FLOWFIELD BEHIND THE C-130 WITH CARGO RAMP OPEN"

Journal of Aircraft, Vol. 55, No. 3, May-June 2018, pp. 1103-1121.

Simulation results are presented for a C-130 aircraft configured to perform cargo airdrop operations. Flight operations with the cargo ramp open lead to strong vortical flow structures and unsteady flows, which can adversely affect airdrop operations and parachute deployments. The results document complex wake structures formed behind the C-130 with the cargo ramp open at 0 and 50 percent flap settings. In particular, the wake contains two asymmetric counter-rotating vortices formed between the open ramp and the upsweep section of the aircraft and near the rear edges of the ramp. The flow separates along these edges because of the sharp turn that flow makes as it enters inside cargo compartment. The separated flow then rolls up into two vortices. These vortices move outward and upward, and then they pass very near the lower surface of the horizontal stabilizer. These vortical flows lead to unsteady air loads on the horizontal stabilizer, and thus the aircraft. The wake effects are larger behind the upper upsweep section and are minimum at the lower positions. Grid and time sensitivity studies are performed for several geometries to ensure numerical simulations are accurate for the separated and vortical flows. The results show that, as the grid becomes more refined in the region behind the upsweep section of the aircraft, the localized wake structures and unsteady effects are better captured by the flow solver.

"WELL-BALANCED, CONSERVATIVE FINITE DIFFERENCE ALGORITHM FOR ATMOSPHERIC FLOWS"

AIAA Journal, Vol. 54, No. 4, April 2016, pp. 1370-1385.

The numerical simulation of meso-, convective-, and microscale atmospheric flows requires the solution of the Euler or the Navier-Stokes equations. Nonhydrostatic weather prediction algorithms often solve the equations in terms of derived quantities such as Exner pressure and potential temperature (and are thus not conservative) and/or as perturbations to the hydrostatically balanced equilibrium state. This paper presents a well-balanced, conservative finite difference formulation for the Euler equation with a gravitational source term, where the governing equations are solved as conservation laws for mass, momentum, and energy. Preservation of the hydrostatic balance to machine precision by the discretized equations is essential because atmospheric phenomena are often small perturbations to this balance. The proposed algorithm uses the weighted essentially non-oscillatory and compact-reconstruction weighted essentially non-oscillatory schemes for spatial discretization that yields high-order accurate solutions for smooth flows and is essentially non-oscillatory across strong gradients; however, the well-balanced formulation may be used with other conservative finite difference methods. The performance of the algorithm is demonstrated on test problems as well as benchmark atmospheric flow problems, and the results are verified with those in the literature.

"ROTOR CONFIGURATIONAL EFFECT ON ROTORCRAFT BROWNOUT"

AIAA Paper No. 2010-4238, June-July 2010, Chicago, Illinois.

One of the major problems faced by rotorcraft undergoing aerodynamic maneuvers at low altitude in arid desert regions is in-flight visibility restriction due to the formation of dust clouds in the air. This phenomenon known as Brownout is caused by dust and sand particle entrainment into the air by the impinging downwash of the rotor. One of the various factors which influence the characterization of brownout is rotor configuration. This paper describes the analysis of rotor configurational (single-rotor, tandem-rotor, tilt-rotor, and quad-rotor) effect on ground footprint, wake and brownout using Computational Fluid Dynamics. In this study, the flow field is calculated by solving Reynolds averaged Navier-Stokes equation using the SIMPLER algorithm. To solve for turbulence properties, realizable kappa-epsilon equation is used. The rotor is modeled as momentum source whereas the dust behavior is solved using an Eulerian-based dust transport equation.

"BEHAVIOR OF A TRAILING VORTEX IN A FAVORABLE PRESSURE GRADIENT"

AIAA Journal, Vol. 1, No. 3, March 1963, pp. 705-706

The purpose of this study is the investigation of a streamwise vortex in low-turbulence channel flow, with particular attention to the high-shear region of the vortex core. Transverse-velocity profiles through the flow indicate that nearly discrete cylindrical vortex sheets are formed.

Gibbs, J.

"EXPERIMENTAL DETERMINATION OF LIFT AND LIFT DISTRIBUTIONS FOR WINGS IN FORMATION FLIGHT"

MS Thesis, January 2005, Virginia Polytechnic Institute and State University, Blacksburg, VA.

Experimental methods for the investigation of trailing vortex strengths, total lift, and lift distributions for three-dimensional wings in close-proximity flight were developed. With these experiments we model compound aircraft flight either docked tip-to-tip, or flying in formation. There is a distinct lack of experimental formation flight data using three-dimensional wing models for tests. The absence of fixed walls on either end of the wing permits the development of the asymmetric shedding of vortices, and the determination of the asymmetric circulation distribution induced by the proximity of the leading wing. The pair consisted of a swept NACA-0012 non-cambered wing simulating one half of a leading aircraft and a rectangular cambered NACA 63-420 wing simulating the trailing aircraft. Important aspects of the work included theoretical development, experimental setup, data acquisition and processing, and results validation. Experimentally determining the lift for formation flight, in addition to

the local flow behavior for a pair of wings, can provide valuable insight for the proposition of flying actual aircraft in formation to increase mission efficiency. To eliminate the need for bulky mounting stings and direct load measurement devices that can potentially interfere with the local flow field, a minimally invasive velocity probe method is developed. A series of experiments were performed to assist with the development of the method. Velocity and vorticity distributions obtained along a near-field plane were processed to calculate wingtip vortex strengths. Additionally, vortex position instabilities and the shedding of vorticity inboard of the wingtips were observed. To determine the circulation distributions for the trailing wing, the initial method is modified. By processing velocity information acquired in a near-field plane, both the lift and induced drag was calculated for the trailing aircraft. Comparisons are made to directly measured loads and to results reported earlier. Directly measured lift and drag coefficients were found to agree with existing literature.

Gibbs, J. D., Vlachos, P. P. and Telionis, D. P.

"EXPERIMENTAL DETERMINATION OF LIFT AND LIFT DISTRIBUTIONS FOR WINGS IN FORMATION FLIGHT"

AIAA Paper No. 2005-843, Reno, NV, January 2005.

Methods to experimentally determine trailing vortex strengths and spanwise circulation distributions for two wings in formation flight using a flow measurement probe are presented. With these experiments we model compound aircraft flight either docked tip-to-tip, or flying in formation. Data were collected for the case of a full wing trailing a larger wing. The absence of fixed walls on either end of the wing permits the development of asymmetric shedding of vortices, and the determination of the asymmetric circulation distribution induced by the proximity of the leading wing. The pair consisted of a swept NACA 0012 non-cambered wing simulating one half of a leading aircraft and a rectangular cambered NACA 63-420 wing simulating the trailing aircraft. Velocity and vorticity distributions obtained along a near-field plane were processed to calculate wingtip vortex strengths. Vortex position instabilities and the shedding of vorticity inboard of the wingtips were observed. Circulation distributions for the trailing wing are measured. Comparisons are made to directly measured loads and to results reported earlier. Directly measured lift and drag coefficients were found to agree with existing literature.

Gibson, J. S.

"NON-ENGINE AERODYNAMIC NOISE INVESTIGATION OF A LARGE AIRCRAFT"

NASA CR-2378, October 1974, Lockheed-Georgia Company, Marietta, GA.

A series of flyover noise measurements have been accomplished utilizing a large jet transport aircraft with engine power reduced to flight idle. It was determined that the aerodynamic (non-engine) noise levels did occur in the general range that had been predicted by using small aircraft (up to 17,690 kg gross weight) prediction techniques. The test procedures used are presented along with discussions of

the effects of aerodynamic configuration on the radiated noise, identification of noise sources, and predicted aerodynamic noise as compared with measurements.

Gierens, K. M.

"NUMERICAL SIMULATIONS OF PERSISTENT CONTRAILS"

Vol. 30, March 1995, Institut für Physik der Atmosphäre, Wessling, Germany

Numerical (2D) simulations of persistent contrails have been performed. The simulations begin in the vortex phase (i.e. when the aircraft wake dynamics are dominated by the pair of downward travelling vortices) and pursue the evolution for half an hour. It will be shown that the lateral expansion of a contrail is mainly horizontal when the air inside it assumes a constant potential temperature during the vortex phase as a result of thermal isolation from the ambient air. If, however, the air inside the contrail becomes stably stratified as a result of strong thermal contact with a stably stratified environment, the lateral expansion will be more isotropic. The cross section spreading rate ranges from 110-240 meters squared per second. The expansion is mainly caused by the secondary and higher order vortices that develop in the reaction of the atmosphere on the downward travelling pair of primary vortices which in turn are produced by the aircraft itself. Humidity and temperature of the ambient air control the growth of the ice particles and, therefore, all properties that depend on crystal size and the overall ice production rate. Radiative cooling and release of latent heat are thermodynamically inefficient and do not induce convective motions in the contrail.

Gierens, K. M. and Strom, J.

"A NUMERICAL STUDY OF AIRCRAFT WAKE INDUCED ICE CLOUD FORMATION"

Journal of the Atmospheric Sciences, Vol. 55, No. 21, November 1, 1998, pp. 3253-3263

Numerical simulations of ice cloud formation in the wake of an aircraft flying at cruise altitude have been performed. The engine exhaust has been excluded from the simulations in order to study cloud formation due solely to aerodynamic effects. The ice is formed via homogeneous freezing nucleation of ambient haze droplets in the upwelling limbs of the vortex pair behind the aircraft. Properties of wake ice clouds are compared with properties of contrails obtained within situ measurements and recent simulations. In particular, the authors find that aerodynamically induced ice clouds are similar in microphysical and radiative respects to contrails that are formed from the nucleation of exhaust particles. This means that under cold and moist conditions contrails as young as 2-5 min may consist of similar amounts of aerodynamically produced and exhaust triggered ice crystals.

Gilbert, G. A.

"BUSINESS JET ACCIDENTS FOCUS ON WAKE VORTEX"

Business and Commercial Aviation, Vol. 74, Issue 2, February 1994, p. 18

Investigators believe wake vortices from Boeing 757s may have caused at least four accidents or incidents involving GA aircraft. These include the fatal crashes of two business jets: a Citation at Billings, Montana in December 1992 and a Westwind at Santa Ana, California in December 1993. In January, the FAA instructed ATC to provide specific Boeing 757 wake turbulence advisories, and agency administrator David Hinton sent a letter to all U.S. pilots reminding them of wake turbulence avoidance guidelines.

Gilbert, G. A.

"FAA'S WAKE-VORTEX HANDLING PROMPTS INTERNAL REVIEW"

Business and Commercial Aviation, Vol. 75, Issue 3, September 1994, p. 16

An internal FAA/DOT review critical of the way the FAA disseminated information about wake vortices generated by Boeing 757s calls for several improvements - especially in the agency's handling of safety issues. Prompting the review was the FAA's failure to act on reports of possible B-757 wake turbulence problems as early as 1988 and again in 1992. The agency did not issue any warnings or increase separation standards for smaller aircraft flying behind B-757s until two fatal accidents in 1993 involving corporate jets.

Gilbert, T.

"AERODYNAMIC INFLUENCES DURING MINIMUM INTERVAL TAKEOFFS AND AERIAL REFUELING"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 12-1 - 12-10

The concept and purpose of the Minimum Interval Takeoff (MITO) is to get a large number of aircraft off the ground safely in a relatively short period of time. The military routinely performs MITOs with as little as 12 seconds between aircraft. This spacing between aircraft can vary, depending upon weather conditions, aircraft configuration (performance factors) as well as type of aircraft. The very things that make MITOs potentially hazardous are the reasons behind the safe separation concept - wing tip vortices. The effects of a MITO are actually felt during the takeoff roll. Airspeed fluctuations as high as 20 knots can be experienced due to the preceding aircraft's wake. Slight wing rock can occur but is easily controllable. Due to the preceding aircraft's climb rate, downwash effects are minimal and not noticeable to the following aircraft once airborne. Wing tip vortices, however, are a large problem and if not properly compensated for, can be disastrous possibly leading to the loss of control of the aircraft.

"WAKE INTEGRATION FOR THREE-DIMENSIONAL FLOWFIELD COMPUTATIONS: THEORETICAL DEVELOPMENT"

Journal of Aircraft, Vol. 36, No. 2, March-April 1999, pp. 357-373.

This paper examines the analytical, experimental, and computational aspects of the determination of the drag acting on an aircraft in flight, with or without powered engines, for subsonic/transonic flow. Using a momentum balance approach, the drag is represented by an integral over a crossflow plane at an arbitrary distance behind the aircraft. Asymptotic evaluation of the integral shows the drag can be decomposed into three components corresponding to streamwise vorticity and variations in entropy and stagnation enthalpy. These are related to the established engineering concepts of induced drag, wave drag, profile drag, and engine power and efficiency. This decomposition of the components of drag is useful in formulating techniques for accurately evaluating drag using computational fluid dynamics calculations or experimental data.

Gill, G. C.

"THE HELICOID ANEMOMETER, A LONG NEGLECTED BUT VALUABLE ANEMOMETER"

Atmosphere, Vol. 11, No. 4, 1973, pp. 145-155.

Although the helicoid anemometer has been known since 1887 (W. H. Dines) it was not until the 1940's that a rugged, accurate and reliable instrument was built (The Aerovane, by Bendix Friez). Some of the outstanding features of the helicoid anemometer are as follows: it is a primary sensor -- it is not essential to calibrate in a wind tunnel; its rate of turning is linearly proportional to wind speed over a wide speed range; some versions have a very low starting speed; and some helicoids, fixed in position, measure only that component of the wind that is parallel to the axis of the helicoid.

Gill, P. G.

"AVIATION TURBULENCE FORECAST VERIFICATION"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 13, 2016, Springer International Publishing Switzerland, pp. 261-284.

Forecast verification is an essential part of any forecast system. Verification results can be used in many ways: in the development process to ensure changes are leading to the desired improvements and to assure users and relevant authorities the forecasts have the required level of skill and can help to maximize the value a user gains from the forecast. In this section, we look at the challenges of verifying both deterministic and probabilistic turbulence forecasts. We investigate the different potential sources of truth data for use in verification with some discussion of the advantages and disadvantages of each. We also look at the possible methodologies and metrics that can be applied with some suggestions on the most appropriate ways to verify turbulence forecasts.

Gilliam, Jr., F. T.

"INVESTIGATION OF THE EFFECTS OF DISCRETE WING TIP JETS ON WAKE VORTEX ROLL UP"

Ph.D. Thesis, August 1983, Air Force Inst. of Tech., Wright-Patterson AFB, OH

A water tunnel experiment and a computational flow field model show that discrete wing tip jets can strongly affect the roll up of the wing tip vortex and apparently decrease its rolled up strength at moderate levels of blowing. The key factor in vortex alleviation was the extent of the local flow interactions between the discrete jets and the developing wing tip vortex. Vortex trajectory in both the spanwise and vertical directions was influenced by the jets. An outboard shift of the wing tip vortex indicated that discrete wing tip jets may be able to produce improved wing aerodynamics during cruise flight. The counterrotating pair of vortices generated by a jet in a cross flow were clearly seen in the water tunnel and appeared to be very effective in reducing the intensity of the wing vortex system. Two types of periodic secondary vortices were also observed in the water tunnel for heavy jet blowing. These were spin-off vortices which periodically developed in the rolling up tip vortex but rapidly spun outboard and above the wing; and entrained vortices which was a set of periodic vortices laterally connecting the wing tip vortex to the vortices embedded in the jet. These secondary vortices are oriented such that they will greatly accelerate the spreading of wake vorticity through the vortex stretching term of the Helmholtz equation. This influence was confirmed in the water tunnel tests.

"PARTICIPATION OF METEO-FRANCE IN WAKE VORTICES STUDIES"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

To reduce aircraft separation standards defined by ICAO, Meteo-France has developed different wake vortices studies, as requested by the STNA (Service Technique de la Navigation Aérienne). In the first study, the effect of crosswind on wake vortices trajectory is analyzed by using the VORTEX model, developed by CERFACS (Centre Européen de Recherche et de Formation Avancée en Calcul Scientifique). This model allows real-time evaluation of hazards associated with the wake vortices. The work has led to the definition of crosswind classes related to hazard duration, which corresponds to the time the two vortices stay inside the safety corridor (defined as the range <45 m from the runway axis). These classes depend on the number of runways and their distance. Regarding the configuration 'separation of 3NM on independent runway' two classes of crosswind are needed: smaller than 3 m/s and larger or equal to 3 m/s. The second study analyzes the evolution of wake vortices at small scale in 2D by using the French Meso-NH model, an atmospheric simulation code developed in cooperation between Meteo-France and the CNRS (Centre National de Recherche Scientifique). This model is initialized with the Idaho Falls experimental data. Different crosswind, stratification and wind profile are simulated for stable and mixed convective boundary layer. The work on the crosswind leads to about the same classes as with the VORTEX model. The VORTEX model could be improved in a further step by using the results on stratification and windshear.

Gilpin, T. J.

"A UK ASSESSMENT OF APPROPRIATE TECHNOLOGIES FOR DETECTING AND TRACKING WAKE VORTICES IN THE APPROACH AREA"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 51-1 - 51-20

In response to the signing of a Memorandum of Cooperation between the US FAA and the UK CAA on wake vortex research the UK was asked specifically to investigate technologies which might lead to a ground based real-time wake vortex detection and tracking unit. If the precise position and track of vortices in the approach area are accurately known then under some meteorological conditions it might be possible to safely decrease the separation and hence reduce delays in favorable conditions at runways. Initially three technologies were considered, laser, radar and sodar. A Memorandum of Cooperation was signed with the French DGAC who were supporting work on the detection of vortices by sodar leaving the UK to concentrate on laser and radar technology. This paper describes two recent field trials carried out in the UK using these technologies to attempt to detect wake vortices.

"LATERAL CONTROL REQUIRED FOR SATISFACTORY FLYING QUALITIES BASED ON FLIGHT TESTS OF NUMEROUS AIRPLANES"

NACA Technical Report No. 715, January 1941, Langley Memorial Aeronautical Laboratory, Hampton, VA.

An analysis has been made of the aileron control characteristics of numerous airplanes tested in flight by the National Advisory Committee for Aeronautics. In the correlation of satisfactory and unsatisfactory characteristics with measured values, it was found that the helix angle $pb/2V$, which expresses the lateral displacement of the wing tip in a given forward travel of the airplane, was the measure of the aileron effectiveness appreciated by the pilots. It was also found that regardless of size or category of the airplanes tested, which included pursuit, transport, training, and bomber types, a value of $pb/2V$ of 0.07 represented a criterion of minimum satisfactory aileron effectiveness. By the use of previously developed theory, the observed values of $pb/2V$ for the various wing-aileron arrangements were examined to determine the effective section characteristics of the various aileron types.

Gilson, W. H.

"RADAR MEASUREMENTS OF AIRCRAFT WAKES AT KWAJALEIN, R.M.I."

Airborne Windshear Detection and Warning Systems - Fifth and Final Combined Manufacturers' and Technologists' Conference, DOT/FAA/RD-94/14-II, Langley Research Center, Hampton, VA, July 1994, pp. 603-62.

A series of multi-frequency radar measurements of aircraft wakes at altitudes of 5,000 to 25,000 ft. were performed at Kwajalein, R.M.I., in May and June of 1990. Two aircraft were tested, a Learjet 35 and a Lockheed C-5A. The cross-section of the wake of the Learjet was too small for detection at Kwajalein. The wake of the C-5A, although also very small, was detected and measured at VHF, UHF, L-, S-, and C-bands, at distances behind the aircraft ranging from about one hundred meters to tens of

kilometers. The data suggest that the mechanism by which aircraft wakes have detectable radar signatures is, contrary to previous expectations, unrelated to engine exhaust but instead due to turbulent mixing by the wake vortices of pre-existing index of refraction gradients in the ambient atmosphere. These measurements were of necessity performed with extremely powerful and sensitive instrumentation radars, and the wake cross-section is too small for most practical applications.

"FEASIBILITY STUDY OF RADIOMETRY FOR AIRBORNE DETECTION OF AVIATION HAZARDS"

NASA/CR-2001-210855, June 2001, Georgia Tech Research Institute, Atlanta, GA.

Radiometric sensors for aviation hazards have the potential for widespread and inexpensive deployment on aircraft. This report contains discussions of three aviation hazards - icing, turbulence, and volcanic ash - as well as candidate radiometric detection techniques for each hazard. Dual-polarization microwave radiometry is the only viable radiometric technique for detection of icing conditions, but more research will be required to assess its usefulness to the aviation community. Passive infrared techniques are being developed for detection of turbulence and volcanic ash by researchers in this country and also in Australia. Further investigation of the infrared airborne radiometric hazard detection approaches will also be required in order to develop reliable detection/discrimination techniques. This report includes a description of a commercial hyperspectral imager for investigating the infrared detection techniques for turbulence and volcanic ash.

Ginevsky, A. S. and Zhelannikov, A. I.

"VORTEX WAKES OF AIRCRAFT"

Springer-Verlag Berlin Heidelberg, 2009 [English translation of book published by FIZMATLIT, Moscow, 2008].

This monograph covers the methods for mathematical modeling of vortex wakes behind aircraft at altitude and near the ground during takeoff and landing operations. The modeling is based on extensive use of the discrete vortex method and on the combination of this method with the integral method for computation of the turbulent boundary layer generated in the near-wall transverse flow induced by an aircraft's vortex system at takeoff and landing. In the latter case, the interaction between the aircraft's vortex wake and secondary vortices caused by boundary-flow separations is taken into consideration. The methods for simulation of the near and far vortex wakes of turbojet and propeller-driven aircraft are discussed separately. Examples of computed vortex wakes behind some Russian-built and Western aircraft are presented with due consideration for atmospheric turbulence, stratification and crosswinds at landing and takeoff. In modeling vortex wakes with the proposed methods the required computer execution time is three-four orders of magnitude less in comparison with known numerical methods. A nonlinear unsteady mathematical model is presented for predicting the motion of light aircraft encountering the vortex wake of a heavy aircraft and a possible severe upset of wake-penetrating aircraft. Computed data are compared with experimental results.

Gingras, D. R., Player, J. L. and Blake, W. B.

"STATIC AND DYNAMIC WIND TUNNEL TESTING OF AIR VEHICLES IN CLOSE PROXIMITY"

AIAA Paper No. 2001-4137, Montreal, Canada, August 2001.

Bihrlé Applied Research Inc. has developed unique capabilities for investigating the aerodynamic effects on aircraft in close formation. Wind-tunnel experiments were conducted at the Langley Full-Scale Tunnel using special hardware and computer equipment developed specifically for formation testing. It was demonstrated that static and dynamic force and moment data, as well as surface pressure data and wake survey data, can be acquired and utilized to analyze and model vehicle in close formation flight. The data acquired is well suited for use in flight vehicle simulation for development of control laws for automated formation flight and automated refueling. Unique to this wind tunnel testing was the simultaneous collection of force and moment data from two separate models positioned differently during each run. Also unique was the dynamic testing conducted to determine the control surface deflections required to trim the trail vehicle in various formation positions.

Giovannini, A. and Boisson, H.-C.

"DYNAMIC MIXED LES OF A VORTEX PAIR IN A TURBULENT CHANNEL"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

In order to determine the main features of an In-Ground-Effect vortex wake in a cross wind, Large-Eddy Simulations have been performed. The flow studied is a counter-rotating vortex pair evolving in a turbulent wall channel boundary layer. This study was developed to solve the test case retained for comparison for task 3.1.1-3 of the FAR-Wake project. The sub-grid scale model used is a Dynamic Mixed Model based on a double spatial filtering that takes account of energy backscatter in the interaction between resolved and unresolved turbulent fields. The numerical approach has been tested in a longitudinal vortex flow. First the transition to turbulence is simulated in the channel, and the vortex pair is introduced in the fully turbulent flow. Evolution of this vortex pair in the near wall region is analyzed. It is found that (1) for the upwind vortex when the wind velocity is low a rebound is active giving a weakening of the vortex hazard by 50 percent between non-dimensional time stations of 2 and 3, and (2) for the downwind vortex, the rebound is efficient for the axial flow equal to the decent velocity but it is inhibited for the axial flow equal to twice the descent velocity, due to a strong destruction process at shorter time. The weakening of the vortex hazard reaches 90 percent and the onset of this destruction process is earlier in time (between non-dimensional time of 1 and 3).

Giulietti, F., Innocenti, M., Napolitano, M. and Pollini, L.

"DYNAMIC AND CONTROL ISSUES OF FORMATION FLIGHT"

Aerospace Science and Tech., Vol. 9, Issue 1, January 2005, pp. 65-71

Two aspects of formation flight are addressed in this paper: dynamic modeling and formation control. In formation flight aircraft dynamics are coupled by aerodynamic effects due to the vortices leaving the lifting surfaces, such as changes in lift and drag forces and lateral/directional effects that do not appear in a steady-level 'isolated' flight. These aerodynamic effects are properly modeled with a three-dimensional code based on a Distributed Horse-Shoe Technique. A formation controller allowing both trajectory tracking and formation geometry keeping is then designed. It is shown that the designed controller yields satisfactory performance in a two-aircraft formation.

Giuni, M.

"FORMATION AND EARLY DEVELOPMENT OF WINGTIP VORTICES"

PhD Thesis, January 2013, University of Glasgow, Glasgow, Scotland.

Wingtip vortices are extremely important phenomena in fluid dynamics for their negative effects in many applications. Despite the many studies on this particular flow, the current understanding is still poor in providing a firm base for the design of effective tip geometry modifications and vortex control devices. A rectangular wing with squared and rounded wingtips was tested to identify the main mechanisms involved in the formation of the vortex on the wing and in its early development in the wake. The complementarity of several experimental techniques adopted, such as surface flow visualizations, wall pressure measurements, smoke visualizations, and stereoscopic particle image velocimetry (SPIV) gave a richer insight of the physics and the basic mechanisms of the vortex development. Furthermore, many configurations were tested exploring the effects of several parameters such as wing chord, aspect ratio, wingtip geometry, angle of attack and Reynolds number. The development of the vortex along the wing showed the formation of several secondary vortices which interacted with the primary vortex generating low frequency fluctuations. The structure of the flow at this stage was analyzed introducing a compact description through characteristic lines of the vortex system defined from the velocity vector field in the vicinity of the wing surface. The high spatial resolution achieved by the SPIV arrangement allowed a deeper understanding of the vortex structure in the early wake and the turbulence production and dissipation within the vortex core. The relaminarization process of the vortex core promoted by centrifugal motion was observed. The relation between vortex meandering, turbulence, secondary vortices, and wake sheet was discussed. A comparison of different methods for the averaging of instantaneous planar vector fields was performed showing the effects and importance of the meandering. An axial acceleration of the flow within the vortex was observed and the formation of different axial flow distributions was discussed. A minimum wake-like flow of 0.62 and a maximum jet-like flow of 1.7 times the freestream velocity were measured and a linear relation between a vortex circulation parameter and the axial velocity peak was found.

Giuni, M. and Benard, E.

"ANALYTICAL/EXPERIMENTAL COMPARISON OF THE AXIAL VELOCITY IN TRAILING VORTICES"

AIAA Paper No. 2011-0990, January 2011, Orlando, FL.

The axial velocity of a vortex is a parameter which is known to be strongly related to the vortex breakdown, yet to date a complete description of its physical origins has not been achieved. A series of experiments studying the vortex trailed from a NACA 0015 wing using stereoscopic particle image velocimetry is presented and the axial velocity studied in detail. The problem of centering the instantaneous vector fields is addressed showing a high sensitivity of the results from the centering method which is adopted. It is shown that a strong axial velocity excess exists and a linear relationship between the axial velocity and a circulation parameter of the vortex is shown. The experimental data are compared with the analytical descriptions of the velocity in the center of a simplified vortex giving new insights of the viscous effects in the development of the axial flow.

Giuni, M. and Green, R. B.

"VORTEX FORMATION ON SQUARED AND ROUNDED TIP"

Aerospace Science and Technology, Vol. 29, 2013, pp. 191-199.

The vortical flow originated from the tip of a NACA 0012 rectangular wing is described in its initial formation and development over a rounded and a squared tip. Smoke visualizations show the rolling-up kinematic and evolution of the vortical systems moving the plane towards the trailing edge. The presence of intense secondary vortices affects the primary vortex unsteadiness and shape during the formation and in the early wake. Stereoscopic Particle Image Velocimetry is used to describe vorticity, axial velocity, and turbulent kinetic energy distributions of the vortex during the formation and in the early wake at different angles of attack of the wing. The rolling-up of the vorticity sheet around the vortex system is strongly influenced by the vortex shape and the intensity of secondary vortices. Turbulence coming from secondary structures and shear layers is wrapped into the roll-up of the vortex and high levels of turbulence are measured in the vortex core. However, a laminar vortex core is observed for the lower angle of attack in the early wake. Comparing the meandering of the vortex for the two wingtip geometries, two different sources of the vortex fluctuation in the wake are identified: the interaction of secondary vortices moving around the primary vortex and the rolling-up of the vorticity sheet. Lastly, measurements in the wake of the wing at zero incidence are also presented showing a distinctive counter rotating vortex pair.

Giuni, M., Green, R. B. and Benard, E.

"INVESTIGATION OF A TRAILING VORTEX NEAR FIELD BY STEREOSCOPIC PARTICLE IMAGE VELOCIMETRY"

AIAA Paper No. 2011-0992, January 2011, Orlando, FL.

High spatial resolution experiments in the near field of a trailing vortex using a SPIV technique have been carried out. A particular attention on the measurement technique is presented highlighting the importance of the laser pulses delay between the two frames in a double-frame/single-pulse method and of the images processing characteristics in the evaluation of velocity profiles and turbulence quantities. The number of samples needed for the statistical convergence of the mean flow and the

turbulent quantities has also been found. A study on the vortex aperiodicity correction method has revealed how the instantaneous vector fields centering affects the velocity profiles across the vortex. The importance in the choice of the vortex quantity which is used for the vortex center detection is presented.

Gjessing, D. T., Hjelmstad, J. and Tønning, A.

"SYSTEM FOR DETECTION AND MEASUREMENT OF ATMOSPHERIC MOVEMENT"

US Patent 6,070,461, June 2000.

A system for the detection and measurement of atmospheric air movement irregularities such as wind velocity vector, wind shear, downdraft, clear air turbulence, aircraft induced vortices and turbulence, in particular along a glidepath near airports, whereby an air volume under investigation is illuminated by a radio wave transmitter with a beam of coherent electromagnetic energy and a resulting wave field is received and processed in processor means to derive information on the existence of said atmospheric irregularities and furthermore to give specific measurements of related parameters, comprising at least one receiver for said resulting wave field, which is due to scattering in said air volume, positioned at a bistatic location having a selected distance from said transmitter, characterized by acoustic transmitter means located between said transmitter and said at least one receiver, and adapted to emit acoustic waves into said air volume, with frequency and beamwidth of the acoustic waves chosen such that a resulting disturbance of the dielectric constant of air in said air volume, contributes to said scattering.

"RESULTS OF THE STUDY OF THE MIRAGE G8'S WAKE AT THE F2"

DERAT-20/5025AYD, November 1987, Centre d'Etudes et de Recherches de Toulouse, Dept. d'Etudes et de Recherches en Aerothermodynamique, Toulouse, France

A detailed presentation is given of results from the second round of trials at the F2 (wind tunnel) of the Mirage G8's wake. Additional laser measurements were made, as well as soundings using a four hot-wire probe. Although the distance between probe stations was large, an attempt was made to determine the different elements of the model's wake. [In French.]

Glotov, G. F.

"INTERFERENCE BETWEEN A VORTEX FILAMENT AND SHOCK WAVES IN FREE FLOW AND IN NONISOBARIC JETS"

Uchenya Zepiski TsAGI, Vol. 20, No. 5, 1989, pp. 21-32.

The interaction between a vortex filament generated by a wing cantilever at angles of attack of 5-20 degrees and shock waves in free stream (Mach 1.8-3.5) in an under-expanded jet (Mach 1.0) was

investigated experimentally in the relative pressure range of 1.5-7. It is shown that the interaction between the vortex filament and a central shock wave in the jet leads to the formation of a freely suspended recirculation zone. Vortex breakdown limits are determined for a jet, a convergent nozzle, and supersonic flow at conical shock waves of maximum intensity.

"A COUPLED PROBABILISTIC WAKE VORTEX AND AIRCRAFT RESPONSE PREDICTION MODEL"

NASA-TM-2016-219193, May 2016, NASA Langley Research Center, Hampton, VA.

Wake vortex spacing standards along with weather and runway occupancy time, restrict terminal area throughput and impose major constraints on the overall capacity and efficiency of the National Airspace System. The National Aeronautics and Space Administration has been conducting research on characterizing wake vortex behavior in order to develop wake decay and transport prediction models. This paper presents a methodology for the development and integration of probabilistic wake vortex model with an aircraft response model for air traffic management applications. The two modules of the proposed system 1) probabilistic wake prediction, and 2) aircraft response to wake vortex encounter, are evaluated independently using data from field experiments and wind tunnel tests with favorable results. The methodology as described in this report is well-suited for systems-level design and safety analysis of new advanced air traffic management concepts as well as forensic reconstruction of accidents due to inadvertent wake encounters. It is also envisioned that at a later stage of maturity, these models could potentially be used operationally, in ground-based spacing and scheduling systems as well as on the flight deck.

Glushkov, N. N.

"ON DECREASING THE DIMENSION OF UNSTEADY AERODYNAMIC PROBLEMS FOR LOW SUBSONIC SPEEDS"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 151-163

The possibility has been investigated of a simplification of computing unsteady aerodynamic characteristics of an aircraft encountering the zone of disturbances behind a wake-generating aircraft. To model the unsteady aerodynamics of aircraft, the discrete vortex method was chosen. The problem of computing unit step functions for thin lifting surfaces in incompressible fluid was considered in a linear formulation. It was shown that the increments of aerodynamic forces due to vortex shedding into the flow are determined by velocity changes in the vicinity of the leading edge. This circumstance allows one to decrease the dimension of the problem and reduce it to the computation of the wing's aerodynamic loading in a steady flow, but with the section twists varying in time. Examples of the unit step functions' computations for wings are presented. Exact solutions were obtained for two-dimensional flow and a comparison was made between them and theoretical results. Corresponding

integral equations were obtained for the derivatives of unit step functions when passing from discrete vortex distributions to continuous ones. [In Russian.]

Glushkov, N. N.

"APPLICATION OF THE EQUIVALENT FORM METHOD TO THE PROBLEMS OF UNSTEADY AERODYNAMICS"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 185-191

The potentialities of simplifying the algorithms for computing unsteady aerodynamic characteristics are considered. The linear discrete vortex method is used. The flow is assumed incompressible. The case is considered of a stepped change in boundary conditions at a lifting surface, which necessitates calculating transient functions. The time changing of aerodynamic loads on the wing is connected with corresponding changes in the form of an equivalent wing immersed in a uniform flow. The wing aerodynamic loads are shown to be only dependent on the time changing of the sectional twist angles of the equivalent wing. The forms of the wing chordwise sections are not changed. Because of this the problem dimensionally is reduced by one geometric variable. This substantially simplifies the computation of unsteady loads at low flight speeds (in takeoff and landing).

Glushkov, N. N., Dyachevsky, A. P. and Mikhailov, Y. S.

"APPROXIMATE METHOD FOR TAKING INTO CONSIDERATION THE NONLINEAR EFFECTS WHEN COMPUTING AIRCRAFT AERODYNAMIC CHARACTERISTICS IN A NONUNIFORM VELOCITY FIELD"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 180-184.

An engineering method is proposed for assessing nonlinear components of aerodynamic forces and moments exerted on an aircraft encountering the vortex flow generated by a leading aircraft. The method is based on the use of a linear theory with constraints placed on circulation strengths around wing sections. The constraints result in the nonlinear variations of aerodynamic characteristics. Computed results are compared with experimental data for the aircraft model immersed in the nonuniform flow field.

"QUASI-WAVELET MODEL OF VON KARMAN SPECTRUM OF TURBULENT VELOCITY FLUCTUATIONS"

Boundary-Layer Meteorology, Vol. 112, 2004, pp. 33-56.

The von Karman spectra of turbulent temperature and velocity fluctuations have been widely used in the literature on turbulence and electromagnetic, seismic, and acoustic wave propagation in random media. In this paper we provide a phenomenological motivation for the von Karman velocity spectrum in terms of the quasi-wavelet model of turbulence developed recently. In this model, turbulence is represented as a superposition of self-similar localized eddies of many different scales. We find a functional form for these eddies that yields the von Karman velocity spectrum exactly. We also show that other eddy functions produce velocity spectra that have the same general form as the von Karman spectrum, and we consider possible quasi-wavelet representations of the 'Kansas' and the '-1' spectrum. We also present a systematic determination, based on turbulence similarity theories, of the parameters of the von Karman spectra of temperature and velocity fluctuations in an unstable atmospheric boundary layer.

"TIP-VORTEX INVESTIGATION ON A ROTATING AND PITCHING ROTOR BLADE"

Journal of Aircraft, Vol. 55, No. 5, September-October 2018, pp. 1792-1804.

The blade-tip vortex of a rotating and pitching DSA-9A blade was investigated numerically and experimentally. Numerical computations were performed using DLR, German Aerospace Center's finite volume solver TAU, and experimental data were gathered by using particle image velocimetry carried out in a stereoscopic setup at the rotor test facility in Gottingen. Algorithms deriving the vortex position, swirl velocity, circulation, and core radius were implemented. The agreement is better the lower the wake age is, with numerical dissipation enlarging the blade-tip vortex in an artificial manner with increasing wake age. Nevertheless, the numerical simulations can predict swirl velocity and circulation well and help understanding the growth and development of the blade-tip vortices. A comparison with a nonrotating version of this blade showed that the circulation of the nonrotating blade was in the same order.

Goff, R. W.

"AIRCRAFT WAKE VORTEX BEHAVIOR STUDY, VORTICES AND RUNWAY UTILIZATION"

ER73-4300, July 1973, Raytheon Company, Sudbury, M.

This report contains a survey and description of Air Traffic Control equipment which may be modified to provide the warning signal for a vortex detection system (the vortex warning device will alert landing aircraft of a vortex hazard). Since an important aspect of implementing new Air Traffic Control equipment is its integration with existing equipment and procedures, general information relevant to that problem is also provided.

Goff, R. W.

"STUDY OF THE PERFORMANCE REQUIREMENTS OF A VORTEX MONITORING SYSTEM"

DOT-TSC-141-1, March 1972, Raytheon Company, Sudbury, MA

This study involved four basic task items. The first was a general review of the characteristics of trailing vortex wakes. The second task item involved the generation of envelopes showing the expected vortex drift for the Boeing 747 and 727 aircraft. The third task item was an investigation of the environmental factors with which a vortex monitoring system would interact. The final task item was the application of the vortex drift data and operational usage considerations to the investigation of the performance requirements for a vortex monitoring system.

Goff, R. W.

"AIRCRAFT WAKE VORTEX BEHAVIOR STUDY"

ER73-4319, August 1973, Raytheon Company, Sudbury, MA

This report presents an analysis of the variations in wind magnitude and direction occurring at various times of day at Logan and Kennedy Airports, and an analysis of the aircraft spacing required to preclude an aircraft-vortex encounter in the approach corridor beyond the middle marker.

Gold, N. and Visser, K. D.

"AERODYNAMIC EFFECTS OF LOCAL DIHEDRAL ON A RAKED WINGTIP"

AIAA Paper No. 2002-0831, Reno, NV, January 2002

An experimental study was conducted to examine the impact of dihedral in the tip region of a wing on the induced drag as previous theoretical work has indicated a potential for drag reduction. Wake profiles were obtained with a seven-hole probe for a systematic variation of the dihedral and sweep of a raked tip on a 30 swept wing. These profiles were analyzed with the Boeing Universal Wake Survey Data Analysis Code to obtain lift and drag distributions. The data indicated that the tips with negative dihedral, and associated smaller span, yielded a lower induced drag than the greater span, zero dihedral configuration. The tips with positive dihedral showed no decrease of induced drag, within experimental error, compared to the zero-dihedral case. The raked tip with the lower sweep angle exhibited a lower induced drag than the tip with the higher sweep in all cases. Several unexpected dynamics were observed in the flow field, possibly because of the highly curved tip. A second vortical structure was present inboard of the main trailing vortex and the axial velocity in the trailing vortex displayed a dual 'jet like' (high velocity) and 'wake like' (low velocity) nature. Lift and drag distributions indicated that this second vortex locally decreased the lift and increased the induced drag.

Goldshtik, M. and Hussain, F.

"THE NATURE OF INVISCID VORTEX BREAKDOWN"

Phys. Fluids, Vol. 9, No. 2, February 1997, pp. 263-265

We show that vortex breakdown appears as a jump bifurcation due to structural instability of swirling flows when their solution locally fails to exist and the flow transits to another stable or metastable state. The flow pattern inside the steady separation zone and, consequently, the vortex breakdown features depend on the flow history. Therefore, we consider the flow pattern inside the separation zone. The stagnation zone model (without velocity jump) excels the traditional analytic continuation method (leading to a recirculation zone) in that solutions always exist, and, for large enough inflow swirl, exhibit non-uniqueness and folds due to smooth variations of flow parameters, thus predicting the experimentally observed hysteretic jump transitions.

Goldstein, A. and Meyer, J. W.

"ISOLATED AND CASCADE AIRFOILS WITH PRESCRIBED VELOCITY DISTRIBUTION"

NACA TR-869, 1947, Langley Aeronautical Laboratory, Langley Field, VA

An exact solution of the problem of designing an airfoil with a prescribed velocity distribution on the suction surface in each uniform flow of an incompressible perfect fluid is obtained by replacing the boundary of the airfoil by vortices. By this device, a method of solution is developed that is applicable both to isolated airfoils and to airfoils in cascade. The conformal transformation of the designed airfoil into a circle can then be obtained and the velocity distribution at any angle of attack computed. Numerical illustrations of the method are given for the airfoil in cascade.

Goldstone, L.

"AN INVESTIGATION INTO WAKE TURBULENCE INCIDENTS"

CAA Report DTRD/7301, November 1973, Civil Aviation Authority, London, England.

A working group was set up in March 1972 by the Director of Technical Research and Development to consider wake turbulence incidents reported in the United Kingdom from January 1972. The paper contains an analysis of these incidents and presents certain conclusions regarding factors which are relevant to the formation and persistence of the wake.

Golubev, V., Kazarin, P., Moreno, C. and MacKunis, W.

"ON WAKE VORTEX SAFETY ANALYSIS AND CONTROL FOR UAV"

31st Congress of the International Council of the Aeronautical Sciences (ICAS 2018), Paper 11.7.4, September 2018, Belo Horizonte, Brazil.

External disturbances, such as turbulence wind gust and upstream wake vortex can significantly affect the dynamics and flight trajectory of an unmanned aerial vehicle (UAV). These effects can pose danger to UAV. Thus, the integration of Unmanned Aerial Systems (UAS) into National Airspace System (NAS) requires close consideration of these effects. This paper presents a robust nonlinear control method that can be proven to achieve altitude and roll regulation in the presence of several types of

disturbances such as wake vortex and wind gust disturbance. Side-by-side simulation comparisons with H sub infinity linear control method are provided. The results demonstrate the capability of the proposed nonlinear controller to asymptotically reject disturbances in the presence of parametric uncertainty. In addition, the nonlinear controller is designed with a computationally simplistic structure, which does not require complex calculations or function approximations in the control loop. Hence, the proposed controller is a great choice for small UAV applications with limited computational resources.

Gomez, S., Gilkey, L. N., Kaiser, B. E. and Poroseva, S. V.

"COMPUTATIONAL ANALYSIS OF A TIP VORTEX STRUCTURE SHED FROM A BIO-INSPIRED BLADE"

AIAA Paper 2014-3253, June 2014, Atlanta, GA.

This study analyzes the effects that a bio-inspired blade shape has on the size and structure of a tip vortex. The blade prototype was selected based on the analysis of various insect orders with the purpose of finding wing profiles most suitable for the design of small rotorcraft propellers. Flow simulations are conducted around the bio-inspired blade and in its near wake using commercial CFD software Star-CCM+. Results are compared with those for a rectangular blade. A vortical structure is captured downstream of both blades. Flow data related to these structures is used to show that the bio-inspired shape produces weaker vortices, making it more desirable for rotorcraft implementation.

Gonzalez, L M. and Theofilis, V.

"TEMPORAL STABILITY ANALYSIS OF TWO-VORTEX SYSTEMS"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

Highly resolved solutions of the two-dimensional incompressible Navier-Stokes and continuity equations, describing the evolution of a counter-rotating pair of vortices, have been obtained accurately and efficiently by spectral collocation methods and an eigenvalue decomposition algorithm. Such solutions have formed the basic state for subsequent three-dimensional BiGlobal eigenvalue problem (EVP) linear instability analyses, which monitor the modal response of these vortical systems to small-amplitude perturbations, periodic along the homogeneous axial spatial direction, without the need to invoke an assumption of azimuthal spatial homogeneity. A finite-element methodology (FEM) has been adapted to study instability of vortical flows and has been validated on the Batchelor vortex. Subsequently, the instability of the counter-rotating dipole has been analyzed; aspects monitored have been the dependence of the results on (i) the Reynolds number, (ii) the value of the (non-zero) axial velocity considered and (iii) the time at which the quasi-steady basic flow has been monitored. Essential to the success of the analysis has been the appropriate design of a calculation mesh, as well as exploitation of the symmetries of the basic state. The spatial structure of the amplitude functions of all unstable eigenmodes reflects the inhomogeneity of the basic state in the azimuthal spatial direction, thus providing a-posteriori justification for the use of the BiGlobal EVP concept.

Goodhart, H. C. N.

"A NOTE ON THE MEASUREMENT OF THE INDUCED DRAG FACTOR (k) OF A GLIDER"

Technical Soaring, Vol. I, No. 4, 1972, pp. 7-9.

There appears to be a good case for treating lift dependent drag as being composed of two separate terms varying as $(C_{sub l})^2$. One is purely the induced drag (with a k value to cover non-ellipticity of lift distribution) which is inversely proportional to aspect ratio. The other is the variation of wing profile drag coefficient and is independent of aspect ratio. In the Reynolds Number range normally used by gliders and for Wortmann wing sections, it appears that this variation of wing profile drag coefficient contributes a slope of about 0.0038 to the $((C_{sub d})/((C_{sub l})^2))$ plot.

Goodman, T. R.

"THE VORTEX CORE JET NEAR THE POINT OF GENERATION"

72-91, April 1972, Oceanics Inc., Plainview, NY

Near the point of generation of a wing tip vortex the axial velocity in the vortex core can be considerably greater than the free stream velocity. The present analysis describes the velocity field under these circumstances and shows that a self-similar solution exists that satisfies all the boundary conditions. The resulting two-point boundary value problem is solved on a digital computer and shows qualitative agreement with experiments.

"NUMERICAL SIMULATION OF WINGTIP VORTICES"

AIAA Paper No. 2012-3328, June 2012, New Orleans, LA.

A numerical study of the formation and propagation of the tip vortices from a round-tip wing is performed. The application of a standard eddy viscosity model resulted in an extremely diffused vortex downstream of the wing which does not corroborate with the experimental results. Applying a modification to this model by changing the way in which eddy viscosity is produced dramatically improves the prediction of the vortical structures. The results indicate that a decent level of accuracy can be achieved by using lower order numerical schemes albeit only in the near wake of the wing.

"STATE-SPACE MODELING AND IDENTIFICATION OF DELTA WING VORTEX-COUPLED ROLL DYNAMICS"

J. Aircraft, Vol. 46, Jan.-Feb. 2009, pp. 36-45

This paper develops a new state-space model for vortex-coupled 65-degree delta wing aircraft system based on a modified nonlinear indicial response method combined with an internal state-space representation. Relationships between vortex breakdown location, rolling moment coefficient, and roll angle dynamics are determined. The state-space equations derived are subject to state delays and are also nonlinear in the vortex-coupled rolling moment coefficient. Linear and nonlinear parameter identification methods are developed to empirically estimate the rolling moment coefficient as a function of the roll angle and primary vortex breakdown locations. A comparison between numerical simulations and experimental data indicates close agreement for several different initial conditions.

Gordon, A. A.

"METHOD AND APPARATUS FOR MICROBURST AND WAKE TURBULENCE DETECTION FOR AIRPORTS"

U.S. Patent 5,262,773, Nov. 1993

A method and apparatus was developed for detecting specialized meteorological conditions such as a microburst and the wind condition generated behind an aircraft known as wake turbulence. The method and apparatus of the present invention is designed to display the location of the microburst directly on the flight controller's monitoring screen with the flight controller then being able to so inform any pilot of an aircraft of the microburst so that the pilot can take evasive action. The display on the flight controller's screen is to be in color. The displaying of the microburst on the screen is to be by means of a computer which utilizes as inputs the conventional aircraft surveillance radar, weather radar and ground radar as well as additional inputs of wind direction and velocity information obtained from detection devices mounted directly adjacent to the aircraft runway and along the approach and take-off areas for the runway.

Gordon, A. A.

"SYSTEM FOR DETECTING AND VIEWING AIRCRAFT-HAZARDOUS INCIDENTS THAT MAY BE ENCOUNTERED BY AIRCRAFT LANDING OR TAKING-OFF"

US Patent 5,657,009, August 1997

A system and method has been developed for detecting and viewing aircraft hazardous incidents such as flying aircraft and meteorological phenomena which includes microbursts, thunderstorms, tornadoes, and the wake turbulence of aircraft. The aircraft hazardous incidents are positionally and horizontally displayed to the pilot on a display, that is located in the aircraft cockpit, in relation to the flight path of the aircraft. The timely displaying of any of the aircraft hazardous incidents permits the pilot to take evasive action to avoid a potentially dangerous incident.

Gorstein, M.

"WAKE VORTEX DETECTION AND AVOIDANCE SYSTEMS"

USSR/US Aeronautical Technology Symposium, Moscow, USSR, July 1973.

A Wake Vortex Avoidance System (WVAS) to improve air transport safety and airport efficiency is being developed by the Transportation Systems Center for the FAA. The WVAS will detect and/or predict the current movement of vortices in nearby airport corridors, assess them as potential hazards to following aircraft, and provide warning to controllers and pilots to prevent hazardous encounters. The paper briefly discusses vortex behavior characteristics, vortex sensors, an in-process experimental program, and several possible wake vortex avoidance system concepts.

Gorstein, M., Hallock, J. N. and McWilliams, I. G.

"AIRCRAFT WAKE VORTEX AVOIDANCE SYSTEMS"

Proceedings of Electronics and Aerospace Systems Convention, IEEE, 1972, pp. 64-69

The behavior, detection, and prediction of the motion of aircraft wake vortices in the airport environment is discussed. Preliminary designs of wake vortex avoidance systems based upon the current assessment of aircraft vortex hazards are presented.

Gorstein, M., Hallock, J. N., McWilliams, I. G. and Goff, R. W.

"SYSTEM PERFORMANCE REQUIREMENTS FOR MONITORING TRAILING VORTICES IN A TERMINAL ENVIRONMENT"

National Aerospace Electronics Conf., Dayton, OH, May 1971

The paper discusses the performance requirements for systems capable of monitoring trailing vortices in three situations: (1) the approach and departure corridors, (2) between adjacent runways, and (3) at runway intersections. The monitoring requirements are shown to depend upon the vortex characteristics, the airport-runway geometry, and the operations characteristics of the airport (separation standards, runway usage and runway selection based upon the wind velocity). The significance of these factors are discussed and examples are given for several vortex monitoring situations at Logan Airport in Boston.

"FLOW ENVIRONMENT STUDY NEAR THE EMPENNAGE OF A 15-PERCENT SCALE HELICOPTER MODEL"

NASA-TP-2000-210085, March 2000, NASA Langley Research Center, Hampton, VA

Development of advanced rotorcraft configurations has highlighted a need for high-quality experimental data to support the development of flexible and accurate analytical design tools. To provide this type of data, a test program was conducted in the Langley 14- by 22-Foot Subsonic Tunnel to measure the flow near the empennage of a 15-percent scale powered helicopter model with an operating tail fan. Three-component velocity profiles were measured with laser velocimetry (LV) one

chord forward of the horizontal tail for four advance ratios to evaluate the effect of the rotor wake impingement on the horizontal tail angle of attack. These velocity data indicate the horizontal tail can experience unsteady angle of attack variations of over 30 degrees due to the rotor wake influence. The horizontal tail is most affected by the rotor wake above advance ratios of 0.10. Velocity measurements of the flow on the inlet side of the tail fan were made for a low-speed flight condition using conventional LV techniques. The velocity data show an accelerated flow near the tail fan duct, and vorticity calculations track the passage of main rotor wake vortices through the measurement plane.

"ROTOR WAKE STUDY NEAR THE HORIZONTAL TAIL OF A T-TAIL CONFIGURATION"

Journal of Aircraft, Vol. 39, No. 4, July-August 2002, pp. 645-653

Development of advanced rotorcraft configurations has highlighted a need for high-quality experimental data to support the development of robust and accurate analytical design tools. To provide high-quality experimental data, a test program was conducted in the NASA Langley Research Center 14- by 22-Foot Subsonic Tunnel to measure the flow near the empennage of a 15% scale powered helicopter model with an operating tail fan and a T-tail configuration. Three-component velocity profiles were measured forward of the helicopter tail for four advance ratios using laser velocimetry to evaluate the effect of the rotor wake impingement on the horizontal tail angle of attack. These velocity data indicate the horizontal tail can experience unsteady angle-of-attack variations of over 30 deg due to the rotor wake influence. The horizontal tail is most affected by the rotor wake at and above advance ratios of 0.10.

"SIMULATION OF NORMAL VORTEX-CYLINDER INTERACTION IN A VISCOUS FLUID"

J. Fluid Mech., Vol. 431, 2001, pp. 371-405.

A computational study of three-dimensional vortex-cylinder interaction is reported for the case where the nominal orientation of the cylinder axis is normal to the vortex axis. The computations are performed using a new tetrahedral vorticity element method for incompressible viscous fluids, in which vorticity is interpolated using a tetrahedral mesh that is refit to the Lagrangian computational points at each timestep. Fast computation of the Biot-Savart integral for velocity is performed using a box-point multipole acceleration method for distant tetrahedra and Gaussian quadrature for nearby tetrahedra. A moving least-square method is used for differentiation, and a flux-based vorticity boundary condition algorithm is employed for satisfaction of the no-slip condition. The velocity induced by the primary vortex is obtained using a filament model and the Navier-Stokes computations focus on development of boundary-layer separation from the cylinder and the form and dynamics of the ejected secondary vorticity structure. As the secondary vorticity is drawn outward by the vortex-induced flow and wraps around the vortex, it has a substantial effect both on the essentially inviscid flow field external to the boundary layer and on the cylinder surface pressure field.

Gottschall, J.

"GALION LIDAR PERFORMANCE VERIFICATION"

Technical Report, May 2013, Fraunhofer Institute for Wind Energy and Energy System Technology, Bremerhaven, Germany.

The observed performance of the Galion Lidar in the considered test setup, expressed in the presented verification results, meets the ScurrEnergy in-house criteria (i.e. the OLS regression slope is within 2 percent of unity, and R-squared greater than 0.98), indicating an acceptable performance of the device under test. Given that the measurements were performed in moderately complex (and definitely not perfectly flat) terrain, and that the Galion Lidar was operated in a mode that is not aimed at a best possible agreement with the reference measurements but has further advantages, the results of the verification test indicate a good agreement with the reference mast. The arc scan mode of operation may be recommended for applications where a horizontal distance between the location of the measurement device and its measurements is necessary, e.g. for a power performance assessment offshore with the Galion Laser installed on the transition piece of the test turbine. It is expected that the measurement uncertainties for such an application are even smaller than for the presented Galion Laser performance verification since the influences of the terrain would be less significant for an offshore site.

"LIDAR PROFILERS IN THE CONTEXT OF WIND ENERGY -- A VERIFICATION PROCEDURE FOR TRACEABLE MEASUREMENTS"

Wind Energy, Vol. 15, 2012, pp. 147-159.

The need for measuring wind speed and direction at greater heights and at several levels simultaneously gains importance as wind turbines become larger and higher. For this purpose, remote-sensing profilers become very attractive for resource assessment and power performance testing. However, the existing standards only permit the use of cup anemometers as standard instruments. The main issue preventing the use of remote sensors in such standards is the need to maintain the traceability of the measurements in the international standard system. In this paper, we describe a verification procedure for lidar profilers that enables us to achieve the required traceability. The procedure is based on a direct comparison of the measurements from the lidar and reference sensors mounted on a mast at various height levels. First, the data are corrected and filtered to obtain a representative data set ensuring a repeatable test. Second, a linear regression is applied to the data for each height. The third step is a bin-average analysis of the lidar error, i.e. the difference between the lidar and reference measurements, forming the basis for the ensuing uncertainty estimation. The results of the verification test are both used to correct the lidar measurements and to derive a corresponding uncertainty budget. A significant limitation of the procedure is the considerable uncertainty introduced by the reference sensors themselves. The decision as to whether to apply the

derived correction as a lidar calibration or not therefore mainly depends on the interpretation of this reference uncertainty and the assumed and observed biases.

"CURVATURE CORRECTIONS TO IMPROVE THE ACCURACY OF FREE-VORTEX METHODS"

Journal of Aircraft, Vol. 53, No. 2, March-April 2016, pp. 378-386.

The accuracy of discretized induced velocity calculations using straight-line vortex segmentation has been examined using an induced velocity correction (curvature correction) based on a curved element with a thin core. The validity of the curvature correction has been evaluated for the prediction of helicopter rotor wakes using a free-vortex method. Numerical techniques were developed to incorporate the correction into the self-induced velocity calculations to improve the accuracy for a given discretization or to reduce the discretization for a required accuracy or computational cost. The correction was analyzed in detail to understand its validity based on its thin-core assumptions and to quantify the effect of the correction as it affects the evolution of the rotor wake. It is shown that, while the inclusion of the curvature correction can, in some cases, improve the accuracy of the induced velocity calculation for a given level of discretization, its applicability to helicopter wake problems is not guaranteed or universal.

"PARTICLE-CLUSTERING ALGORITHMS FOR THE PREDICTION OF BROWNOUT DUST CLOUDS"

AIAA Journal, Vol. 51, No. 5, May 2013, pp. 1080-1094.

Particle-clustering methods have been explored for application to the problem of predicting brownout conditions, which can occur when a rotorcraft operates over surfaces covered with loose sediment and stirs up large dust clouds that impede the pilot's outward visibility. A significant issue in such simulations is the tracking of the very large number of particles needed to predict with acceptable fidelity the dual-phase flow properties and optical characteristics of the dust clouds. To this end, computationally efficient Lagrangian approaches were explored for the simulation of dilute carrier-particle suspensions at low Reynolds numbers of the relative particle motion. The algorithms examined were the Gaussian method, the k-means method, and Osipov's method, which were all compared in terms of their accuracy versus computational cost against solutions obtained by directly solving for the individual particle motions. Specific results were computed for a prototypical flow field that mimics the highly unsteady, two-phase vortical particle flow responsible for the development of brownout conditions. It is shown that although clustering algorithms can be problem dependent and have bounds of applicability, in some conditions they offer the potential to significantly reduce the computational costs of brownout dust cloud simulations while still retaining good accuracy.

"FLOW IN A TURBULENT TRAILING VORTEX"

Phys. Fluids, Vol. 14, No. 10, October 1971, pp. 2074-2080

The structure of turbulent line vortices is examined. A general argument is constructed to show that the vortex must develop an overshoot of circulation if it entrains fluid at a rate greater than that due to molecular diffusion. A weak hypothesis on the distribution of Reynolds stress leads to the logarithmic profile of Hoffman and Joubert and an estimate of the maximum Reynolds stress. The results of a turbulence model due to Saffman are presented and shown to be poor.

"ANALYSIS OF EFFECT OF WAKE VORTICES ON AIR DATA SENSORS"

Symposium on Applied Aerodynamics and Design of Aerospace Vehicle, November 2011, Bangalore, India.

An essential part of operational clearance of a new aircraft is to certify that it is safe to fly even when wake vortices generated by another aircraft are encountered. For certification, it must be demonstrated that the aircraft can safely cross the wake at a certain separation distance. When the wake is encountered, air data sensors that measure the directional of airflow in terms of Angle of Attack (AOA/Alpha), Angle of Side Slip (AOSS/Beta/SSA) and pressures (Total and Static Pressure) show large fluctuations. The ADS measurements are used for feedback to the fly-by-wire control laws. These large and rapid fluctuations in the ADS signals affects the commands generated by the fly-by-wire control laws and in turn results in generating high loads on the aircraft. Therefore, before actual flight tests it is necessary to predict the behavior of Air Data System (ADS) encountering the wake. Appropriate wake encounter protection features should be incorporated in the ADS algorithms. The behavior of the ADS including the wake protection features during wake must be cleared in a simulation environment. The simulation environment for wake analysis, behavior of the ADS measurements with and without wake protection features are presented in this paper for a generic high-performance aircraft. Paper also presents the wake protection features incorporated in the ADS algorithms.

"SOLUTIONS OF THE NAVIER-STOKES EQUATIONS FOR VORTEX BREAKDOWN"

J. Fluid Mech., Vol. 75, Part 3, June 1976, pp. 525-544

A numerical investigation of vortex breakdown has been undertaken in an attempt to understand its properties, and the mechanisms responsible for it. Solutions of the full steady axisymmetric Navier-Stokes equations for breakdown in an unconfined viscous vortex have been obtained for core Reynolds numbers up to 200, for a two-parameter family of assumed upstream velocity distributions. Diffusion and convection of vorticity away from the vortex core, and the strong coupling between the circumferential and axial velocity fields in highly-swirling flows, are shown to lead to stagnation and

reversal of the axial flow near the axis. The various theories of vortex breakdown are considered in light of the present numerical solutions.

Gracey, W.

"MEASURED MOMENTS OF INERTIA OF 32 AIRPLANES"

NACA TN-780, October 1940, Langley Aeronautical Lab., Langley Field, VA.

A compilation of the experimentally determined moments of inertia of 32 airplanes is presented. The measurements were obtained at the laboratories of the NACA by means of a pendulum method. The airplanes tested are representative of several types of aircraft of gross weight less than 10,000 pounds. The results are presented in coefficient as well as in dimensional form. An elementary analysis of the data disclosed the possibility of grouping the results according to wing type of the airplane, as low-wing monoplanes, parasol and high-wing monoplanes, and biplanes. The data are shown to provide a convenient means of rapidly estimating the moments of inertia of other airplanes. A three-view drawing of each of the 32 airplanes is included.

Gracey, W.

"THE EXPERIMENTAL DETERMINATION OF THE MOMENTS OF INERTIA OF AIRPLANES BY A SIMPLIFIED COMPOUND-PENDULUM METHOD"

NACA TN-1629, June 1948, Langley Aeronautical Lab., Langley Field, VA.

A simplified compound-pendulum method for the experimental determination of the moments of inertia of airplanes about the x and y axes is described. The method is developed as a modification of the standard pendulum method reported previously in NACA report, NACA-467. A brief review of the older method is included to form a basis for discussion of the simplified method.

"COMBINING PIV, POD AND VORTEX IDENTIFICATION ALGORITHMS FOR THE STUDY OF UNSTEADY TURBULENT SWIRLING FLOWS"

Measurement Science and Technology, Vol. 12, 2001, pp. 1422-1429.

Particle image velocimetry (PIV) measurements are made in a highly turbulent swirling flow. In this flow, we observe a coexistence of turbulent fluctuations and an unsteady swirling motion. The proper orthogonal decomposition (POD) is used to separate these two contributions to the total energy. POD is combined with two new vortex identification functions, γ_1 and γ_2 . These functions identify the locations of the center and boundary of the vortex based on the velocity field. The POD computed for the measured velocity fields shows that two spatial modes are responsible for most of the fluctuations observed in the vicinity of the location of the mean vortex center. These two modes are also responsible for the large-scale coherence of the fluctuations. The POD computed from

the gamma sub 2 scalar field shows that the displacement and deformation of the large-scale vortex are correlated to these modes. We suggest the use of such a method to separate pseudo-fluctuations due to the unsteady nature of the large-scale vortices from the fluctuations due to small-scale turbulence.

Graham, A. and Raper, D. W.

"TRANSPORT TO GROUND OF EMISSIONS IN AIRCRAFT WAKES. PART I: PROCESSES"

Atmospheric Environment, Vol. 40, Issue 29, September 2006, pp. 5574-5585

An aircraft exerts a downward force on the air, so aircraft exhausts tend to descend toward the ground within the aircraft's wake. The wake of an airplane descends in an essentially inviscid and thus long-lived manner, through the action of a pair of trailing counterrotating vortices on one another. The vortices derive from the circulation about the wings yielding the lift. Exhaust pollutants may thus be conveyed to the ground close to airports, far more effectively than through ambient atmospheric dispersion alone, as has hitherto been assumed occurs within air-quality models. The presence of the vortices in the vicinity of airports is well-established, as it is the need to wait for their decay or movement out of the flight corridor -- for the safety of the following aircraft -- that caps departure and arrival rates at busy periods. The dynamics of the transport are elucidated, so that the impact of the transport on pollutant concentrations at ground level in an airport environment may be established.

Graham, A. and Raper, D. W.

"TRANSPORT TO GROUND OF EMISSIONS IN AIRCRAFT WAKES. PART II: EFFECT ON NO_x CONCENTRATION IN AIRPORT APPROACHES"

Atmospheric Environment, Vol. 40, Issue 30, September 2006, pp. 5824-5836

Predictions as to the transport of aircraft NO_x emissions to ground level in the vicinity of an airport are made, taking account of the vortical dynamics of the aircraft wake. A model is used to calculate mean ground-level concentrations. It employs a kinematic approach, harnessing results from dynamical models in the literature. Two aircraft types are considered, a B737-300 (twin turbofan), taken as representative of short-range aircraft, and a B747-400, taken as representative of long-range aircraft. Airport and meteorological parameters are assigned values as holding in the case of Manchester Airport, UK, during a fortnight in May 1999 (prior to the opening of a second runway there). The airport operated at a capacity of about 45 aircraft movements per hour in the peak morning period, with frequencies in the middle of the day being about half this. Aircraft of maximum takeoff weight more than 120 tons accounted for some 6% of all movements. The simulations predict mean NO_x concentrations of maximum 3 ug per cubic meter at the center of the runway arising because of the vortex-mediated transport (as expressed on conversion of all NO to NO₂), with concentrations on the order of 1 ug per cubic meter arising 0.5 km laterally from the runway.

Graham, J. A. H. and Phillips, W. R.

"REYNOLDS STRESS AND VELOCITY MEASUREMENTS IN A TURBULENT TRAILING VORTEX"

TN-75-1, Apr. 1975, McGill Univ., Montreal, Canada

The results of a series of experiments conducted in a circular blower wind tunnel on a turbulent trailing vortex of Reynolds number $\Gamma/\nu = 57000$ are given. The results include the rotational and axial velocity components and the complete Reynolds stress tensor, for five cases of axial momentum, two jets, two wakes and a case of zero momentum increment. All measurements were made with a hot wire anemometer linked to an on-line digital computer. Results are given at three downstream locations, $x/c = 45, 78$ and 109 where c is the average chord width of the vortex generator.

Graham, J. A. H., Newman, B. G. and Phillips, W. R.

"TURBULENT TRAILING VORTEX WITH CENTRAL JET OR WAKE"

International Council of the Aeronautical Sciences Paper 74-40, Haifa, Israel, 1974

The concentrated trailing vortices from the wing of heavy aircraft contain significant rotational velocities which may persist for minutes. To reduce this time, the turbulence level in the core of the vortex may be increased by superimposing a longitudinal jet or wake. A series of experiments have been conducted in a circular wind tunnel with a trailing vortex along the center line. Jets or wakes of varying momentum were added to the center of the vortex. The mean velocity and the complete Reynolds stress tensor were measured at various azimuthal positions.

Graham, W. R.

"OPTIMISING WING LIFT DISTRIBUTION TO MINIMISE WAKE VORTEX HAZARD"

Aeronautical Journal, Vol. 106, August 2002, pp. 413-426

The aim of this work is to investigate how the wake vortex hazard generated by an aircraft can be reduced by modifying the wing lift distribution. The wake associated with a given lift distribution is simulated with a two-dimensional, inviscid 'vortex method'. A numerical optimization technique is used to guide the modifications so that a hazard measure, based on the rolling moment induced on a following aircraft encountering the wake, is minimized. The results show that a significant (~20-25%) reduction in hazard compared with conventional high-lift configurations can be achieved, via lift distributions that have a local minimum between the regions contributing to the flap and tip vortices. The counter-signed vorticity associated with this minimum appears to prevent the tip and flap vortices from merging, resulting in a safer wake. Furthermore, the hazard reduction is robust to variations in other features of the lift distribution and should thus be achievable in practice.

Graham, W. R.

"AN ASSESSMENT OF THE 2D VORTEX METHOD IN AIRCRAFT WAKE SIMULATION"

Aeronautical Journal, December 2001, pp. 653-666

Recent interest in aircraft vortex wakes has highlighted the need to identify appropriate algorithms for their simulation. The problem is not well-suited to grid-based techniques, due to the large domain and the need to avoid introducing artificial viscosity. A promising alternative is offered by Lagrangian formulations. This work aims to assess the usefulness of one such approach - the 2D vortex method - via comparison with experimental results. One in-house and two external (from DLR and ONERA) data sets are used. The results show generally good agreement in vortex locations and size, with the calculation performing best when initialized downstream of the strongly-three-dimensional trailing edge region. The neglect of viscosity can lead to some asymmetry in the vortex cores, but, even here, excellent agreement can be obtained when the field is integrated to give circulation (as a function of radius). The 2D vortex method is thus an accurate and efficient tool for wake vortex prediction.

Graham, W. R.

"EXPERIMENTAL ASSESSMENT OF THE EXTENDED BETZ METHOD FOR WAKE VORTEX PREDICTION"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, Trondheim, Norway, May 1996, pp. 9-1 TO 9-12

The extended Betz method, whereby wake vortex velocity predictions are obtained from a given wing lift distribution, is assessed by comparison with experimental results for wake cross-flow velocities behind a wing model with flaps. The required lift distributions are found from overall lift data and a lifting-line calculation, and the comparison is made for both clean and high-lift configurations. In each case it is found that the fundamental Betz assumption of effectively two-dimensional, inviscid flow in the wake is well supported, but that a proposed approximate invariant, the second moment of vorticity, is not conserved. In spite of this, the theoretical predictions for the single vortex shed by each half of the clean wing are found to be accurate. However, the multiple vortices arising from the wing in high-lift configuration are not as well predicted, and in this case the usefulness of the method seems to be restricted to providing estimates of the number of vortices, and their overall circulations.

Graham, W. R. and Bertenyi, T.

"MERGER OF CO-ROTATING VORTEX PAIRS"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

The investigation has centered around wind tunnel experiments on co-rotating vortex pairs, generated by wings attached to the tunnel floor and side wall. Traverses with a single-tube yawmeter (effectively a five-hole probe) have been carried out over cross-flow planes at a range of downstream locations, yielding an extensive set of mean-flow data. These measurements have subsequently been analyzed to obtain the vortex circulations, core diameters and separations at each plane. For equal

circulations, the results show that each vortex retains an independent, essentially axisymmetric identity for most of the distance to merger. During this phase, core sizes increase and separation decreases. Merger then occurs over a short distance, after which a single axisymmetric vortex emerges. Unequal strength vortices behave similarly, in that the distance over which they merge is relatively short. However, notable differences in behaviour are observed; the weaker vortex is significantly distorted during the rotation before merger, and is then wrapped around the stronger as they combine. Lastly, the degree to which the merging process can be described as 'two-dimensional' is investigated via consideration of the theoretical 2D flow invariants. The results suggest that three-dimensional effects are not strong, and thus that vortex merging can be simulated using 2D flow computations.

Graham, W. R., Berteny, T. and David, L.

"THE EFFECT OF FLAP-END ADDITIONS ON AIRCRAFT TRAILING VORTICES"

Aeronautical Journal, February 2004, pp. 109-115

The influence of flap-end geometry modifications on the near-field wake behind a generic high-lift wing/flap configuration is investigated experimentally with a single-tube yawmeter. It is found that flap-end additions tend to split the concentrated area of streamwise vorticity shed by the flap into two less intense regions, associated with the tips of the flap and the addition. For shorter additions, these regions tend to roll up together, resulting in a slightly more diffusive flap vortex of almost unchanged circulation. For larger additions the outer region is captured by the tip vortex, which correspondingly gains in circulation at the expense of the flap vortex. In all cases, the vorticity centroid of the rolled-up wake is shifted outboard, and the overall circulation slightly increased. However, the associated lift increase implies a decrease in overall circulation at a given lift coefficient.

Graham, W. R., Park, S.-W. and Nickels, T. B.

"TRAILING VORTICES FROM A WING WITH A NOTCHED LIFT DISTRIBUTION"

AIAA Journal, Vol. 41, No. 9, September 2003, pp. 1835-1838

In this Note, a proof-of-concept tow-tank experiment on a novel, notched form of wing lift distribution has been described. The results confirm the fundamental conclusion of earlier numerical simulations, namely, that the flap and tip vortices shed by a wing with the novel distribution remain distinct and unmerged, unlike those associated with conventional high-lift distributions. This feature will lead to a reduced rolling moment on a follower aircraft encountering the wake and may also facilitate the development of rapidly growing instability modes. It is thus a promising avenue for wake hazard reduction and worthy of further work. This will consist of hazard reduction quantification and elucidation of the underlying mechanisms in more detail.

Graham, W. R., Park, S.-W. and Nickels, T. B.

"LIFT DISTRIBUTIONS FOR REDUCED WAKE VORTEX HAZARD"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

Since spacings, or 'separation distances', are imposed to protect the following aircraft from the trailing vortices of the leader, efforts have concentrated either on better characterization and assessment of the hazard, or on its reduction via modifications to the airframe configuration. The latter approach is particularly pertinent at present, with the launch of the A380 'super-jumbo' program. One promising method is to design a configuration that encourages early development of mutually-induced instabilities of the trailing vortex pair. An alternative approach is to aim to alleviate the wake vortex hazard in the absence of any instability. Here one would seek to distribute the shed vorticity in an optimal way, subject to the constraints of the aircraft's lift requirement. This approach is the subject of this paper. The method employed is 'steepest decent' optimization, which finds a minimum of a 'performance measure' with respect to the set of parameters that characterize the system. Here the performance measure used is an averaged rolling moment coefficient for a following aircraft, and the characterizing parameters are the coefficients of the lift distribution (represented as a Fourier series).

Grahame, W. E.

"A PRELIMINARY METHOD FOR THE PREDICTION OF MINIMUM INTERVAL TAKEOFF (MITO)"

TM 80-9.2/1, February 1980, Calspan Corp., Los Angeles, CA

Methodology to predict minimum interval takeoff (MITO) has been developed by Calspan from full-scale flight test wake vortex data and from analytical procedures which determine aircraft roll characteristics due to wake vorticity. The method has been applied to SAC-based aircraft, including the FB-111, KC-135, B-52 and B-1, which were 'flown' behind a 747 (E-4) aircraft to determine MITO time sequences. Appropriate expressions for circulation and vortex peak vorticity decay based on 747 flight test data were applied. From these expressions, values of vortex core radius were calculated and applied in a roll moment function to determine variations of the vortex-induced roll moment coefficient with time. Values of vortex-induced rolling moment as a function of time were calculated and compared against maximum roll capability to indicate 'safe' time intervals for MITO.

Graham-Rowe, D.

"VANQUISH THE VORTEX"

New Scientist, Vol. 173, Issue 2332, February 2002, p. 9

The swirling turbulence caused by jets taking off and landing can be a danger for planes in their wake. But a couple of rollers fixed to each wing could solve the problem. In a 2D simulation of air flowing across a square block, wake vortices formed as normal. But when two rollers along the back edge of the block rotated towards each other, they drew air into the space behind the block and the swirls straightened out, disappearing completely when the rollers rotated 50 per cent faster than the air flow. The researchers suggest you could install the rollers along the trailing edge of airplane wings to stop the

wake at its source, without increasing drag. But first they need to show that the trick would work in three dimensions.

Granger, R.

"STEADY THREE-DIMENSIONAL VORTEX FLOW"

J. Fluid Mech., Vol. 25, Part 3, July 1966, pp. 557-576.

A theory is developed for an incompressible fluid in a steady three-dimensional rotational flow. Solutions are obtained subject to the restriction of small perturbations and are determinant provided that the vorticity distribution along the axis of rotation is known. Effects of viscosity are included.

"COMPUTERISED ANIMATION OF PIV MEASUREMENTS AND LASER SHEET VISUALISATION IN THE WAKE OF A PASSENGER AIRCRAFT MODEL IN A LARGE, LOW-SPEED, WIND-TUNNEL"

8th International Symposium on Flow Visualization, Sorrento, Italy, 1998, pp. 277.1-277.

A particle image velocimetry (PIV) and laser sheet visualization (LSV) study of the flow behind a 1/12.81 scale model of a representative passenger aircraft was undertaken in a 10 ft. by 12 ft. closed return wind tunnel. Measurements were made in planes, normal to mean flow, at various downstream positions, for different model configurations. The data images were analyzed to extract raw velocity vectors after which the data were processed to obtain velocity measurements on a regular grid. From this information vorticity, divergence and cross flow energy were calculated. In addition, animations of the data were assembled to show both typical local temporal flow variation at one downstream plane and flow variation with downstream distance from the model wing tip. These procedures are discussed and examples of the data sets presented.

"A PIV AND LSV STUDY IN THE WAKE OF AN AIRCRAFT MODEL"

Journal of the Visualization, Vol. 2, No. 1, July 1999

An experimental investigation was undertaken of the wake aerodynamics of a 1/12.81 model of a commercial passenger aircraft. The tests were undertaken in the 3.05 m by 3.66 m working section of a closed-return wind-tunnel. The program made use of laser sheet visualization (LSV) and particle image velocimetry (PIV) in planes, normal to the mean flow, to obtain images of flow-following, seed particles. The images were processed to obtain raw velocity vectors, flow divergence, vorticity, cross-flow energy and high-quality visualizations. Image sequences obtained under identical incident flow conditions were used to conceptualize the variability of principal wake features such as regions of fluid of high vorticity.

"AN EXPERIMENTAL AND NUMERICAL STUDY OF THE VORTEX FILAMENTS IN THE WAKE OF AN OPERATIONAL, HORIZONTAL-AXIS, WIND TUBINE"

Journal of Wind Engineering and Industrial Aerodynamics, Vol. 85, 2000, pp. 177-189.

The paper describes a wind-tunnel study of the wake dynamics of an operational, horizontal-axis wind turbine. The behavior of the vorticity trailing from the turbine blade tips and the effect of interference on wake development were considered. Laser sheet visualization techniques were used to measure the trajectories of the trailing vorticity under various conditions of turbine yaw and blade azimuth. Selected results obtained in the experimental study were compared with the predictions of a prescribed wake model and are being used in the further development of the method.

"SHOCK-WAVE-VORTEX INTERACTIONS: SHOCK AND VORTEX DEFORMATIONS, AND SOUND PRODUCTION"

Theoretical and Computational Fluid Dynamics, Vol. 13, 2000, pp. 421-45.

In this paper we study the interaction of a shock wave with a cylindrical vortex. The objective of the study is to characterize the shock and vortex deformations and the mechanism of sound generation. The approach relies on the solution of the two-dimensional Euler equations by means of a high order finite volume weighted-ENO scheme. To provide some guidance into the analysis, we have also developed an acoustic analogy of the problem by formulating a wave equation for the pressure disturbance that is solved analytically by means of Green's functions. A systematic study has been conducted by investigating the effects of vortex intensity and shock strength. Specifically, we have determined the dependence of shock distortion and vortex compression, and its subsequent nutation upon shock and vortex strengths. The acoustic field generated through shock-vortex interactions has been found to evolve in three stages and to exhibit a three sound quadrupolar directivity. In the early stages of the interaction the sound generated due to shock distortion shows a dipolar character, which then changes to a quadrupolar one due to a restoring mechanism that acts during the interaction of the shock with the rear part of the vortex. In the third stage secondary sounds are formed, which also show a quadrupolar directivity. The acoustic analogy applied to weak shock-vortex interactions also confirms the numerically predicted sound generation mechanism.

"SURFACE PRESSURE MEASUREMENTS AT TWO TIPS OF A MODEL HELICOPTER ROTOR IN HOVER"

NASA Contractor Report 3281, May 1980, Georgia Institute of Technology, Atlanta, GA.

Blade-tip surface pressure distribution data for a single-bladed, hovering, model helicopter rotor with two tip shapes are compared. The rotor had a constant-chord, untwisted blade with a square, flat tip and the pressure distributions on this blade are compared with those measured on the same blade with a half-body of revolution tip. Pressure measurements were made on each blade along the chordwise direction at six radial stations outboard of the 94 percent blade radius. Data on each blade were taken at blade collective pitch angles of 0, 6.18, and 11.4 degrees. The Reynolds number based on tip speed and blade chord was 736,000 and the tip Mach number was 0.25. For a blade pitch angle of 0 degrees, a small difference in pressure distribution between the two blades occurred very near the tip. For the pitch angles of 6.18 and 11.4 degrees, the chordwise pressure distributions at the 94 percent radius station were essentially unaffected by the tip shapes investigated. The largest differences in the pressure distributions were near the tip and toward the trailing edge, and were associated with the rearward sweep of the tip vortices over the upper surfaces of the blades. The extent of the affected surface areas was greater for the larger blade pitch angles in each case. However, for the same blade pitch angle, the affected surface area was smaller for the blade with the body-of-revolution tip since the path of its tip vortex was outboard of that of the blade with the square, flat tip.

"MEASUREMENT OF THE MOMENTS OF INERTIA OF FULL SCALE AIRPLANES"

NACA TN-265, January 1927, Langley Aeronautical Lab., Langley Field, VA.

This paper contains a description of the method of measuring the moments of inertia of full-scale airplanes as practiced by the National Advisory Committee for Aeronautics at the Langley Laboratory. The method, while not at all new, is published for information and guidance of others who may desire to make similar measurements. The paper includes as an appendix the computations for the moments of inertia of the O-2 airplane.

"MEASUREMENTS OF THE ORTHOGONAL BLADE-VORTEX INTERACTION USING A PARTICLE IMAGE VELOCIMETRY TECHNIQUE"

Experiments in Fluids, Vol. 29, 2000, pp. 369-379.

This paper describes the results of application of a particle image velocimetry (PIV) technique to an orthogonal blade-vortex interaction experiment. To help resolve the problem of vortex meander during the tests, two PIV systems were used, which produced two velocity vector maps closely separated in time. During the PIV analysis an image-based vector validation scheme was used, which was shown to reduce significantly the number of wild vectors reaching the vector map. Preliminary results from the tests showed that, close to the blade, a significant radial outflow was superimposed on the vortex flow field. The radial flow is thought to be due to the dispersion of the vortex axial core flow during vortex cutting, which distorts the vortex flow field and enlarges the vortex. Further away from the blade, no significant radial flow was detected and the vortex remained undisturbed.

"THE FLOW FIELD AROUND A ROTOR IN AXIAL DESCENT"

J. Fluid Mech., Vol. 534, 2005, pp. 237-261

Measurements of the flow field around a model rotor descending axially into its own vortex wake have been performed using particle image velocimetry (PIV). At low descent rates, the expected cylindrical down-flow structure below the rotor is observed. At slightly higher descent rate, the flow enters the so-called vortex ring state (VRS) where the vorticity from the rotor accumulates into a toroidal structure near the rotor tips, and a large recirculation zone forms above the rotor disk. In the VRS, the flow below the rotor shows a significant upwards component, with a small up-flow zone penetrating right up to the rotor disk. Measurements show there to be a range of descent rates just before the onset of the VRS over which the flow may be interpreted to be in an incipient VRS condition. In this range, analyses of individual PIV measurements indicate that the flow near the rotor intermittently switches between the down-flow topology found at lower descent rates and the flow topology found in the fully developed VRS. The frequency of excursions of the flow into the VRS topology increases as the descent rate of the rotor is increased until, at high enough descent rate, the flow remains locked within its toroidal state.

Green, S. I.

"CORRELATING SINGLE PHASE FLOW MEASUREMENTS WITH OBSERVATIONS OF TRAILING VORTEX CAVITATION"

J. Fluids Engineering, Vol. 113, March 1991, pp. 125-129

The single phase and cavitating tip vortex shed by a NACA 66-209 rectangular planform, rounded tip hydrofoil has been studied. Single-phase measurements of instantaneous flow velocity were made by taking double-pulsed holograms of microbubbles moving in and around the vortex core. The tailored air bubble technique of Ooi and Acosta (1983) was employed to measure both the mean and fluctuating single phase vortex core static pressure. Cavitation inception was determined visually. The flow in the vortex core is highly unsteady; the rms axial velocity fluctuation can be as high as 0.2 times the freestream velocity. Core pressure fluctuations greater than the freestream dynamic pressure have been observed. These fluctuations are commensurate with the axial velocity unsteadiness. Cavitation inception in saturated water occurs at mean core pressures above the vapor pressure. However, the pressure fluctuations are certainly substantial enough to account for these elevated inception indices. The rapid establishment of fully developed trailing vortex cavitation when the cavitation number is reduced below inception is attributable to the small variation in mean core pressure with downstream distance. The inception index increases substantially with dissolved air content. The cause of this dependence is not presently known.

Green, S. I.

"WING TIP VORTICES"

Fluid Vortices, 1st ed., Kluwer Academic Publishers, The Netherlands, 1995, pp. 427-470

One of the most conspicuous features of an airplane flying at high altitude is its white contrails. These contrails, which are formed by the condensation of engine exhaust water vapor, clearly delineate the location of the wing tip vortices. This chapter aims to explain the origin of tip vortices and review their technological relevance. The chapter then summarizes lifting line theory, the simplest finite wing theory, and synthesizes our knowledge of tip vortex behavior.

Green, S. I. and Acosta, A. J.

"UNSTEADY FLOW IN TRAILING VORTICES"

J. Fluid Mech., Vol. 227, June 1991, pp. 107-134

The instantaneous velocity distribution in trailing vortices generated by lifting hydrofoils has been measured. Two different rectangular planform hydrofoils with small aspect ratios were tested. Double-pulsed holography of injected microbubbles, which act much as Lagrangian flow tracers, was used to determine instantaneous axial and tangential velocities. Measurements were made at various free-stream velocities, angles of attack, and downstream distances. The vortex core mean axial velocity is consistently greater than the free-stream velocity near the hydrofoil trailing edge, and decreases with downstream distance. The mean axial velocity is strongly Reynolds-number dependent. Axial flow in the trailing vortex is highly unsteady for all the flow conditions studied; peak-to-peak fluctuations on the centerline as large as the free-stream velocity have been observed. Certain unusual structures of the vortex core - regions in which the flow direction quickly diverges from the free-stream direction, and then equally quickly recovers - have been labelled 'vortex kinks'.

Green, S. I. and Duan, S. Z.

"THE DUCTED TIP -- A HYDROFOIL TIP GEOMETRY WITH SUPERIOR CAVITATION PERFORMANCE"

Journal of Fluids Engineering, Vol. 117, December 1995, pp. 665-672.

A novel hydrofoil design, consisting of a small diameter flow-through duct affixed to the tip, has been studied. The tip vortex cavitation inception index of this hydrofoil geometry is about a factor of 2 lower than that of a conventional rounded hydrofoil tip. This inception improvement comes with little associated performance penalty. For angles of attack greater than 8 deg the non-cavitating lift-drag ratio is superior to that of an induced hydrofoil of equal span, although with lower wing loadings the hydrofoil performance is diminished by application of the ducted tip. The ducted tip is effective at reducing the tip vortex inception index because, in contrast with the rounded tip, for which vorticity in the Trefftz plane is confined to a line, the ducted tip shed vorticity at the trailing edge is distributed over a line and circle. Distributing the vorticity in this fashion causes the trailing vortex to roll up less tightly, and hence have a higher core pressure and lower cavitation convection index than a conventional hydrofoil tip. It is also suspected that the interaction at the microscale level between the

flow through the duct, and the flow around it, makes the vortex core size larger, and therefore cavitation inception index smaller. The ducted tip design has many potential marine applications, including to ship and submarine propellers, submarine control fins, and ship rudders.

Green, S. I., editor

"FLUID VORTICES"

1st ed., Kluwer Academic Publishers, The Netherlands, 1995

Fluid Vortices is an advanced, graduate-level, textbook covering all salient flows in which fluid vortices play a significant role. Topics addressed include fundamental vortex flows (mixing layer vortices, vortex rings, wake vortices, vortex stability, etc.), industrial and environmental vortex flows (aero-propulsion system vortices, vortex-structure interaction, atmospheric vortices, computational methods with vortices, etc.), and multiphase vortex flows (free-surface effects, vortex cavitation, and bubble and particle interaction, with vortices).

Greenberg, M. D. and Kaskel, A. L.

"INVISCID FLOW FIELD INDUCED BY A ROTOR IN GROUND EFFECT"

NASA CR-1027, May 1968, Therm Advanced Research Inc., Ithaca, NY

The inviscid flow field induced by a rotor in ground effect is calculated based upon an actuator disk model of the rotor, for the case of a constant circulation distribution over the blade radius. The governing nonlinear integral equations are solved by a systematic iterative scheme which is like the Newton-Raphson method for the solution of nonlinear algebraic equations. Numerical results are presented for both the ground-effect case and the out-of-ground effect limit.

Greenblatt, D.

"MANAGEMENT OF VORTICES TRAILING FLAPPED WINGS VIA SEPARATION CONTROL"

AIAA Paper No. 2005-0061, Reno, NV, January 2005

A pilot study was conducted on a flapped semi-span model to investigate the concept and viability of near-wake vortex management via separation control. Passive control was achieved by means of a simple fairing and active control was achieved via zero mass-flux blowing slots. Vortex sheet strength, estimated by integrating surface pressure ports, was used to predict vortex characteristics by means of inviscid rollup relations. Furthermore, vortices trailing the flaps were mapped using a seven-hole probe. Separation control was found to have a marked effect on vortex location, strength, tangential velocity, axial velocity, and size over a wide range of angles of attack and control conditions. In general, the vortex trends were well predicted by the inviscid rollup relations. Manipulation of the separated flow near the flap edges exerted significant control over both outboard and inboard edge vortices while producing negligible lift excursions. Dynamic separation and attachment control was found to be an

effective means for dynamically perturbing the vortex from arbitrarily long wavelengths down to wavelengths less than a typical wingspan. In summary, separation control has the potential for application to time-independent or time-dependent wake alleviation schemes, where the latter can be deployed to minimize adverse effects on ride-quality and dynamic structural loading.

Greenblatt, D.

"CONTROL OF FLAP VORTICES"

45th Israel Annual Conf. on Aerospace Science, Haifa, Israel, February 2005.

A wind tunnel investigation was carried out on a semi-span wing model to assess the feasibility of controlling vortices emanating from outboard flaps and tip-flaps by actively varying the degree of boundary layer separation. Separation was varied by means of perturbations produced from segmented zero-efflux oscillatory blowing slots, while estimates of span loadings and vortex sheet strengths were obtained by integrating wing surface pressures. These estimates were used as input to inviscid rollup relations as a means of predicting changes to the vortex characteristics resulting from the perturbations. Surveys of flow in the wake of the outboard and tip-flaps were made using a seven-hole probe, from which the vortex characteristics were directly deduced. Varying the degree of separation had a marked effect on vortex location, strength, tangential velocity, axial velocity, and size for both outboard and tip-flaps. Qualitative changes in vortex characteristics were well predicted by the inviscid rollup relations, while the failure to account for viscosity was presumed to be the main reason for observed discrepancies. Introducing perturbations near the outboard flap-edges or on the tip-flap exerted significant control over vortices while producing negligible lift excursions.

Greenblatt, D.

"FLUIDIC CONTROL OF A WING TIP VORTEX"

AIAA Journal, Vol. 50, No. 2, February 2012, pp. 375-386.

A novel technique of active wing tip vortex control was studied in a wind tunnel by deflecting a flap mounted at the tip of a semispan NACA 0015 wing model and then modifying the shear layer above the flap by means of zero mass-flux, fluidic perturbations. Primary data acquired included surface pressure measurements and particle image velocimetry of the flap region and of the vortex downstream of the wing tip. The shear layer above the flap was particularly responsive to fluidic perturbations, requiring small relative momentum to produce large changes to the layer and consequently the vortex. However, integrated surface pressures showed that deflection of the shear layer, and even eliminating separation completely, has a relatively small effect on the overall aerodynamic loads. Deflection of the shear layer had the effect of moving the vortex outboard and changing the axial velocity at the vortex center from wake-like to jet-like flow. The spanwise deflection of the vortex centroids correlated with the nature of the loading near the wing tip: forward loading corresponded to inboard vortex movement; aft loading corresponded to outboard vortex movement. Variation of the vortex axial velocity was described using

the mechanical energy equation where changes from wake-like to jet-like flow were, respectively, comparable to the magnitude of the freestream velocity.

Greenblatt, D.

"MANAGING FLAP VORTICES VIA SEPARATION CONTROL"

AIAA Journal, Vol. 44, No. 11, November 2006, pp. 2755-2764

A pilot study was conducted on a flapped semispan model to investigate the concept and viability of near-wake vortex management by means of boundary layer separation control. Passive control was achieved using a simple fairing and active control was achieved via zero mass-flux blowing slots. Vortex sheet strength, estimated by integrating surface pressures, was used to predict vortex characteristics based on inviscid roll-up relations and vortices trailing the flaps were mapped using a seven-hole probe. Separation control was found to have a marked effect on vortex location, strength, tangential velocity, axial velocity, and size over a wide range of angles of attack and control conditions. In general, the vortex trends were well predicted by the inviscid roll-up relations. Manipulation of the separated flow near the flap edges exerted significant control over either outboard or inboard edge vortices while producing small lift and moment excursions. In summary, separation control has the potential for application to time-independent or time-dependent wake alleviation schemes, where the latter can be deployed to minimize adverse effects on ride-quality and dynamic structural loading.

Greenblatt, D., Pack-Melton, L. G., Yao, C.-S. and Harris, J.

"ACTIVE CONTROL OF A WING TIP VORTEX"

AIAA Paper No. 2005-4851, Toronto, Canada, June 2005.

Active control of a wing tip vortex was studied by deflecting a flap mounted at the tip of a semi-span wind tunnel model and then varying the degree of boundary layer separation by means of zero mass-flux perturbations. Qualitative trends were predicted based on well-known theoretical approaches. Static and dynamic pressure measurements were made to assess the loads on the wing and particle image velocimetry was used to map the flow above the flap and in the wake. Varying the degree of flow separation, and even eliminating separation completely on the tip-flap, was seen to have a small effect on the overall aerodynamic loads. Nevertheless, the flow above the flap was also seen to be amenable to separation control, requiring small control momentum to produce large changes to the vortex. Reduction of the flap-separated region eliminated the axial velocity deficit and ultimately generated an axial velocity surplus near the center of the vortex. This was accompanied by significant increases in streamwise vorticity. Separation control was found to be well suited to dynamically perturbing the trailing vortex from arbitrarily long wavelengths to wavelengths very much shorter than the wingspan. Dynamic perturbation of the vortex at length-scales less than the wing chord were achieved at the separation control frequencies. Longer wavelengths were perturbed using dynamic separation and attachment control.

Greenblatt, D., Vey, S., Paschereit, O. C. and Meyer, R.

"FLAP VORTEX MANAGEMENT USING ACTIVE GURNEY FLAPS"

AIAA Journal, Vol. 47, No. 12, December 2009, pp. 2845-2856.

An experimental study was conducted to assess the applicability of limited-span Gurney flaps for altering the flap-edge vortex characteristics of a swept constant-chord half-model with a commercial aircraft airfoil and high-lift system (slat and flap). The strategy employed was based on the well-known vortex roll-up relations between the span loading and the wake that were extended and modified to include configurations with flapped wings. Phase I of the study involved the testing of static Gurney flaps mounted at the trailing edge and flap edge, in which different flap heights and fractions of flap span were evaluated. Data acquisition included particle image velocimetry measurements downstream of the flap edge, six-component load measurements, and surface pressure measurement on the main element and in the flap-edge region. The Gurney flaps produced significant variation of the vortex centroids, up to 5.39% of the semispan (13.1% of chord), with corresponding small changes to lift and drag coefficients. Phase II of the study, involved the evaluation of dynamically deployed Gurney flaps, in which phase-averaged particle image velocimetry measurements were made of the vortex trailing the flap. This was motivated by the desire to periodically perturb the vortex centroids, with a view to exciting wake instabilities and thus triggering a faster decay. When driving the Gurney flap and hence perturbing the vortices at wavelengths shorter or longer than the wingspan, the authority over the vortex centroids did not materially change.

Greenblatt, D., Yao, C.-S., Vey, S., Paschereit, O. C. and Meyer, R.

"ACTIVE MANAGEMENT OF FLAP-EDGE TRAILING VORTICES"

AIAA Paper No. 2008-4186, June 2008, Seattle, WA.

The vortex hazard produced by large airliners and increasingly larger airliners entering service, combined with projected rapid increases in the demand for air transportation, is expected to act as a major impediment to increased air traffic capacity. Significant reduction in the vortex hazard is possible, however, by employing active vortex alleviation techniques that reduce the wake severity by dynamically modifying its vortex characteristics, providing that the techniques do not degrade performance or compromise safety and ride quality. A series of experiments were performed. The investigations demonstrated the basic mechanism for managing trailing vortices using retrofitted devices that are decoupled from conventional control surfaces. The basic premise for managing vortices advanced here is rooted in the erstwhile forgotten hypothesis of Albert Betz, as extended and verified ingeniously by Donaldson and his collaborators. Using these devices, vortices may be perturbed at arbitrarily long wavelengths down to wavelengths less than a typical airliner wingspan and the oscillatory loads on the wings, and hence the vehicle, are small. Significant flexibility in the specific device has been demonstrated using local passive and active separation control as well as local circulation control via Gurney flaps. The authors believed that this method will have significant appeal from an industry perspective due to its retrofit potential with little to no impact on cruise (devices tucked away in the cove or retracted); low operating power requirements; small lift oscillations when

deployed in a time-dependent manner; and significant flexibility with respect to the specific devices selected.

Greene, G. C.

"AN ENTROPY METHOD FOR INDUCED DRAG MINIMIZATION"

SAE Paper 89-2344, September 1989, Anaheim, CA.

A fundamentally new approach to the aircraft minimum induced drag problem is presented. The method, a 'viscous lifting line' is based on the minimum entropy production principle and does not require the planar wake assumption. An approximate, closed form solution is obtained for several wing configurations including a comparison of wing extension, winglets, and in-plane wing sweep, with and without a constraint on wing-root bending moment. Like the classical lifting-line theory, this theory predicts that induced drag is proportional to the square of the lift coefficient and inversely proportional to the wing aspect ratio. Unlike the classical theory, it predicts that induced drag is Reynolds number dependent and that the optimum spanwise circulation distribution is non-elliptic.

Greene, G. C.

"FAA'S RESEARCH STRATEGY"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Wake turbulence is an international concern that currently limits airport capacity and constrains the implementation of new technologies and procedures which might increase airport efficiency. Therefore, wake turbulence research must be a significant consideration in any plan addressing the capacity of the air traffic system. Recently, both the FAA and the Boeing Co. released plans for significantly enhancing air traffic system capacity. This talk addressed the FAA's research strategy for ensuring that wake turbulence considerations do not limit the implementation of these planned enhancements. Specific topics included near term research on closely spaced parallel runway operations, evolution of NASA AVOSS technology for operational use, and international cooperation in wake turbulence research.

Greene, G. C.

"CURRENT STATUS AND APPLICATION OF HAZARD DEFINITION TECHNOLOGY"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 342-350

This talk discusses the preliminary application of wake vortex hazard technologies to evaluate current aircraft separation standards. The purpose of the current research is to evaluate the state of technology for operational use and identify promising areas for future research. The study was based

on analysis tools for 1) estimating the initial wake strength, 2) estimating the effects of the atmosphere on the wake, and 3) estimating the effects of the wake on an encountering aircraft. Using a specified definition of an acceptable vortex encounter, minimum aircraft separation times were determined. The results were used as input to an optimizer for determining an optimum set of aircraft categories which would maximize a simple model of airport capacity. For a given maximum level of wake hazard exposure, it was found that optimizing aircraft categories by wing span, rather than weight, provided a modest increase in airport capacity. It was also found that categories for maximum airport capacity depended on the traffic mix and therefore optimum standards would be airport dependent.

"WAKE VORTEX RESEARCH - CURRENT ISSUES AND FUTURE DIRECTION"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 39-40.

This paper will briefly review past research leading up to some of the current issues in wake vortex research. Recent US experience in changing aircraft separation standards will be used to highlight some of the current issues. One view of future research requirements will be presented.

Greene, G. C.

"EFFECTS OF WEATHER ON AIRCRAFT WAKE TURBULENCE EXPERIENCED DURING CRUISE FLIGHT"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

Weather effects on aircraft wake turbulence in the terminal area are a current topic of international research. Due to recent reductions in vertical aircraft spacing over the north Atlantic Ocean, there is increasing international interest in the effects of wake turbulence during cruise operations. This paper presents an analytical study of the effects of weather and aircraft size on the potential for wake turbulence in cruise. A simple model of wake motion and decay is used to estimate the effects of winds, atmospheric turbulence, and temperature lapse rate on the maximum distance which a wake might descend. An estimate is also provided as to whether the wake remains coherent or descends as a series of crude rings due to the Crow Instability. The wing span of the generating aircraft is shown to be a critical parameter in addition to the weather.

Greene, G. C.

"WAKE VORTEX ALLEVIATION"

AIAA Paper No. 1981-0798, Atlantic City, NJ, May 1981.

This paper describes some of the National Aeronautics and Space Administration's (NASA's) recent and current research on aerodynamic techniques for minimizing the aircraft trailing vortex hazard. The potential benefits and operating problems of the more promising concepts are discussed. Recent

flight-test results are presented which show that essentially total vortex alleviation can be achieved at a 3 nautical mile separation distance by oscillating the aircraft's lateral-control surfaces. While not operationally practical, these results suggest that it may be possible to minimize the wake hazard by exciting longitudinal instabilities.

Greene, G. C.

"AN APPROXIMATE MODEL OF VORTEX DECAY IN THE ATMOSPHERE"

Journal of Aircraft, Vol. 23, No. 7, July 1986, pp. 566-573.

An approximate analysis of atmospheric effects on wake vortex motion and decay is presented. The effect of density stratification, turbulence, and Reynolds number are combined in a single model so that the relative importance of different parameters can be estimated. Predicted wake motion is shown to be in good agreement with limited data from ground facility and flight test measurements taken under low-turbulence conditions. Wake decay was found to depend strongly on both density stratifications and turbulence. For typical levels of turbulence, wake decay was found to result from the Crow instability except under strongly stratified conditions.

Greene, G. C.

"WAKE VORTEX MINIMIZATION"

Potential Impacts of Advanced Aerodynamic Technology on Air Transportation System Productivity, NASA TM-109154, edited by D. Bushnell, NASA Langley Research Center, Hampton, VA, September 1994, p. 94

A review was given of wake vortex minimization efforts. Considerable research was undertaken in the 1970's to help reduce the adverse effects of an airplane wake, but the assumptions in this early research were that maximum vortex velocities were associated with the vortex hazard without the concern for the whole vorticity throughout the flow field. Since then, an improved understanding has merged to show the powerful effect inboard vortices have on the primary (tip) vortex, and the importance of atmospheric coupling.

Greene, G. C.

"HISTORY OF WAKE VORTEX RESEARCH: PROBLEMS AND ACCOMPLISHMENTS"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 23-32

This talk presents a history of wake vortex research with emphasis on significant problems and accomplishments. Early lessons in wake physics from wake alleviation research conducted in wind

tunnels and in-flight tests are discussed. The effects of atmospheric conditions and test techniques on the reliability of existing data are emphasized. Significant events, such as the British Vortex Incident Reporting System, which have had a long-term effect on wake vortex research are described. Remaining questions and challenges for implementing an operational wake vortex system are summarized. Although much has been learned through technical research, the primary challenges are to solve the operational wake vortex issues which face the international community.

Greene, G. C.

"A380 INTERNATIONAL WAKE VORTEX WORKING GROUP OVERVIEW"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

The Airbus A380 will be larger and heavier than existing commercial air transport aircraft. To maintain the operational safety of other aircraft, air traffic service providers/national aviation safety regulators need assurance of the adequacy of the separation standards to be applied to the A380. Due to the increase in mass/size of the A380 compared to current aircraft types, a special study was deemed necessary to investigate the A380's wake vortex characteristics and to compare them with other existing types of aircraft. To accomplish this study and ensure that the results would be applied internationally, a Steering Group was established with members from CJAA, Eurocontrol, FAA, ICAO Secretariat, and Airbus. This Steering Group forms appropriate Working Groups as required, consisting of experts and specialists in appropriate areas. At the initial meeting, a Technical Working Group was formed to accomplish the more scientific aspects of this effort. This talk provides an overview of the composition and responsibilities of the Steering Group and Technical Working Group and introduces two additional talks, which address the approaches to be taken in assessing the A380 wake turbulence risk.

Greene, G. C., Dunham, Jr., R. E., Burnham, D. C., Hallock, J. N. and Rossow, V. J.

"WAKE VORTEX RESEARCH LESSONS LEARNED"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 2-1 - 2-13

During the 1970's and the early 1980's, the FAA and NASA conducted extensive wake vortex research programs with the goal of safely increasing airport capacity. The FAA program focused on developing an extensive data base and the technology for predicting and/or detecting the presence of a vortex and advising controllers when aircraft separations could be safely reduced. The NASA program emphasized reducing the wake hazard through changes to the aerodynamic characteristics of the aircraft. Both programs made significant technical progress even though neither program resulted in an implementable solution. Current research has the same goal and many of the same challenges as the earlier research. This paper discusses the most important lessons learned from prior research by both

the FAA and NASA and, in particular, how prior research has shaped the issues, requirements, and constraints which will affect any proposed solution.

"AIRCRAFT VORTICES - JUNCTURE, WING, AND WAKE"

AIAA Paper No. 1988-3742, Cincinnati, OH, July 1988.

Many real aircraft flows contain regions of three-dimensional separation with vortices. This paper presents selected results for three representative flows: juncture vortex, lifting-wing vortex, and wake vortex. Due to the difficulty of studying vortices, flow visualization was used as a primary research tool. Vortices are found to depend in subtle ways on details of the configuration, Reynolds number, or the environment. Examples showing the effect of filleting on the juncture flow, Reynolds number on the wing flow, and density gradients on the wake flow are presented.

"PROJECT SOCRATES: USE OF LASER BEAMS TO SENSE ACOUSTIC EMANATIONS FROM AIRCRAFT WAKE VORTICES"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

Development of a new technology that uses low-power laser beams to detect acoustic energy emanating from aircraft wake vortices is being sponsored by the Federal Aviation Administration and the National Aeronautics and Space Administration. A system based on this technology was used to monitor aircraft landings at JFK International Airport. Acoustic signals from wake vortices recorded by the system and the results of their analysis are described.

Greenhalgh, S.

"LIFT ENHANCEMENT DEVICE"

US Patent 5,226,618, July 1993

A lift enhancing device for an inextensible, membranous wing is disclosed. The device comprises the 'forced' reattachment of a section of the trailing edge back to the trailing edge so that a warp is introduced therein. The section is reattached with flexible tape to allow oscillation of the section, and increased lift from the wing, at prescribed airspeeds.

"TURBULENCE KINETIC ENERGY BUDGET PROFILES DERIVED FROM DOPPLER SODAR MEASUREMENTS"

Journal of Applied Meteorology, Vol. 28, February 1989, pp. 99-106.

Doppler sodar wind measurements made in light wind conditions in September 1979 near a power plant in Turbigo, Italy, are used to derive terms in the turbulence kinetic energy (TKE) budget. Measurements on five days are grouped into two classes: fair-weather conditions and boundary layer interaction with subsiding air. Profiles of $(\sigma w^3)/z$ are used to obtain the surface heat flux and the vertical velocity scaling parameter, as well as the buoyancy production term in the TKE budget. The vertical transport of TKE is derived from the profiles of the averaged w' cubed. The horizontal components are approximated using a parameterization based on the data of Lenschow et al. Dissipation in the TKE budget is obtained from a spectral analysis of the Doppler sodar data in the inertial subrange. The resulting TKE budget profiles for the two classes are compared with budgets obtained previously, using several different methods.

Greenwell, D. I.

"PITFALLS IN THE INTERPRETATION OF DELTA WING FLOW VISUALIZATION"

RTO-MP-069, March 2003, NATO Research and Technology Organization, Neuilly-Sue-Seine Cedex, France.

This paper illustrates some pitfalls in the interpretation of flow visualization images of delta wing leading-edge vortices. Numerical simulations of tracer particle trajectories in around straight and helical vortices are presented, representing unburst and burst delta wing vortices respectively. For straight vortices, the appearance of the 'smoke-ring' effect in wind tunnel testing is analyzed, and shown to be unrelated to the size or presence of a viscous inner core in the vortex. The role of the swirl-induced radial pressure gradient in the vortex centerline trace seen in water tunnels is demonstrated. For helical (burst) vortices, the crossflow topology visualized with upstream tracer injection is shown to depend on the vortex core size and the helix pitch. Typical vortex helices are close to a flow regime which can produce visualized flow structures resembling axisymmetric bubble breakdowns. It is postulated that the intermittent open-ended bubble burst seen in delta wing vortices is in fact an artifact of the tracer flow visualization technique, as transient disturbances temporarily reduce the pitch of the fundamental helical burst structure.

Greenwell, D. I.

"PITFALLS IN THE INTERPRETATION OF DELTA WING FLOW VISUALIZATION"

RTO AVT Symposium on Advanced Flow Management: Part A -- Vortex Flows and High Angle of Attack for Military Vehicles, May 2001, Loen, Norway.

This paper illustrates some pitfalls in the interpretation of flow visualization images of delta wing leading-edge vortices. Numerical simulations of tracer particle trajectories in around straight and helical vortices are presented, representing unburst and burst delta wing vortices respectively. For straight vortices, the appearance of the 'smoke-ring' effect in wind tunnel testing is analyzed, and shown to be unrelated to the size or presence of a viscous inner core in the vortex. The role of the

swirl-induced radial pressure gradient in the vortex centerline trace seen in water tunnels is demonstrated. For helical (burst) vortices, the crossflow topology visualized with upstream tracer injection is shown to depend on the vortex core size and the helix pitch. Typical vortex helices are close to a flow regime which can produce visualized flow structures resembling axisymmetric bubble breakdowns. It is postulated that the intermittent open-ended bubble burst seen in delta wing vortices is in fact an artifact of the tracer flow visualization technique, as transient disturbances temporarily reduce the pitch of the fundamental helical burst structure.

"EFFECT OF TRACER PARTICLE CHARACTERISTICS ON VISUALISATION OF DELTA WING VORTICES"

9th International Symposium on Flow Visualization, Paper No. 111, 2000, pp. 111-1-111-10

Preliminary investigations of the effect of tracer particle characteristics on flow visualization in a steady delta wing leading-edge vortex are presented, using both 3D simulations of particle trajectories and a simplified analysis of the radial equilibrium conditions. It is shown that many of the flow structures apparently seen in wind and water tunnel visualization studies of delta wing vortices are an artifact of the tracer particle characteristics. In particular, the 'smoke tube' or 'hole' effect often seen in smoke flow visualization in wind tunnels does not (contrary to popular usage) indicate the size of the viscous sub-core and is not a reliable indicator of the vortex structure.

Greenwood, J. S.

"WAKE VORTEX SENSORS"

CS Report 9346, November 1993, Chief Scientist's Division, National Air Traffic Services, London, England.

This report reviews research into wake vortex sensors which has been conducted by the Chief Scientist's Division (CSD) of the National Air Traffic Services (NATS) and other organizations, and sets out options for future work. Further development of a Laser Doppler Velocimeter is recommended.

Greenwood, J. S. and Vaughan, J. M.

"MEASUREMENTS OF AIRCRAFT WAKE VORTICES AT HEATHROW BY LASER DOPPLER VELOCIMETRY"

Air Traffic Control Quarterly, Vol. 6, No. 3, September 1998, pp. 179-203

Measurements of aircraft wake vortices by Laser Doppler Velocimetry can provide unique, full-scale information on vortex generation, evolution, trajectory, and decay in the real atmosphere. During trials at Heathrow nearly 3,000 records of vortices from landing aircraft were made over 25 days spread between November 1994 and September 1995. Examples of some of the initial results are presented, including characteristic vortex signatures and profiles from different aircraft, analysis of vortex strength and trajectory, and an unusual record of a B747 vortex that initially descended but then returned to the

glideslope with virtually undiminished strength 70 seconds after its generation. The way in which this information has been deduced from the measurements is explained fully, and the tradeoffs between the resolution and coverage of measurements are described.

"DEVELOPMENT OF AN ALGORITHM FOR NUMERICAL SIMULATION OF WATER CONDENSATION IN THE JET-VORTEX WAKE OF AN AIRCRAFT AT LOW ATMOSPHERE"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 310-323

The paper presents a physio-mathematical model of the jet-vortex wake behind an aircraft with allowance for heterogeneous condensation of water vapor, inert droplets collisions due to micro-fluctuations of the carrying medium and with modified anisotropic turbulence. In imposing boundary conditions, results of flight tests involving C-130 and OV-10 aircraft were used together with the wind-tunnel data obtained by teams of researchers at NASA and Boeing. Numerical algorithm and tests for a B-747-type heavy aircraft are briefly described in the present work. The materials presented can be used in assessing optical properties of aerosols behind an aircraft with the aim of visualization of its trailing vortices.

Grinats, E. S., Kashevarov, A. V. and Stasenko, A. L.

"NUMERICAL STUDY OF THE JET-VORTEX WAKE BEHIND A HEAVY AIRCRAFT FLYING NEAR THE GROUND"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 137-145

As applied to the problem of aircraft wake visualization over an airfield, gas dynamic and optical characteristics of engine exhaust jets and vortex wakes have been numerically explored with consideration for the heterogeneous condensation of water vapors both being exhausted by the engines and contained in the atmosphere. The influence of the turbulent characteristics of the airflow behind an aircraft was considered on the dissipation rate of the exhaust jets in the near wake. The vicinity of the ground was taken into consideration in studying the mechanics and phase composition of the jet-vortex wake. The spatial distributions were found for concentrations of water vapor and condensate, particle sizes as well as some moments over the particles' mass spectrum, which characterize the dispersive properties of the wake. The calculations were performed for the landing conditions of a B-747 type heavy four-engine aircraft [In Russian].

"LIGHT SCATTERING BY CONDENSATE PARTICULATES IN THE VORTEX-JET WAKE BEHIND A CIVIL AIRCRAFT AT LOW HEIGHT"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 113-120

The light scattering by an axisymmetric jet and vortex-jet wake, containing condensate particulates, has been numerically investigated on the basis of Mie's theory of electromagnetic radiation scattering by a single spherical dielectric particulate and the principle of superposition of contributions from individual particulates. Results of the numerical investigations of scattered light characteristics are given for the case of the B-747-type heavy civil aircraft near the ground.

Griswold, II, R. W.

"VORTEX ALLEVIATING WING TIP"

US Patent 4,477,042, October 1984

A wing tip is contoured and shaped to bring about a controlled merger of fluid flows across the upper and lower wing surfaces and alleviation of the resulting vortex when the wing is producing lift or thrust. Control through geometry of the wing tip can be augmented by discharging fluid into the merging flows which weakens the strength of the vortex and results in more rapid dissipation in the wake of an aircraft. Additionally, the origin of the vortex is prevented from migrating inboard of the wing tip which improves overall wing efficiency.

Groenenboom, J. and Levalts, J.

"WING VORTEX VISUALIZATION AND INTERFERENCE PATTERNS"

AIAA Paper No. 1977-0309, Washington, DC, 1977

Two symmetrical airfoils with an elliptical lift distribution were tested in the Iowa State University low-turbulence wind tunnel to determine through visualization the effects of vortex interaction. The first portion of the study was devoted to determining the best method of vortex visualization. It was found that steam injected into the flow forward of the airfoils gave the best delineation. The two wings were tested to determine what effect circulation strength and direction and separation distance had on the vortices at various downstream locations. Test results showed that the vortices interacted by wrapping around one another and merging. The degree of interaction was primarily dependent on separating distance and circulation strength.

"SIMULATING THE INTERACTION OF A THREE-DIMENSIONAL VORTEX WITH AIRFOILS USING CAA"

AIAA Paper No. 2001-2137, Maastricht, The Netherlands, May 2001

The noise generated by the interaction of localized three-dimensional vorticity with the leading edge of Joukowski-type airfoils is calculated numerically. As governing equations, the linearized Euler-

equations are solved in curvilinear coordinates. For spatial discretization the well-known DRP-scheme is used and for time marching the classical explicit 4th order Runge-Kutta scheme is employed. The mean-flow is pre-calculated analytically. Calculations are performed for three-dimensional vorticity spots striking the leading edge of the airfoil. The influence of the principal fluctuation component on noise generation is assessed by different rotational axes of the vorticity. The investigated airfoils have a thickness of 6, 12 and 18 percent. As limiting case the simulations are also performed for an infinite thin flat plate. Directivity patterns are evaluated and compared.

"REQUIRED SURVEILLANCE PERFORMANCE FOR REDUCED MINIMAL-PAIR ARRIVAL SEPARATIONS"

Eleventh USA/Europe Air Traffic Management Research and Development Seminar (ATM2015), June 2015, Lisbon, Portugal.

This paper will investigate and propose preliminary Required Surveillance Performance (RSP) requirements associated to a longitudinal arrival separation of 2.0 NM. Just as new regulations requiring navigation are using Required Navigation Performance (RNP) to disassociate the regulation from a particular type of technology and substitute general performance requirements for any current or future navigation technology, an effort is needed to assign RSP requirements in separation minima. RSP requirements have already been set in Europe for 5 NM and 3 NM horizontal separations in en-route flight. Currently referred to as the minimal-pair radar separation, non-wake turbulence longitudinal arrival separations are set by ICAO at 3 NM (or 2.5 NM if conditions permit). Part of the effort in the SESAR 6.8.1 project is to propose a new, non-wake turbulence longitudinal arrival separation of 2.0 NM enabled through Required Surveillance Performance (RSP). The proposed preliminary requirements for a 2 NM minimal-pair arrival separation were achieved using the separation model developed within the RESET project. This model uses the current separation minima and their influencing factors to create a separation assurance budget software tool, identifying the various budget components and influencing factors that contribute to the establishment of separation minima. Although several approaches are possible, this formalization considers the uncertainties in the position, velocity, and aircraft intent as well as all the factors needed for perception, comprehension, and projection of the status of aircraft. This formalization provides the homogeneous means for the technological and procedural assessments in term of contribution to separation minima. To ensure the required TLS, a safety assessment needs to be done to analyze the other factors to present a complete safety case. However, the preliminary results of this study show that a RSP associated with ADS-B seems to be sufficient for a 2 NM minimal-pair arrival separation with current TLS.

Groskreutz, A. R. and Mayer, G. R.

"ANALYSIS OF 2NM SEPARATION FOR MINIMAL PAIR ARRIVALS"

Fifth SESAR Innovation Days, December 2015, Bologna, Italy.

This paper presents preliminary results regarding the conditions in which a 2 NM arrival separation can be implemented taking into consideration the relationship between arrival separation, runway occupancy time, and exit location. The analysis was carried out using expert workshops and Monte Carlo simulations, where the recommendations of the experts were put into simulated conditions. To better simulate various airport conditions, various traffic mix samples were used, varying the percentage of aircraft that could take advantage of the reduced separation between 50 and 80 percent. The proposed re-categorization separation matrix was also used to better simulate future conditions. Average arrival Runway Occupancy Times (AROTs) were given to each aircraft category defined and these values were varied to simulate different exit taxiway layouts. In addition to fast-time simulations, a workshop on the relation between minimal-pair separations and AROT was held. Controllers, pilots and operational experts were in attendance. The objective was to discuss not only the factors that can limit the AROT, but also means to reduce it to take advantage of the reduced separations. It was then shown that these means are sufficient to reduce the AROT so that the 2 NM separations can be used for most aircraft pairs that are not wake turbulence limited. It was also shown that the arrival results show between a 6 and 30 percent capacity improvement depending on the scenarios compared, even without using intelligent sequencing of the aircraft. Further studies are warranted with the inclusion of this type of arrival sequencing.

Grow, T. L.

"THE EFFECT OF WING GEOMETRY AND LOWER SURFACE BOUNDARY LAYER ON THE ROLLED-UP TIP VORTEX"

M.S. Thesis, June 1967, Penn. State Univ., University Park, PA.

A theoretical and an experimental analysis were performed to determine the effect the wing geometry and the boundary layer on the lower surface of the wing have on the size and strength of the rolled-up tip vortex. The theoretical analysis was limited by the inherent three-dimensional properties of the flow. An extensive experimental investigation provided results which adequately described the vortex strength and geometry for the many wing configurations which were tested. From these results the size and strength of the rolled-up tip vortex can be predicted for any wing with similar geometry and Reynolds number.

Grow, T. L.

"EFFECT OF A WING ON ITS TIP VORTEX"

Journal of Aircraft, Vol. 5, No. 2, March-April 1968, pp. 37-41

A theoretical and an experimental analysis was performed to determine the effect that the wing geometry and the boundary layer on the lower surface of the wing have on the trailing rolled-up tip vortex. Model test results are presented for the vortex structure downstream of wings of varying aspect ratio and taper ratio. The geometry and strength of the rolled-up tip vortices were measured over a range of lift coefficients. In general, it was found that the strength of the vortex is less than one

would predict based on the midspan circulation about the wing. Conclusions are given regarding the size and strength of a vortex as they relate to the wing aspect ratio, taper ratio, and lift coefficient.

Gryazin, V. E.

"ALLEVIATION OF THE WAKE VORTEX EFFECT ON THE TRAILING AIRCRAFT THROUGH AUTOMATION OF THE FLIGHT-DIRECTOR CONTROL AT LANDING APPROACH"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 247-254

The author considers feasible means to alleviate hazardous effects of the aircraft wake on a trailing aircraft after it has been detected by the onboard automatic wake detection system [Gryazin and Poyedinok 1997]. Both lateral maneuver, to avoid the vortex core, and automatic additional deflection of the control surfaces are shown to solve the problem. Piloted simulation of the aircraft landing approach has proven sufficient effectiveness of the proposed means.

Gryazin, V. E.

"ANALYSIS OF THE WAKE VORTEX DETECTION SYSTEM NOISE IMMUNITY UNDER CONDITIONS OF TURBULENT ATMOSPHERIC BOUNDARY LAYER"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 255-262

The paper dwells upon modeling algorithms for the surface air turbulence presented as a 3D velocity field, thus enabling modeling of the wind gusts distribution over the aircraft airframe. These algorithms are then employed to assess noise immunity of the vortex detection system in the conditions of atmosphere turbulence.

Gryazin, V. E.

"RESEARCH ON AIRCRAFT FLIGHT SAFETY IN WAKE TURBULENCE CONDITIONS THROUGH PILOT-IN-THE-LOOP SIMULATION"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 225-228

A piloted simulation has been carried out of the flight dynamics of a transport category aircraft ($G=25$ t - weight, $S=82$ square meters - wing area, $l=30$ m - wing span) during landing approach in wake turbulence conditions. It was shown that according to opinions of test pilots who flew the simulation aircraft wakes pose a significant hazard to encountering aircraft ($PR > 6$, i.e. the third level of pilot's perceive handling qualities rating) when the wake-induced rolling moments exceed 50% of the maximum rolling moment at full aileron deflection. In such conditions, roll angles can exceed the maximum allowable value (10 degrees). If the pilot is provided with information on his aircraft

approaching a vortex wake, he will be able to counteract the rolling moment induced by the wake, such a moment sometimes reaching the aircraft maximum roll control authority.

Gryazin, V. E. and Poyedinok, V. M.

"ALGORITHMS OF VORTEX WAKE DETECTION AND FLIGHT-DIRECTOR CONTROL FOR EXECUTING WAKE-AVOIDANCE MANEUVERS"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 121-131.

The algorithms for the on-board vortex-wake detection system has been synthesized. The existing airborne equipment is shown to allow timely detecting of wake vortices and determining their position relative to the aircraft. Algorithms have been proposed for the flight-director control system intended for executing a side vortex-wake-avoidance maneuver. Being employed the system can help to reduce now adopted safe-separation distances in landing approach.

"COOPERATIVE GUST SENSING AND SUPPRESSION FOR AIRCRAFT FORMATION FLIGHT, PHASE II"

Leading Edge Aeronautics Research for NASA (LEARN) research report, December 2016, West Virginia University, Morgantown, WV.

Autonomous formation flight is an enabling technology for many future concepts of operations involving both manned and unmanned aircraft. Its potential benefits include energy saving and improved aircraft coordination within a high-density airspace. However, with the following aircraft constantly flying in the leader's wake, several technical challenges need to be overcome before commercial aircraft and Unmanned Aerial Vehicles (UAVs) can routinely and safely fly in formation. Many challenges are related to the modeling, prediction, and real-time sensing of the dynamic airflow field, which includes both ambient and wake-induced wind gust disturbances. The objective of this overall research effort was to develop and experimentally validate a cooperative strategy for gust sensing and suppression within a close formation flight setting. During the Phase I effort, a real-time wind estimation algorithm was developed. Additionally, the concept of cooperative wind sensing was validated in simulation studies. Furthermore, autonomous close formation flights were achieved using two sub-scale research aircraft at a 5x wingspan distance. The effects of the wake vortices were successfully recorded by sensors onboard the follower aircraft. During the Phase II effort, wake identification from UAV formation flight data was performed. An integrated aerodynamics and flight dynamic simulator for UAS wake encounters was developed using the vortex lattice method. Four different wind speed estimation algorithms were developed and compared using simulated and flight data. The research test beds were upgraded with new sensors, propulsion systems, communication devices, and newly designed avionics. Over 45 flight testing experiments were performed for supporting system integration tasks and for collecting research data. A relative navigation algorithm fusing measurements provided by a carrier phase differential GPS receiver, inertial sensors, and ranging

radios was developed to improve the robustness of the navigation solution. A novel computer vision-based airflow angle estimation method was also developed and validated with flight data. Each of these technical developments are presented in this report.

Guerin, D.

"CONSIDERATION OF WAKE TURBULENCE DURING THE INTEGRATION OF REMOTELY PILOTED AIRCRAFT INTO THE AIR TRAFFIC MANAGEMENT SYSTEM"

Proceedings of the 2015 International Conference on Unmanned Aircraft Systems (ICUAS), June 2015, Denver, CO, pp. 926-935.

The last decade has witnessed both the growth in Remotely Piloted Aircraft (RPA) numbers and the introduction of the Airbus A380, the largest passenger aircraft to enter commercial service. Both introduce extremes at either end of the spectrum for weight and wingspan: into an Air Traffic Management (ATM) where wake vortex separation minima have been unchanged for three decades. However, airport congestion may compel a rethink, and the mandated separation distances in place for wake turbulence are under scrutiny. Remotely Piloted Aircraft Systems (RPAS) will inject yet another permutation into deliberation for separation standards and wake turbulence considerations. However, aside from complicating the space, RPA offer a means to reduce the mandated gaps, and subsequently alleviate capacity issues. This paper examines wake turbulence and its effects and proposes trials to reinforce reductions or expansions of present and future separation minima.

Guerreiro, N. M. and Neitzke, K. W.

"SIMULATED WAKE CHARACTERISTICS DATA FOR CLOSELY SPACED PARALLEL RUNWAY OPERATIONS ANALYSIS"

AIAA Paper 2012-5642, September 2012, Indianapolis, Indiana.

A simulation experiment was performed to generate and compile wake characteristics data relevant to the evaluation and feasibility analysis of closely spaced parallel runway (CSPR) operational concepts. While the experiment in this work is not tailored to any particular operational concept, the generated data applies to the broader class of CSPR concepts, where a trailing aircraft on a CSPR approach is required to stay ahead of the wake vortices generated by a lead aircraft on an adjacent CSPR. Data for wake age, circulation strength, and wake altitude change, at various lateral offset distances from the wake-generating lead aircraft approach path were compiled for a set of nine aircraft spanning the full range of FAA and ICAO wake classifications. A total of 54 scenarios were simulated to generate data related to key parameters that determine wake behavior. Of particular interest are wake age characteristics that can be used to evaluate both time- and distance-based in-trail separation concepts for all aircraft wake-class combinations. A simple first-order difference model was developed to enable the computation of wake parameter estimates for aircraft models having weight, wing span and speed characteristics similar to those of the nine aircraft modeled in this work.

Guerreiro, N. M., Neitzke, K. W., Johnson, S. C., Stough III, H. P., McKissick, B. T. and Syed, H. I.

"CHARACTERIZING A WAKE-FREE SAFE ZONE FOR THE SIMPLIFIED AIRCRAFT-BASED PAIRED APPROACH CONCEPT"

AIAA Paper No. 2010-7681, Toronto, Canada, August 2010.

The FAA has proposed a concept of operations geared towards achieving increased arrival throughput at U.S. Airports, known as the Simplified Aircraft-based Paired Approach (SAPA) concept. In this study, a preliminary characterization of a wake-free safe zone (WSZ) for the SAPA concept has been performed. The experiment employed Monte-Carlo simulations of varying approach profiles by aircraft pairs to closely-spaced parallel runways. Three different runway lateral spacings were investigated (750 ft, 1000 ft and 1400 ft), along with no stagger and 1500 ft stagger between runway thresholds. The paired aircraft were flown in a leader/trailer configuration with potential wake encounters detected using a wake detection surface translating with the trailing aircraft. The WSZ is characterized in terms of the smallest observed initial in-trail distance leading to a wake encounter anywhere along the approach path of the aircraft. The results suggest that the WSZ can be characterized in terms of two primary altitude regions, in ground-effect (IGE) and out of ground-effect (OGE), with the IGE region being the limiting case with a significantly smaller WSZ. Runway stagger was observed to only modestly reduce the WSZ size, predominantly in the OGE region.

"FINITE ELEMENT SOLUTION OF THE 3D COMPRESSIBLE NAVIER-STOKES EQUATIONS BY A VELOCITY-VORTICITY METHOD"

Journal of Computational Physics, Vol. 107, 1993, pp. 176-187

This paper presents an alternative formulation to the primitive variable form of the Navier-Stokes equations. The approach is based on the use of the velocity and vorticity variables as a logical extension of the stream function-vorticity method which is quite effective for two-dimensional flows. Second-order equations are obtained for the variables and discretization is through a weak-Galerkin finite element method, followed by Newton linearization. The velocity and vorticity components are solved simultaneously by a direct solver. The scheme is demonstrated for two-dimensional and three-dimensional incompressible and subsonic internal enclosed flow problems.

Guha, T. K.

"ACTIVE CONTROL OF WINGTIP VORTICES USING PIEZOELECTRIC ACTUATED WINGLETS"

PhD Thesis, Summer 2017, Florida State University, Tallahassee, FL.

Wingtip vortices develop at the tips of aircraft wings due to a pressure imbalance during the process of generating lift. These vortices significantly increase the total aerodynamic drag of an aircraft at high-lift flight conditions such as during take-off and landing. The long trailing vortices contain strong circulation and may induce rolling moments and lift losses on a trailing aircraft, making them a major

cause for wake turbulence. A mandatory spacing between aircraft is administered by civil aviation agencies to reduce the probability of hazardous wake encounters. These measures, while necessary, restrict the capacity of major airports and lead to higher wait times between take-off and landing of two aircraft. This poses a major challenge in the face of continuously increasing air traffic volume. Wingtip vortices are also known as a potent source of aerodynamic vibrations and noise. These negative effects have made the study of wingtip vortex attenuation a critical area of research. The problem of induced drag has been addressed with the development of wingtip device, like winglets. Tip devices diffuse the vortex at its very onset leading to lower induced drag. The problem of wake turbulence has been addressed in studies on vortex interactions and co-operative instabilities. These instabilities accelerate the process of vortex breakdown, leading to a lower lifetime in the wake. A few studies have tried to develop active mechanisms that can artificially excite these instabilities. The aim of the present study is to develop a device that can be used for both reducing induced drag and exciting wake instabilities. To accomplish this objective, an active winglet actuator has been developed with the help of piezoelectric Macro-Fiber Composite (MFC). The winglet is capable of oscillating about the main wing-section at desired frequency and amplitude. A passive winglet is a well-established drag reducing device. An oscillating winglet can introduce perturbations that can potentially lead to instabilities and accelerate the process of vortex breakdown. A half-body model of a generic aircraft configuration was fabricated to characterize and evaluate the performance of actuated winglets. Two winglet models having mean dihedral orientations of 0 degree and 75-degree were studied. The freestream velocity for these experiments was 20 m/s. The angle of incidence of the wing-section was varied between 0 degree and 8-degree. The Reynolds number based on the mid-chord length of the wing-section is 140000. The first part of the study consisted of a detailed structural characterization of the winglets at various input excitation and pressure loading conditions. The second part consisted of low-speed wind tunnel tests to investigate the effects of actuation on the development of wingtip vortices at different angles of incidence. Measurements included static surface pressure distributions and Stereoscopic (ensemble and phase-locked) Particle Image Velocimetry (SPIV) at various downstream planes. Modal analysis of the fluctuations existing in the baseline vortex and those introduced by actuation is conducted with the help of Proper Orthogonal Decomposition (POD) technique. The winglet oscillations show bi-modal behavior for both structural and actuation modes of resonance. The oscillatory amplitude at these actuation modes increases linearly with the magnitude of excitation. During wind tunnel tests, fluid structure interactions lead to structural vibrations of the wing. The effect of these vibrations on the winglet oscillations decreases with the increase in the strength of actuation. At high input excitation, the actuated winglet can generate controlled oscillations suitable for perturbing the vortex. The vortex associated with a winglet is stretched along its axis with multiple vorticity peaks. The center of the vortex core is seen at the root of the winglet while the highest vorticity levels are observed at the tip.

Guha, T. K. and Kumar, R.

"CHARACTERISTICS OF A WINGTIP VORTEX FROM AN OSCILLATING WINGLET"

Experiments in Fluids, Vol. 58, 2017, pp. 8-1 to 8-18.

Initial perturbations in the wingtip vortices can potentially lead to instabilities that significantly reduce their lifetime in the wake of an aircraft. An active winglet capable of oscillating about its point of attachment to the main wing-section is developed using piezoelectric macro fiber composite, to actively perturb the vortex at its onset. Resonance characteristics of the actuated winglet oscillations are evaluated at different excitation levels and aerodynamic loading. Mean near-field characteristics of the vortex, developing from a stationary and an oscillating winglet, are investigated with the help of stereoscopic particle image velocimetry. Results show that the amplitude of winglet oscillations increases linearly with input excitation, to a highest attainable value of nearly four times the airfoil thickness at the winglet tip. The vortex developing from a winglet is stretched along its axis, having an elliptical core with non-uniform vorticity distribution. Actuation leads to spatial oscillations of the vortex core together with a reduction in the mean peak vorticity levels. The amplitude of the actuated core oscillations remains constant in the investigated region of the wake.

"ACTIVE CONTROL OF WINGTIP VORTICES USING PIEZOELECTRIC ACTUATED WINGLETS"

AIAA Paper 2016-0323, January 2016, San Diego, CA.

Wingtip vortices are caused by the pressure difference between the upper and lower surface of a wing equalizing at the tip. In the present study, piezoelectric Marco Fiber Composite (MFC) actuated winglets have been designed and developed to control the initiation and development of wingtip vortices. A half model of a generic aircraft configuration was fabricated to characterize and evaluate the performance of actuated winglets. Actuated winglets are capable of oscillating about their mean dihedral position with varying amplitudes and frequencies. Measurements include surface pressure distributions, planar and stereoscopic (ensemble averaged and phase locked) Particle Image Velocimetry at various downstream locations to study the effect of actuation on wingtip vortex development and diffusion. Vortex developing around a winglet has a core that is stretched along the axis of the winglet, and the vorticity distribution show two unequal peaks. This vortex stretching indicates that the net circulation is distributed over a large region leading to lower levels of peak vorticity, which translates into lower induced drag and faster decay. With MFC actuation, there appears to be further stretching in the tip vortex leading to lower peak vorticity levels.

"BOEING 767 PROXIMITY EVALUATION WITH F/A-18C AND S-3B AIRCRAFT"

NAWCADPAX/RTR-2001/17, March 2001, Naval Air Warfare Center Aircraft Division, Patuxent River, MD

The Boeing company participated in the Future Strategic Tanker Aircraft program which was intended to provide aerial refueling and aerial transport capability. This study was to determine if an area of acceptable wake turbulence existed in the proximity of a 767 in order to perform the aerial refueling mission. This was accomplished by evaluating the 767 aerodynamic and wake turbulence effects on two receiver aircraft (F/A-18C and S-3B) at locations behind the 767, which approximated potential

aerial refueling engagement areas. A Lear 35 cinematography aircraft was used to document test results.

Guignery, F., Vancassel, X., Montreuil, E. and Thual, O.

"NUMERICAL SIMULATION OF CONTRAIL FORMATION USING A SIMPLIFIED WING-INJECTOR CONFIGURATION"

AIAA Paper No. 2009-3868, San Antonio, Texas, June 2009.

Contrail formation is a complex topic, since several physical processes are involved, covering a large range of space and time scales, from the engine exit to the atmospheric global scale. In the near field of the aircraft, contrail formation is mainly dominated by microphysics and mixing processes between the propelling jets and the external flow and more precisely during the jet-vortex interaction. In this paper, we present a new approach to focus on the influence of the wing/nacelle configuration on contrail onset. The originality of this work is to provide a preliminary study to consider a complex aircraft geometry in further jet vortex numerical simulations using the ONERA multi-physics code CEDRE.

"A VORTICITY-VELOCITY METHOD FOR THE NUMERICAL SOLUTION OF 3D INCOMPRESSIBLE FLOWS"

Journal of Computational Physics, Vol. 106, 1993, pp. 286-298

A new method for the numerical solution of the 3D Navier-Stokes equations written in terms of vorticity-velocity is presented. The advantages of this formulation with respect to primitive variables and vorticity-vector-potential ones are discussed in view of physical as well as engineering applications. A suitable form of the continuum equations, the most appropriate discretization scheme, and variable location in order to guarantee the solenoidality of the velocity and vorticity fields are introduced and justified. A 3D lid driven cavity problem for $400 \leq Re \leq 3200$ is chosen as a test case for comparison and validation purposes. A parallel implementation of the method has been performed on a shared memory architecture mainframe. Speedup results and efficiency considerations are given and discussed.

"A NUMERICAL STUDY OF THE AERODYNAMICS OF CESSNA 172 AIRCRAFTS IN ECHELON FORMATION"

AIAA Paper 2014-1107, January 2014, National Harbor, MD.

A vortex-lattice numerical scheme that uses a novel decambering technique to predict post-stall aerodynamic characteristics is used to study the aerodynamics of tandem Cessna 172 aircrafts flying in echelon formation. Results like $C_{L-\alpha}$ from the current method are compared with experiment. Additional results like section C_{L} distributions over wing spans, $C_{M-\alpha}$ and $C_{LW-\alpha}$ (i.e. C_{L} of the leading aircraft for different angles of attack of the trailing

aircraft) and analysis for y -offset, which are available only from the current numerical method are reported that supplement the experimental results. Detailed post-stall numerical analysis and the effect of chord-wise, span-wise and vertical offsets on the aerodynamics of the formation are also reported.

Gunasekaran, S. and Altman, A.

"IS THERE A RELATIONSHIP BETWEEN THE TURBULENCE CHARACTER OF THE WINGTIP VORTEX AND THE WING FREE SHEAR LAYER?"

AIAA Paper 2016-1068, January 2016, San Diego, CA.

PIV experiments were conducted in the wake of an aspect ratio 4 flat plate at the University of Dayton's Low Speed Wind Tunnel (UD-LSWT) to determine the existence of any relationship between the wingtip vortex and the wing's free shear layer. Several modifications were made to the wing boundary layer to investigate sensitivity to a range of boundary layer conditions. To explore this relationship, the mid semi-span free shear layer and the wingtip vortex were interrogated at various chord lengths distance downstream and across an angle of attack range of 1 to 4 degrees in the vicinity of the maximum (L/D) lift condition. The development of the wingtip vortex was examined with three primary fields of view oriented along the three axes (Streamwise, Cross-stream and Spanwise). Then a boundary layer trip was introduced on the upper surface of the flat plate to change the character of the turbulence in the boundary layer. The resulting changes in the turbulence character of the wingtip vortex and free shear layer were interrogated for evidence of an interaction between the free shear layer and the wingtip vortex. A significant relationship between the shear layer and the wingtip vortex was ultimately found and will be elaborated in detail.

Gunasekaran, S. and Altman, A.

"REFINED INSIGHT INTO THE WINGTIP VORTEX-FREE SHEAR LAYER INTERACTION"

AIAA Paper 2017-1705, January 2017, Grapevine, TX.

Interaction between the free shear layer (FSL), the wingtip vortex and aerodynamic efficiency was observed. These results were quantitatively evaluated through Particle Image Velocimetry (PIV) of the wingtip vortex and the free shear layer (FSL) obtained in the Low Speed Wind Tunnel at the University of Dayton (UD-LSWT). The experiments were conducted in the wake of an AR 4 flat plate with and without a boundary layer trip (BLT). The effect of the BLT on both the FSL and the wingtip vortex was previously documented. In the present work, the analysis was extended to explore the role the FSL interaction plays in the wingtip vortex evolution. Additionally, a correlation between this FSL-wingtip vortex interaction and the aerodynamic efficiency of the wing was sought. Streamwise, cross-stream and spanwise plane-oriented PIV of the wingtip vortex shows evidence of the FSL interaction with the wingtip vortex at lower angles of attack. Due to the FSL interaction with the wingtip vortex, vortex profiles predicted using Batchelor's and Brown's models deviate from the experimental data. The composite of the experimentally determined velocity profiles from different planes implied an

exchange of momentum between the FSL and the wingtip vortex in the vicinity of the maximum (L/D) lift condition. At an angle of attack less than that of maximum (L/D), the additional loss of momentum due to the BLT is seen in the wing wake FSL. At an angle of attack greater than that corresponding to the maximum (L/D), the additional loss of momentum due to the BLT is instead seen in the wingtip vortex.

Gunasekaran, S. and Altman, A.

"IDENTIFICATION OF AIRCRAFT BY THEIR UNIQUE TURBULENT WAKE SIGNATURE: PROGRESS WITH EXPERIMENTAL VALIDATION"

AIAA Paper 2013-1120, January 2013, Grapevine, TX.

The theoretical foundation for the identification of aircraft by their unique turbulent wake signature is experimentally validated. A brief review of this theoretical foundation will be discussed wherein the drag coefficient can be used to estimate either a Reynolds Stress distribution or [indirectly] a model of the profile of the fluctuating streamwise velocity component of the turbulent wake. Previously, the Reynolds stress distributions downstream of a circular cylinder, moderate aspect ratio wing and small remote control twin motor aircraft were determined using Particle Image Velocimetry (PIV) in the University of Dayton low speed wind tunnel. Those results were compared to the predicted Reynolds Stress distributions calculated from the drag coefficient obtained through direct force measurement. The cylindrical results validated the implementation of the method. The wing and aircraft results, however, were inconclusive since the wind tunnel test section was not long enough to guarantee that a self-preserved state had been achieved in the wake. For this paper, a wall-to-wall SD7003 wing profile and an aspect ratio 4 flat plate wing are tested in a much longer test section at the Air Force Research Labs Horizontal Free Surface Water Tunnel. The wakes are interrogated in streamwise planes using PIV at distances downstream ranging from 6 to 20 chord lengths. These results are then compared to the predicted Reynolds stress distributions determined from drag data available in the literature and from direct drag force measurement respectively for the two wing models. When using empirical tuning as a surrogate for a more rigorous determination of turbulence eddy viscosity the predicted Reynolds stress distributions compare extremely well across a wide range of angles of attack and chordwise PIV planes of interrogation (from mid semi-span to the wingtip). Asymmetry is present in the Reynolds Stress distribution and the theoretical model can be adjusted to account for it. The presence of the wingtip vortex does not prevent successful application of the model in the finite wing test.

Gundling, C., Roget, B. and Sitaraman, J.

"PREDICTION OF WIND TURBINE PERFORMANCE AND WAKE LOSSES USING ANALYSIS METHODS OF INCREMENTAL COMPLEXITY"

AIAA Paper 2011-0458, January 2011, Orlando, FL.

This paper compares several methods for predicting wind turbine performance, as well as predicting wake interference in a wind farm. The analysis tools range from the full CFD calculations at the high

complexity end to a traditional Blade Element Momentum based approach at the low complexity end. We perform full CFD calculations using the HELIOS (Helicopter Overset Simulations) code. HELIOS provides a novel meshing approach to CFD with body conforming unstructured grids near the solid walls and solution adaptive Cartesian grids away from the walls. This approach is particularly suited for vortex wake dominated flows such as those observed in wind turbine flow fields, where effective wake capturing depends largely on numerical dissipation. The different analytical methods are first applied to a model of the horizontal axis two-bladed rotor of the NREL Phase VI Unsteady Aerodynamic Experiment and then to a model of the 3-bladed turbines of the experimental Sexblerum wind farm. We further compare wake deficits behind an isolated turbine using the subset of methodologies that allow for probing of flow fields. Finally, we apply two of the chosen methodologies for studying performance losses caused by wake interference. In particular, we analyze the performance losses and nature of wind deficit when two turbines are operating, one behind the other, in pure axial flow condition.

Gundling, C., Roget, B., Sitaraman, J. and Rai, R.

"COMPARISON OF WIND TURBINE WAKES IN STEADY AND TURBULENT INFLOW"

AIAA Paper No. 2012-0899, January 2012, Nashville, TN.

This paper presents simulation results of wake effects in a wind farm, under both steady and turbulent inflow conditions. Depending on a wind farm's design, wake interference can cause large power losses and increased turbulence levels. The extent of these wake interference effects depends strongly on the atmospheric inflow conditions. The objective of the present study is to employ several modeling methods to reach an improved understanding of wake effects and to use this information to better optimize a farm's layout. The methods used in order of low to high complexity are: a blade element model with free-vortex wake approach for inflow (UWake), an actuator disk-based Reynolds-averaged Navier-Stokes (RANS) Computational Fluid Dynamics (CFD) method (DiskFlow) and a full blade RANS CFD code (HELIOS) that utilizes adaptive mesh refinement (AMR). The methods are collectively employed to model wind turbines at the Sexblerum wind farm, which allows for comparisons to experimental data and also for cross comparisons between the models. Single turbine wake deficits are modeled using both steady and turbulent inflow. Inflow turbulence is introduced using data from a precursor large eddy simulation (LES) of a neutral atmospheric boundary layer (ABL). A two-turbine exact row case is also modeled to investigate the dependence of the power deficit at the downstream turbine on inflow conditions. The differences in the diffusion of the wake with and without turbulent inflow are presented, and the limitations of each method are discussed.

Gunes, T. and Erdol, N.

"HMM BASED SPECTRAL FREQUENCY LINE TRACKING: IMPROVEMENTS AND NEW RESULTS"

IEEE Proceedings, Vol. 2, May 2006, pp. II-673-II-676

This paper considers the application of Hidden Markov Models to the problem of tracking frequency lines in spectrograms of strongly non-stationary signals such as encountered in aero-acoustics and sonar where tracking difficulties arise from low SNR and large variances associated with spectral estimates. In the proposed method, we introduce a novel method to determine the observation (measurement) likelihoods by interpolation between local maxima. We also show that use of low variance AutoRegressiveMultiTaper (ARMT) spectral estimates results in improved tracking. The frequency line is tracked using the Forward-Backward algorithm.

"VORTICES IN SUPERCONDUCTORS"

In *Vortex Dominated Flows*, edited by D. Blackmore, E. Krause and C. Tung, 2005, World Scientific, New Jersey, Chapter 4, pp. 67-85.

Fluid vortices have fascinated mankind from time immemorial and have been the subject of interest since the dawn of scientific inquiry. Superconducting vortices are of much more recent vintage, but are an equally fascinating phenomenon. Vortices in superconductors are tubes of magnetic flux, or equivalently, cylindrical current loops, that penetrate a material sample. Knowledge about the structure and dynamics of superconducting vortices are of importance both to the understanding of the basic physics of superconductors and to the design of devices. Vortices in superconductors can be modeled on several scales, from the microscopic to the macroscopic. Here, we concentrate on providing a brief review of mesoscopic-scale models for superconductivity, namely the Ginzburg-Landau equations and variants thereof. At this scale, superconducting vortices are analogous to viscous fluid models that consist of a collection of discrete vortices. The basic model holds for homogeneous, isotropic superconductors; the variants can account for inhomogeneities and anisotropies due to impurities, thickness variations, and thermal fluctuations. These all affect the vortex state, as do changes in the applied magnetic field and current strengths and directions. We use computational simulations to illustrate these effects.

Gunzburger, M. D.

"LONG TIME BEHAVIOIR OF A DECAYING VORTEX"

ZAMM, Vol. 53, 1973, pp. 751-760

The motion and decay of a vortex submerged in a two-dimensional inviscid stream is considered with view of seeking solutions valid for all time. A multiple time scale perturbation scheme is used to obtain solutions. The important effects of viscosity near the center of the vortex are included by a systematic procedure. To illustrate the theory solutions are then presented for the motion of a vortex subject to a sudden uniform gust and for the motion of a vortex in the presence of a wall.

"GUST ALLEVIATION OF A LARGE AIRCRAFT WITH A PASSIVE TWIST WINGTIP"

Aerospace, Vol. 2, 2015, pp. 135-154.

This paper presents an investigation into the gust response and wing structure load alleviation of a 200-seater aircraft by employing a passive twist wingtip (PTWT). The research was divided into three stages. The first stage was the design and analysis of the baseline aircraft, including aerodynamic analysis, structural design using the finite element (FE) method and flutter analysis to meet the design requirements. Dynamic response analysis of the aircraft to discrete (one-cosine) gust was also performed in a range of gust radiances specified in the airworthiness standards. In the second stage, a PTWT of a length of 1.13 m was designed with the key parameters determined based on design constraints and, in particular, the aeroelastic stability and gust response. Subsequent gust response analysis was performed to evaluate the effectiveness of the PTWT for gust alleviation. The results show that the PTWT produced a significant reduction of gust-induced wingtip deflection by 21 percent and the bending moment at the wing root by 14 percent in the most critical flight case. In the third stage, effort was made to study the interaction and influence of the PTWT on the symmetric and unsymmetrical maneuvering of the aircraft when ailerons were in operation. The results show that the PTWT influence with a reduction of the aircraft normal velocity and heave motion by 1.7 percent and 3 percent, respectively, is negligible. However, the PTWT influence on the aircraft roll moment with a 20.5 percent reduction is significant. A locking system is therefore required in such a maneuvering condition. The investigation has shown that the PTWT is an effective means for gust alleviation and, therefore, has potential for large aircraft application.

Guo, Y.

"ON NOISE REDUCTION BY FLAP SIDE EDGE FENCES"

Journal of Sound and Vibration, Vol. 277, Issues 1-2, October 1994, pp. 369-390

This paper discusses the effects of fences on side edge cross flows. Experimental data are reviewed to show that fences can modify the cross flow in the side edge region of aircraft flaps in such a way that noise reduction can be achieved. Near field pressure data reveal that fences reduce the characteristic frequency of the flow fluctuations. This leads us to postulate that the fences make the far field noise spectra shift downward in frequency. Because airframe noise spectra typically have a negative slope in the most important mid to high frequency domain, this downward shift in frequency leads to an equivalent reduction of noise levels, when measured by conventional metric such as the effective perceived noise level in aircraft certification. To explain the decrease of the characteristic frequency of the flow fluctuations due to the fences, an analytical model is developed, based on vortex dynamics. The predictions from the model are shown to be in very good agreement with measured data, both for the dominant frequency in the baseline case without the fences and for the trends of the decreasing frequency with increasing fence height.

Guo, Y. P., Joshi, M. C., Bent, P. H. and Yamamoto, K. J.

"SURFACE PRESSURE FLUCTUATIONS ON AIRCRAFT FLAPS AND THEIR CORRELATION WITH FAR-FIELD NOISE"

Journal of Fluid Mechanics, Vol. 415, 2000, pp. 175-202.

This paper discusses unsteady surface pressures on aircraft flaps and their correlation with far-field noise. Analyses are made of data from a 4.7 percent DC-10 aircraft model test, conducted in the 40 x 80 feet wind tunnel at NASA Ames Research Center. Results for various slat/wing/flap configurations and various flow conditions are discussed in detail to reveal major trends in surface pressure fluctuations. Spectral analysis, including cross-correlation/coherence, both among unsteady surface pressures and between far-field noise and near-field fluctuations, is used to reveal the most coherent motions in the near field and identify potential sources of noise related to flap flows. Dependencies of surface pressure fluctuations on mean flow Mach numbers, flap settings and slat angles are discussed. Dominant flow features in flap side edge regions, such as the formation of double-vortex structures, are shown to manifest themselves in the unsteady surface pressures as a series of spectral humps. The spectral humps are shown to correlate well with the radiated noise, indicating the existence of major noise sources in flap side edge regions. Strouhal number scaling is used to collapse the data with satisfactory results. The effects of flap side edge fences on surface pressures are also discussed. It is shown that the application of fences effectively increases the thickness of the flaps so that the double-vortex structures have more time to evolve. As a result, the characteristic timescale of the unsteady sources increases, which in turn leads to a decrease in the dominant frequency of the source process. Based on this, an explanation is proposed for the noise reduction mechanism of flap side edge fences.

Guo, Y., Hallstrom, C. and Spirn, D.

"DYNAMICS NEAR AN UNSTABLE KIRCHHOFF ELLIPSE"

Comm. in Math. Phys., Vol. 245, 2004, pp. 297-354

We describe the dynamics of the Kirchhoff ellipse by formulating a nonlinear equation for the boundary of a perturbed vortex patch in elliptical coordinates. We demonstrate that in the regime for which the linearized equation of motion is unstable, the nonlinear dynamics of a rather general initial perturbation of the Kirchhoff ellipse are determined by the fastest growing mode for the corresponding linearized equation, on a time scale when the nonlinear instability occurs. In particular, we resolve a question suggested by Love's results and prove that such elliptical patches are indeed unstable in the full nonlinear sense.

Gupta, B. P. and Loewy, R. G.

"THEORETICAL ANALYSIS OF THE AERODYNAMIC STABILITY OF MULTIPLE, INTERDIGITATED HELICAL VORTICES"

AIAA Journal, Vol. 12, No. 10, October 1974, pp. 1381-1387.

A small perturbation stability analysis of a doubly infinite array of interdigitated, right circular helical vortices has been formulated. This array corresponds to the vortices trailed from the tips of the blades of a helicopter rotor or propeller in static thrust or axial flight condition and at great distance from the plane of rotation of the blades. A continuum of instability modes has been found associated with all values of wave numbers; only modes with wave numbers 0 and 1 are so much as neutrally stable, and for the case of a single helix. The most unstable modes involve the most axial motion of adjacent vortex segments relative to each other. Maximum divergence rates increase as the helix pitch decreases, increase as the number of helices increase and decrease as the number of cycles of deformations in one turn of the helix (i.e., wave number) increases. The helix filament core diameter can have substantial effect on the stability of a single helix, but not for multiple arrays. The larger the core diameter, the more sensitive the analysis is to how the singularities in the self-induction integrals are eliminated. Increasing core diameters reduces the maximum divergence rates in all cases.

Gupta, M.

"INVESTIGATION OF ACTIVE CONTROL OF AIRCRAFT WING TIP VORTICES AND WAKE TURBULENCE"

MS Thesis, December 2011, Auburn University, Auburn, Alabama.

The present work was focused on study and application of active flow control methods to alleviate the wake turbulence problem in commercial aircraft. Sinusoidal perturbations were introduced into the tip vortex generated off one of the wings in a two-wing system. Various forcing frequencies and oscillation amplitudes were investigated in a towing tank facility. Measurement techniques included invasive and non-invasive methodologies such as flow visualization, hot film anemometry and particle image velocimetry (PIV). Tilting of the plane of the vortices under forcing conditions was observed. The initiation of long-wave Crow instability was observed. This was also confirmed by flow visualization results. For 20Hz forcing frequency, elliptical deformation of the core for both the vortices was observed. This was an indication of short-wave Elliptic instability. When perturbed at a particular frequency and amplitude, the overall system showed earlier onset of instabilities.

Gupta, S. and Leishman, J. G.

"ACCURACY OF THE INDUCED VELOCITY FROM HELICOIDAL VORTICES USING STRAIGHT-LINE SEGMENTATION"

AIAA Journal, Vol. 43, No. 1, January 2005, pp. 29-40

The accuracy of a straight-line segmentation approximation to a series of helicoidal vortices is considered. The problem is examined for different values of the helical pitch, the number of wake turns, and the wake skew angle. Results documenting both the accuracy and the relative errors of the discretized helical vortex and a vortex ring are compared. It is found that with sufficiently small segments, straight-line segmentation of both the vortex ring and of the helical vortex give at least a second-order accurate reconstruction of the induced velocity field. It is shown that the vortex ring can be viewed as a special case of a helical vortex as its pitch tends to zero. Based on the magnitude of the

errors found for the two cases, a vortex ring is shown to be a more stringent test case than a helical vortex when the straight-line segmentation approach is used. The accuracy of the induced velocity field when a skewed helix is represented by straight-line segmentation is shown to be second-order accurate for various combinations of helical pitch and wake skew angle. A comparison with the unskewed helical vortex reveals that the errors in the induced velocity field are almost the same in the two cases.

Gupta, V. P.

"VORTEX-RELATED ACCIDENTS OVER THE TEN YEAR PERIOD 1964-1973"

FAA-EM-75-6, April 1975, MITRE Corp., McLean, VA

Out of the approximately 45,000 aviation accidents that occurred over the ten-year period 1964-73, in the conterminous United States, wake vortices have been cited as a cause or as factor in 147 accidents by the National Transportation Safety Board. These 'vortex-related' accidents have been studied and categorized (by flight phases of the vortex-generating aircraft and the accident aircraft, and other pertinent factors) in the report with the objective of providing historical insight to the Wake Vortex Avoidance System development program. The vortex problem was found to be largely confined to small general aviation aircraft landing or taking off close behind air carrier aircraft under VFR conditions.

"THE DEVELOPMENT OF THE WAKE VORTICES WARNING SYSTEM FOR FRANKFURT AIRPORT, PART I: THEORY AND IMPLEMENTATION"

ATCQ07A7, April 1997, DFS Deutsche Flugsicherung, Frankfurt, German.

A Wake Vortices Warning System (WVWS) was identified as a candidate means for increasing the capacity of Frankfurt Airport. For certain meteorological conditions the WVWS is expected to allow for the suspension of wake vortex separation between aircraft approaching the two parallel runways 25. At present, the close vicinity of these parallel runways does not allow wake-vortex-independent operations as a standard procedure. The task of the WVWS is to model the propagation of wake vortices produced in the atmospheric boundary layer by aircraft approaching the runways 25L and 25R and to forecast the wake vortex transport, which is influenced mainly by the crosswind. The predicted propagation of wake vortices is used to determine the risk for approaching aircraft produced by wake vortices generated in the vicinity of the parallel runway system 25L and 25R. On the basis of this hazard prediction, an appropriate landing/operational procedure will be recommended to the controller.

Gurke, T. and Lafferton, H.

"THE DEVELOPMENT OF THE WAKE VORTICES WARNING SYSTEM FOR FRANKFURT AIRPORT: THEORY AND IMPLEMENTATION"

Air Traffic Control Quarterly, Vol. 5, No. 1, 1997, pp. 3-29

A Wake Vortices Warning System (WVWS) has been identified as a candidate means for increasing the capacity of Frankfurt Airport. For certain meteorological conditions, the WVWS is expected to allow for the suspension of required wake vortex separations between aircraft approaching the airport's two parallel runways 25L and 25R. At present, the proximity of these parallel runways does not allow wake-vortex independent operations as a standard procedure. The task of the WVWS is to model the propagation of wake vortices produced in the atmospheric boundary layer by aircraft approaching the runways, and to forecast the wake vortex transport, which is influenced mainly by the crosswind. This predicted propagation of the wake vortices is used to determine the risk for approaching aircraft that is produced by wake vortices generated in the vicinity of the two runways. On the basis of this hazard prediction, an appropriate landing/operational procedure is recommended to the controller. This paper presents the project history, the basic theory and algorithms of the WVWS, the landing procedures for operational use of the system, the WVWS design and implementation, and the testing and evaluation of the system.

Gursul, I.

"REVIEW OF UNSTEADY VORTEX FLOWS OVER SLENDER DELTA WINGS"

Journal of Aircraft, Vol. 42, No. 2, March-April 2005, pp. 299-318.

A wide range of unsteady phenomena relevant to slender vortex flows over stationary and maneuvering delta wings is reviewed. The origin, characteristics, and physical mechanisms of these unsteady phenomena and their role in buffeting are discussed. Dynamic response of leading-edge vortices for maneuvering wings and mechanisms of hysteresis and time lag effects are reviewed. Issues and challenges for unsteady vortex flows over delta wings are outlined.

Gursul, I. and Rockwell, D.

"VORTEX STREET IMPINGING UPON AN ELLIPTICAL LEADING EDGE"

Journal of Fluid Mechanics, Vol. 211, 2006, pp. 211-242.

The interaction of a Karman vortex street with an elliptical edge is investigated experimentally. Basic types of interaction, as a function of scale and transverse displacement of the incident vortex street, are revealed using flow visualization. Unsteady pressure fields induced by these interactions are measured by a phase-averaging technique and correlated with the visualized flow patterns for basic classes of interactions. For a generic vortex-edge interaction, measurements of the phase-averaged velocity field allow construction of streamlines and vorticity contours showing the details of the interaction, including distortion of the vortical structures near the edge. The pressure field is calculated from the measured velocity field and interpreted in relation to the vortical structures. Simulation of

flow visualization using the measured velocity field demonstrates possible misinterpretations related to the underlying vorticity field.

Gursul, I. and Wang, Z.

"FLOW CONTROL OF TIP/EDGE VORTICES"

AIAA Journal, Vol. 56, No. 5, May 2018, pp. 1731-1749.

Location, strength, and structure of tip and edge vortices shed from wings and bodies can be manipulated by using flow control techniques. Flow physics of these approaches involve flow separation from the edge, roll-up into the vortex, wing flow region, vortex instabilities, vortex-vortex interactions, and vortex-turbulence interactions. Actuators include continuous and unsteady blowing as well as suction, bleed, and control surfaces, which add momentum, vorticity, and turbulence into the vortices. It is noted that activation may have effects on more than one aspect of the flow phenomena. A comparative review of the control of delta-wing vortices, tip vortices, and afterbody vortices is presented. The delay of vortex breakdown and the promotion of flow reattachment require different considerations for slender and non-slender delta wings and may not be possible at all. Tip vortices can be controlled to increase the effective span, to generate rolling moment, to alternate wing rock, and to attenuate vortex-wing interactions. Although there are different approaches for each application, opportunities for future research on turbulence injection, bleed, and excitation of vortex instabilities exist. Recent research also indicates that active and passive flow control can be used to manipulate the afterbody vortices to reduce the drag.

Gursul, I. and Xie, W.

"ORIGIN OF VORTEX WANDERING OVER DELTA WINGS"

J. Aircraft, Vol. 37, No. 2, March-April 2000, pp. 348-350

This Note investigates the origin of the vortex wandering over delta wings. The rms swirl velocity in the vortex core is small when the shear layer does not exhibit the K-H instability at low Reynolds numbers. However, the shear layer is dominated by the vortical structures due to the K-H instability for Reynolds numbers larger than a critical value. The corresponding rms swirl velocity in the vortex core becomes much larger, confirming much increased levels of vortex wandering. The present results demonstrate that the vortex wandering is directly related to the presence of the vortical structures in the shear layer due to the K-H instability. This is explained by the Biot-Savart induction of the small-scale vortices, which displace the primary vortex. Nonlinear interactions of small vortices and the primary vortex lead to the random displacements of the primary vortex core.

Gursul, I., Vardaki, E., Margaris, P. and Wang, Z.

"CONTROL OF WING VORTICES"

Active Flow Control, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 95, 2007, pp. 137-151.

Vortex control concepts employed for slender, non-slender and high aspect ratio wings were reviewed. For slender delta wings, control of vortex breakdown has been the most important objective, which is achieved by modifications to swirl level and pressure gradient. Delay of vortex breakdown with the use of control surfaces, blowing, suction, high-frequency and low-frequency excitation, and feedback control was reviewed. For non-slender delta wings, flow reattachment is the most important aspect for flow control methods. For high aspect ratio wings, vortex control concepts are diverse, ranging from drag reduction to attenuation of wake hazard and noise, which can be achieved by modifications to the vortex location, strength, and structure, and generation of multiple vortices.

Guruswamy, G. P.

"INTERACTION OF FLUIDS AND STRUCTURES FOR AIRCRAFT APPLICATIONS"

Computers and Structures, Vol. 30, Issues 1-2, 1988, pp. 1-13

Strong interactions occur between the flow about an aircraft and its structural components, which result in several important aeroelastic phenomena. These aeroelastic phenomena can significantly influence the performance of aircraft. At present, closed-form solutions are available for aeroelastic computations when flows are in either linear subsonic or supersonic range. However, for complex nonlinear flows containing shock waves, vortices and flow separations, computational methods are still under development. Several phenomena that can be dangerous and can limit the performance of an aircraft are due to the interaction of these complex flows with flexible aircraft components such as wings. For example, aircraft with highly swept wings experience vortex-induced aeroelastic oscillations. The simulation of these complex aeroelastic phenomena requires coupling the fluid and structural analysis. This paper provides a summary of the development of such coupled methods and their applications to aeroelasticity. Results based on the transonic small perturbation equations and the Euler equations are presented.

"ANALYSIS OF THE TURBULENT WAKE OF A CASCADE AIRFOIL"

Journal of Aircraft, Vol. 14, No. 4, April 1977, pp. 350-356

The structure of the wake in an incompressible, turbulent fluid behind an airfoil in a cascade is investigated. Boundary-layer equations containing longitudinal curvature terms are applied to the problem and the similarity properties of the equations are developed. Local similarity solutions are determined for mean velocity profiles at several wake positions, and these results are compared with experimental data for two incidence angles. Good correlation between theory and experiment is obtained beyond approximately a tenth of a chord downstream of the airfoil at small incidence angles.

"LIFT CALCULATIONS BASED ON ACCEPTED WAKE MODELS FOR ANIMAL FLIGHT ARE INCONSISTENT AND SENSITIVE TO VORTEX DYNAMICS"

Bioinspiration and Biomimetics, Vol. 12, No. 1, 2017, pp. 016004-1 to 016004-15.

There are three common methods for calculating the lift generated by a flying animal based on the measured airflow in the wake. However, these methods might not be accurate according to computational and robot-based studies of flapping wings. Here we test this hypothesis for the first time for a slowly flying Pacific parrotlet in still air using stereo particle image velocimetry recorded at 1000 Hz. The bird was trained to fly between two perches through a laser-sheet wearing laser safety goggles. We found that the wingtip vortices generated during mid-downstroke advected down and broke up quickly, contradicting the frozen turbulence hypothesis typically assumed in animal flight experiments. The quasi-steady lift at mid-downstroke was estimated based on the velocity field by applying the widely used Kutta-Joukowski theorem, vortex ring model, and actuator disk model. The calculated lift was found to be sensitive to the applied model and its different parameters, including vortex span and distance between the bird and laser sheet -- rendering these three accepted ways of calculating weight support inconsistent. The three models predict different aerodynamic force values mid-downstroke compared to independent direct measurements with an aerodynamic force platform that we had available for the same species flying over a similar distance. Whereas the lift predictions of the Kutta-Joukowski theorem and the vortex ring model stayed relatively constant despite vortex breakdown, their values were too low. In contrast, the actuator disk model predicted lift reasonably accurately before vortex breakdown, but predicted almost no lift during and after vortex breakdown. Some of these limitations might be better understood, and partially reconciled, if future animal flight studies report lift calculations based on all three quasi-steady lift models instead. This would also enable much needed meta studies of animal flight to derive bioinspired design principles for quasi-steady lift generation with flapping wings.

"MEASUREMENT AND MODELLING OF TIP VORTEX PATHS IN THE WAKE OF A HAWK UNDER YAWED FLOW CONDITIONS"

AIAA Paper No. 2005-0590, Reno, NV, January 2005

Tip vortex locations have been measured in the wake of a model rotor in both axial flow and yaw using quantitative flow visualization. For each setting, the axial force coefficient has been derived as well from measurements. The results seem to agree well with those previously published on the Delft University of Technology model rotor. The main interest is to determine the tip vortex pitch, wake skew angle and wake expansion and to physically interpret the data. The results should also help to validate and construct models. The tip vortex locations data complement the existing skewed wake velocity data from hot-wire anemometry, making it a valuable experimental database.

Haans, W., van Kuik, G. and van Bussel, G.

"THE INVERSE VORTEX WAKE MODEL: A MEASUREMENT ANALYSIS TOOL"

Journal of Solar Energy Engineering, Vol. 130, Issue 3, July 2008, pp. 031009-1 to 031009-14.

To reduce the level of uncertainty associated with current rotor aerodynamics codes, improved understanding of rotor aerodynamics is required. Wind tunnel measurements on model rotors contribute to advancing our knowledge on rotor aerodynamics. The combined recording of blade loads and rotor wake is desired, because of the coupled blade and wake aerodynamics. In general, however, the small size of model rotors prohibits detailed blade load measurements; only the rotor wake is recorded. To estimate the experimental blade flow conditions, a measurement analysis tool is developed: the inverse vortex wake model. The rotor wake is approximated by a lifting line model, using rotor wake measurements to reconstruct the vortex wake. Conservation of circulation, combined with the Biot-Savart law, allows the induced velocity to be expressed in terms of the bound circulation. The unknown bound circulation can be solved for, since the velocity is known from rotor wake measurements. The inverse vortex wake model is subsequently applied to measurements on the near wake of a model rotor subject to both axial and yawed flow conditions, performed at a TUDelft open jet wind tunnel. The inverse vortex wake model estimated the unsteady experimental blade load flow conditions and loads that otherwise would have remained obscured.

Haans, W., van Kuik, G. and van Bussel, G.

"THE INVERSE VORTEX WAKE MODEL: A MEASUREMENT ANALYSIS TOOL"

AIAA Paper No. 2007-422, Reno, NV, January 2007.

The aerodynamics of a Horizontal Axis Wind Turbine (HAWT) rotor is of a three-dimensional, unsteady nature and is characterized by strongly coupled blade and wake aerodynamics. To reduce the level of uncertainty associated with current rotor aerodynamics codes, improved physical understanding of rotor aerodynamics is required. Measurements in the near-wake of a model rotor placed in an open jet wind tunnel at the TUDelft aim at increasing knowledge of yawed flow conditions. Detailed blade loads are not measured though. A measurement analysis tool, based on conservation of circulation, is developed that estimates the experimental blade flow conditions: the inverse vortex wake method. The method constructs a vortex wake from measurements, expresses the velocity measured at given points in the wake in terms of unknown bound circulation and solves the overdetermined system of equations for the unknown bound circulation. The unsteady experimental blade flow conditions are estimated for three cases, with yaw angle = 0 degrees, 30 degrees, 45 degrees, using the inverse vortex wake method.

"COMPARISON STUDY BETWEEN WIND TURBINE AND POWER KITE WAKES"

Wake Conference 2017, Uppsala University, Visby, Sweden, May 2017, In Journal of Physics: Conference Series Vol. 854, 2017, pp. 012019-1 to 012019-7.

Airborne Wind Energy (AWE) is an emerging technology in the field of renewable energy that uses kites to harvest wind energy. However, unlike for conventional wind turbines, the wind environment in AWE systems has not yet been studied in much detail. We propose a simulation framework using Large Eddy Simulation to model the wakes of such kite systems and offer a comparison with turbine-like wakes. To model the kite effects in the flow, a lifting line technique is used. We investigate different wake configurations related to the operation modes of wind turbines and airborne systems in drag mode. In the turbine mode, the aerodynamic torque of the blades is directly added to the flow. In the kite mode, the aerodynamic torque of the wings is directly balanced by an opposite torque induced by on-board generators; this results in a total torque on the flow that is zero. We present the main differences in wake characteristics, especially flow induction and vorticity fields, for the depicted operation modes both with laminar and turbulent inflows.

"AIRCRAFT WAKE VORTICES - A BIBLIOGRAPHY WITH ABSTRACTS"

PB-82-809112, June 1982, NTIS, Springfield, VA

Wake vortices and turbulent flow across aircraft lifting surfaces were investigated in the Government-sponsored research. Aerodynamic characteristics of vortices were reviewed with special attention made to trailing aircraft and aviation safety.

Habig, C.

"WAKE TURBULENCE BEHIND SMALL AIRCRAFT"

Flying Safety, October 1993, pp. 16-18

The wake from an 18,000-pound F-16 could be strong enough to force a 10,500-pound airplane into the ground from 500 feet.

Hackett, J. E.

"VORTEX DIFFUSER"

US Patent 4,190,219, February 1980.

The vortex system behind an aircraft is responsible for more than half of the aircraft drag in cruise flight and sometimes more in other flight conditions. The purpose of the vortex diffuser is to intercept the wing tip vortex just aft of the wing trailing edge, diffuse the trailing vorticity and thereby achieve a reduction in drag. To do this, an airfoil-shaped device is mounted on a trailing boom situated at or near to the wing tip. The airfoil is mounted above the boom at an angle inboard of the vertical. Its height is

a percentage of wing semispan as is also the mean airfoil chord. The aft-mounting feature permits greater drag reduction at high subsonic Mach number and the inboard vane cant provides significant structural relief. In addition to drag reduction by diffusing the wing tip vortex, some reduction in trailing vortex hazard is also obtained.

Hackett, J. E.

"LOCKHEED TECHNICAL EFFORTS IN WAKE TURBULENCE"

Proceedings of the AFFDL/NASA/FAA Wake Turbulence Work Shop, Air Force Flight Dynamics Laboratory, AFFDL-TM-75-16-FGC, 1974, pp. 19-27

An overview is presented of the current wake turbulence research being conducted at Lockheed-California and Lockheed-Georgia. The effects of variations in span loading were examined by solving the general vorticity equation through the superposition of Lamb vortices and extended by allowing the eddy viscosity to vary in the downstream direction. The initial Lamb vortex profile was superimposed on various axial flows, and the second order boundary layer equations integrated to demonstrate how the different axial flows affected vortex decay. Results of a fixed-base simulation of a C-130 encountering a vortex were discussed.

Hackett, J. E. and Evans, M. R.

"VORTEX WAKES BEHIND HIGH-LIFT WINGS"

Journal of Aircraft, Vol. 8, No. 5, May 1971, pp. 334-340

At high wing lift coefficients pertinent to STOL operation, the conventional neglect of vortex roll-up effects can lead to errors when calculating downwash at the tail plane and in the presence of ground or wind-tunnel walls. A classical unsteady treatment in the cross-flow plane, which calculates the roll-up of an initial spanwise row of point vortices, has been modified to allow for the influence of the wing. Additional meaning is thereby given to the streamwise length dimension and hence to aspect ratio and sweep. The effects of height-above-ground and of various tunnel heights and widths are discussed. Under certain limited conditions, notably with part-span flaps or too-narrow a tunnel, part or all of the trailing vortex system may move upwards. Consequent changes in the vertical velocity field are additional to conventional estimates, involving only the appropriate image system.

Hackett, J. E. and Evans, P. F.

"NUMERICAL STUDIES OF THREE-DIMENSIONAL BREAKDOWN IN TRAILING VORTEX WAKES"

Journal of Aircraft, Vol. 14, No. 11, November 1977, pp. 1093-1101

Finite-element three-dimensional relaxation methods are used to calculate the development of vortex wakes behind aircraft for a significant downstream distance. The inclusion of a self-induction term in the solution, dependent upon local curvature and vortex core radius, permits calculation of

finite lifetimes for systems for which infinite life would be predicated two-dimensionally. Single-pair, twin-pair, and multiple-pair studies are described. It is found, in single-pair studies, that there is a lower limit to the wavelengths at which the 'Crow'-type of instability can occur. Below this limit, self-induction effects cause the plane of the disturbance waves to rotate counter to the vortex direction. Self-induction in two-dimensionally generated twin spiral waves causes an increase in axial length, which becomes more marked with decreasing initial wavelength and the time taken for vortex convergence toward the center plane is correspondingly increased. In many cases designed to produce early vortex convergence at the center plane, it is found that the surviving vortex is sufficiently strong for significant hazard to remain. Such cases, which have low flap span, are also characterized by long-wavelength spirals, for which the potential for self-induced wake dispersion is small. There may therefore be a mal-optimum flap-span ratio, in the mid-semispan range, for which time-to-converge maximizes. Limited studies of Boeing 747 configurations show correct qualitative response to removal of the outer flap and to gear deployment, as compared with wind-tunnel and flight-test experience.

Hackett, J. E. and Theisen, J. G.

"VORTEX WAKE DEVELOPMENT AND AIRCRAFT DYNAMICS"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 243-263

Calculations of the sinuous instability of a trailing pair are extended, using a nonlinear vortex modeling technique, and the effects of initial parameters are examined, particularly the initially assumed wavelengths. More complex modes of vortex decay may be demonstrated by flow visualization in water, using the hydrogen bubble technique; vortex bursting is shown to be possible before and/or after the 'wavy' mode. These small-scale measurements are shown to be consistent with flight measurements. In another series of experiments, smoke injected into the core of the trailing vortex behind a 13-foot-span C-130 wind-tunnel model, mounted in a 23-foot by 16-foot working section, showed remarkable coherence until the adverse pressure gradient in the wind-tunnel diffuser caused vortex bursting. The results of a computer simulation are discussed concerning the dynamic response and loads on an aircraft which enters the trailing vortex of a lead aircraft of large size.

"THEORETICAL ANALYSIS AND DATA INTERPRETATION TO ASSIST THE GOVERNMENT IN EVALUATING THE VARIOUS DEVICES PROPOSED FOR ENHANCING VORTEX DECAY AND EXTRAPOLATION OF LABORATORY RESULTS TO FULL-SCALE APPLICATION"

Report LG74ER0152, October 1974, Lockheed-Georgia, Marietta, GA

The efforts briefly described herein evaluated methods for alleviating the aircraft vortex wake hazard problem. Lockheed-Georgia Company scientists and consultants have used both theoretical means (hopefully to predict a physical mechanism for causing premature vortex decay) and correlation with IR&D scaled model tests on aero-mechanical devices or energizing techniques (vortex generators, jets, etc.) to modify the vortex wake without unacceptable compromise in aircraft performance. Principal

tasks include: a) Theoretical study of jet and wake effects on vortex decay; b) Provide span-load distributions for Boeing 747 using potential flow model; c) Study the distortion of a vortex by a lifting surface immersed in the vortex; d) Feasibility study of using a vortex roll-up program iteratively with a vortex-lattice program to determine mutual interaction effect; e) Continuing consultation on a moving-base simulator program at NASA (Ames) jointly with the FAA.

"COMPOSITE TEMPERATURE PROFILES FROM RAMAN LIDAR AND MICROWAVE RADIOMETER"

9th International Symposium on Tropospheric Profiling (ISTP), September 2012, University of L'Aquila, L'Aquila, Italy.

We present two methods to combine Raman lidar and microwave radiometer for profiling atmospheric temperature. The Raman lidar provides profiles with high vertical resolution, but needs frequent calibration with an external measurement. The microwave radiometer provides an accurate measurement of the absolute value of the atmospheric temperature, though, with a coarse vertical resolution. Approach 1 consists of two steps: first, recalibration of the lidar using the radiometer data, and second, merging of the recalibrated lidar profile with the radiometer profile. We show that this approach is capable to correct for instabilities of the lidar system and provide a smooth composite temperature profile. In approach 2 the microwave spectrum measured by the radiometer is inverted applying an optimal estimation method using the lidar measurement as a priori profile. The result is a smooth temperature profile based on the optimized use of the available information.

"PIV MEASUREMENTS OF COMPRESSIBLE VORTEX RINGS GENERATED BY A SHOCK TUBE"

13th International Symposium on Applied Laser Techniques to Fluid Mechanics, June 2006, Lisbon, Portugal.

In this study, fast propagating vortex rings were generated with a small shock tube. The vortex rings were visualized by the laser light sheet and the instantaneous velocity field measured by a 2D-PIV system. The vortex core can be well defined and the streamlines in the vortex ring are visible from the velocity field measurement. The measurements also yield information about the vorticity and the kinetic energy within the vortex ring. The evolution of these values along the ring's propagation path can be compared with existing theories of incompressible vortex rings.

Hageraats, W. A.

"FLUID DYNAMIC SIMULATIONS OF VORTEX-JET INTERACTION"

MS Thesis, Delft University of Technology, Delft, The Netherlands, April 2006

To support towing tank measurements as part of the FAR-WAKE project and to gain knowledge about vortex-jet interaction, simulations are performed using CFD analysis. For this purpose, a generic fuselage-wing model (SWIM model) is used at an angle of attack of 6 degrees and in an uniform free stream velocity of 60 m/s. The main objective of this investigation is to examine the impact of jet with uniform jet velocity on the evolution of the trailing vortex system. The CFD experiments have been benchmarked with wind tunnel data that was obtained for the SWIM model without the application of a jet. This data was collected by the NLR by means of PIV and rake measurements. For the vortex-jet interaction studies it was chosen to use the dimensions of the DNW-LST wind tunnel to model the flow numerically. As the domain of interest extends from the near field behind the model all the way to the far field, it was necessary to simplify the CFD calculations. First, the computational domain has been divided into a 3-dimensional steady part that simulates the roll-up process until all significant streamwise flow gradients have disappeared and an unsteady 2-dimensional part more aft of the body capturing the quasi-2-dimensional behavior, characteristic for the vortex flow in this part of the wake. Other simplifications involve the modeling of a laminar flow condition and omission of several instabilities known to occur in the far field behind the model. Results obtained show that the effect of a laminar jet on the evolution of the vortex wake is small.

"VORTEX GENERATION IN A LOW SPEED WIND TUNNEL AND VORTEX INTERACTIONS WITH A HIGH-LIFT AIRFOIL"

AIAA Paper No. 2012-3024, June 2012, New Orleans, LA.

This paper describes the design, construction and evaluation of a vortex generator in a closed wind tunnel, with the objective to produce well defined disturbances convecting over a high-lift airfoil. The vortex generator produces quasi two-dimensional vortices in transverse direction. The design criteria, the mode of use and the framework of the vortex generator are described. Furthermore, the produced vortices and their propagation are characterized along an otherwise empty test-section as well as their interaction with a high-lift airfoil. To acquire the presented data, several measurement methods, such as Particle Image Velocimetry (PIV), a newly developed time resolving Five Hole Probe (FHP), monitoring the position of the servo-actuators and time resolving as well as static pressure measurements were used. As a result, the vortex generator's ability to create reproducible single vortices, as well as reproducible series of vortices, has been verified.

Hahn, K.-U.

"COPING WITH WAKE VORTEX"

ICAS-2002-7.3.2, Toronto, Canada, September 2002

The hazardous area around a wake vortex can be approximated by the simple geometry of a rectangle or an ellipse according to aircraft pairing, weather dependent decay and available roll control power.

Using specific controllers, vortices can be passed through even if the required control power temporarily exceeds available capacity.

Hahn, K.-U.

"WAKE VORTEX ENCOUNTER AVOIDANCE COMPUTATION OF SAFE AIRCRAFT SEPARATIONS USING THE SHAPE CONCEPT"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

This presentation introduces a concept of wake vortex encounter avoidance using the Simplified Hazard Area Prediction (SHAPE) concept. This approach is based on the definition of a hazard zone around a wake vortex derived from quasi-steady considerations. SHAPE is an element in the Wake Vortex Prediction and Observation System which is under development in the frame of the DLR 'Wake Vortex II' project to reduce aircraft approach separation and to improve flight safety. In any case, the separation distance of approaching aircraft must be established in such a way that no dangerous wake vortex flow will be encountered. This results in the demand that the approach corridor is free of hazardous flow conditions for an approaching aircraft. The question to be answered is what is the meaning of 'hazard free'? Therefore, many investigations and simulator studies have been set up and executed with the aim to find a universal criterion for the definition of wake vortex encounter constraints being hazardous to an aircraft. Although impressive progress has been made it could not be expected that an exact prediction will be possible if an encounter will be hazardous or not. Accepting this fact that a clear criterion of what is hazardous (in terms of encounter boundaries and constraints leading unquestionably into an unsafe situation) is difficult to set up (especially if a pilot is in the loop) an 'inverse' approach of hazard definition is proposed. The presented approach for solving the fundamental hazard assessment problem follows the idea that it is easy to define an area around a wake vortex outside of which the vortex flow is not hazardous to an aircraft. This methodology is more a non-hazard concept than a real safety assessment method. But it seems to be very promising in terms of operational application. The worst-case situation can be assumed to be a wake vortex parallel to the glide path with permanent demand for roll moment compensation. In that quasi-steady case, the threat can easily be calculated from the required control power expressed in terms of normalized aileron deflections. A certain fraction of this expression is identified to present a safe limit in terms of wake vortex encounter depth. The resulting boundaries of the hazardous area to be avoided are investigated by numerous offline simulations.

Hahn, K.-U. and Schwarz, C.

"ALLEVIATION OF ATMOSPHERIC FLOW DISTURBANCE EFFECTS ON AIRCRAFT RESPONSE"

ICAS 2008, September 2008, Hamburg, Germany.

This paper gives an overview of the results of offline simulations, full flight simulator studies and results from in-flight simulation experiments to investigate the alleviation of atmospheric flow

disturbance effects on aircraft response. Gusts and turbulence strongly affect the passenger comfort and the safety of aircraft. Another important air mass motion adversely affecting aircraft operations is wake vortex. This well-known hazardous flow field is produced by aircraft themselves. Active control technology can be applied to alleviate these flow disturbance effects on aircraft motion in case of an encounter. It can be shown that the aircraft response encountering natural and aircraft-induced (wake vortex) turbulence can be improved significantly by a feed-forward controller. Based on a forward-looking sensor, the controller generates aerodynamic surface deflections to counter the vertical accelerations generated by gusts as well as the roll response induced by the lift variations along the wing span. For this investigation it is assumed that a LIDAR sensor can provide the necessary flow field information ahead of the aircraft. In addition to the standard control surfaces (elevator, aileron, and rudder) the aircraft is supposed to be equipped with special flaps for independent direct lift control.

Hahn, K.-U. and Schwarz, C. W.

"WAKE VORTEX AVOIDANCE VERSUS LANDING CAPACITY"

AIAA Paper No. 2006-6322, Keystone, CO, August 2006

Wake vortex separations are limiting factors in landing capacity of airports. The increasing air traffic forms the need for more flexible separation procedures considering the actual weather situation and the parameters of a more individual aircraft pairing. The present separation standards must be investigated carefully with the aim to discover possible margins by improving the limiting constraints without adverse effects on safety. Separation reductions can also be achieved by wake vortex avoidance using prediction systems for the wake related hazard zones their development and movement. Avoiding these zones allows safe and undisturbed flight operations. The definition of a reliable and validated safety criterion is the fundamental element for the determination of hazard areas. The presented definition is based on the normalized required roll control power of the encountering aircraft. For manually controlled aircraft the limit of the acceptable normalized roll control power can be established using full flight simulator studies and in-flight simulations. Parameterization of the relevant parameters leads to the universally applicable concept of the 'Simplified Hazard Area Prediction' method (SHAPE), SHAPE provides the hazard area dimensions for specific approach situations. SHAPE is part of a Wake Vortex Prediction and Monitoring System developed within the DLR project Wirbelschlepp II for creating safe and reduced landing operations. Some general results for specific approach conditions on a single runway are presented.

Hahn, K.-U. and Schwarz, C. W.

"SAFE LIMITS FOR WAKE VORTEX PENETRATION"

AIAA Paper No. 2007-6871, August 2007, Hilton Head, SC.

The strength of the vortices increases with the weight of the vortex generating aircraft. Therefore, weight dependent separation distances have been established to avoid dangerous wake vortex encounters. To solve the future capacity problems at airports, these proven separation distances must

be investigated carefully with the aim to discover possible margins. This demand forms the need for more flexible separation procedures considering the actual weather situation and the parameters of the individual aircraft pairing. In any case the separation distance of approaching aircraft must be determined in such a way that the approach corridor is free of hazardous vortex flows for the trailing aircraft. The question to be answered is what is the meaning of 'hazard free', respectively how close is an aircraft allowed to approach a vortex without adversely affecting undisturbed flight operation? The determination of a reliable threshold is only possible with pilot-in-the-loop investigations. This paper presents the results of flight simulator studies and in-flight simulations using real flight test aircraft. Based on the required normalized roll control power tolerable and safe situations can be distinguished from unacceptable encounters and a threshold value can be established. The tolerable threshold value can be increased if the pilots control task is supported by an automatic controller.

Hahn, K.-U., Fischenberg, D., Niedermeier, D. and Horn, C.

"WAKE ENCOUNTER FLIGHT CONTROL ASSISTANCE BASED ON FORWARD-LOOKING MEASUREMENT PROCESSING"

AIAA Paper No. 2010-7680, Toronto, Canada, August 2010.

Weather dependent delays, incidents and even accidents play an important role in aircraft operation. Any airplane is subject to air motion. Thus, turbulence is an important parameter in aeronautics. The phenomena which are summarized as gusts and turbulence strongly affect the passenger comfort and the safety of aircraft. Especially the turbulence caused by the wake of other aircraft can cause undesired motions mainly roll and vertical displacements. Active control technology can be applied to alleviate wake vortex effects on aircraft and support the pilot to carry out his control task. With the aid of specific controllers such vortices can be safely encountered even if the required control power temporarily exceeds the available capacity. Aircraft equipped with such a controller will be less affected by unforeseen wake vortex encounters or even will be able to follow another aircraft closer than authorized by the current separation distances without any compromise concerning safety. A very promising concept for wake vortex disturbance alleviation is the feed-forward disturbance compensation. The application of such an approach requires the accurate determination of the flow disturbance to calculate the necessary counter measures in terms of required control activities. Thus, the disturbance flow determination plays an important role and needs to be investigated thoroughly. Modern LIDAR technology has the potential to measure the flow field in front of the aircraft and to provide the required disturbance information in advance before it affects the aircraft. The final goal of the DLR approach is the development of an Integrated Ride and Loads Improvement System which is able to cope with the whole frequency range of atmospheric flow disturbances relevant for aircraft operation.

Hahn, K.-U., Schwarz, C. and Friehmelt, H.

"A SIMPLIFIED HAZARD AREA PREDICTION (SHAPE) MODEL FOR WAKE VORTEX ENCOUNTER AVOIDANCE"

ICAS-2004, Yokohama, Japan, September 2004

This paper gives details from offline simulations, full-flight simulator studies and the preparation of a flight test experiment using the In-Flight Simulation capability of DLR's (German Aerospace Center) test aircraft ATTAS (Advanced Technologies Testing Aircraft) to validate safe boundaries around a wake vortex for encounter avoidance. The so developed hazard zone is an element in the Wake Vortex Prediction and Observation System which is under development in the frame of the DLR 'Wake Vortex II' project to reduce aircraft approach separation and to improve flight safety. In any case the separation distance of approaching aircraft must be determined in such a way that the approach corridor is free of hazardous vortex flows for the trailing aircraft. The question to be answered is what is the meaning of 'hazard free'? The presented approach for solving this fundamental problem follows the idea that it is possible to define an area around a wake vortex outside which the vortex flow is not hazardous to an aircraft. The reason for this 'inverse' definition is the fact that a clear criterion of what is hazardous is difficult to set up (especially if a pilot is in the loop). The so defined boundaries of the hazard zone can easily be determined by the developed Simplified Hazard Area Prediction (SHAPE) Model. It allows the computation of hazard zone dimensions for any aircraft pairing (real or non-existing aircraft). This potential of a universal application is based on the parameterization of the relevant aircraft wake vortex characteristics which are fitted by simple functions.

Haider, J.

"DESIGN OF WINGTIP VORTEX TURBINE"

ICAS 2000, August 2000, Harrogate, UK.

During lift the pressure difference across upper and lower sides of the aircraft wing, forces the flow of air to curl around the wing tip resulting in wing tip vortices which in turn creates induced drag. Induced drag has been a great problem of all the aircraft and at times it reaches up to 70 percent of the total drag. The idea of wing tip turbine is to use the energy of the vortices to generate extra power thus reducing induced drag at the same time. However total drag would increase due to profile drag of the turbine. To cater it, this design has been done such that the drag created by turbine in a particular phase should not exceed the induced drag reduced by the turbine. In this way maximum energy is extracted without paying the penalty of drag. The theoretical study is based upon drag type turbine installed on NACA 2418 airfoil whose specifications bear geometric similarity to the wing of T-37 aircraft. The experimental results are based upon the wind tunnel testing of the scale down model of the assumed wing.

Haines, A. L.

"CONCEPTS FOR DETERMINATION OF LONGITUDINAL SEPARATION STANDARDS ON FINAL APPROACH"

MTR-7047, October 1975, Mitre Corp., McLean, VA

The concept of a longitudinal separation standard on final approach requires precise definitions to develop an analytical structure. These are developed in this paper with a view toward identifying the

relationships between separation standards and the variables describing the final approach environment. This provides a basis for systematic evaluation of changes in separation standards due to changes in the environment, particularly through Engineering and Development products. Analytical relationships are developed primarily for IFR conditions, represented by strict adherence to all applicable ATC rules and procedures. For modeling purposes, relationships are also developed for 'standards' for VFR conditions, represented by visual approaches from an IFR flight plan.

Hall, C. M.

"HIGH-ORDER ACCURATE SIMULATIONS OF WAKE AND TIP VORTEX FLOWFIELDS"

MS Thesis, Dec. 1998, Penn State University, University Park, PA.

Accurate simulation of rotorcraft wakes and blade-vortex interaction continues to be a challenge. Of particular importance is the numerical diffusion of vorticity, which has yet to be alleviated sufficiently. One solution to this problem may be the use of numerical algorithms which exhibit very low dissipation. This thesis investigates the use of high-order, unsteady computational fluid dynamics for the simulation of flows dominated by vorticity. A code has been developed which solves the unsteady, three-dimensional Euler equations using explicit, fourth-order Runge Kutta time integration and fourth-order spatial differencing. Similar to dispersion relation preserving methods, this algorithm was chosen for its favorable numerical characteristics regarding dissipation. The effectiveness of the high-order algorithm is demonstrated on two model problems -- vortex convection and near-wake development. Simulations of a line vortex have been carried out to a convection distance of 2000 core radii, much farther than has been found in the literature to date. Studies on the effects of grid density and uniformity across the vortex core have been made, allowing estimates of global grid size for complete rotorcraft wake simulation.

Hall, D. L. and Amodeo, F. A.

"OPPORTUNITIES ANALYSIS OF POTENTIAL ADVANCED VORTEX SYSTEMS SEPARATION STANDARDS"

FAA-EM-79-17, July 1979, Mitre Corp., McLean, VA

The purpose of this study is to provide first order estimates of the benefits of reduced separation standards under Advanced Vortex System (AVS) operations. Benefits associated with conceptual Advanced Vortex Systems (AVS) are quantified from a delay reduction viewpoint. The study is equally applicable to airborne vortex alleviation technology or to ground or air-based vortex avoidance systems. Conducted as a first cut, exploratory analysis, the research compares the delay consequences of three sets of successively closer interarrival standards against the option of maintaining today's rules or a combination of today's and 3 nmi separations. The analysis was performed for only IFR weather conditions, since minimum required separation standards are not defined for VFR conditions. Three sets of standards were selected as representative of possible AVS capabilities. Substantial delay savings are shown to be possible even with demand growth below that projected to occur across the 1985

through 1995 analysis time-period. The benefits are sufficiently large as to warrant a substantial research and development investment into an AVS program.

Hall, J. L.

"AN INTRODUCTION TO VORTEX BREAKDOWN AND VORTEX CORE BURSTING"

NRC-24336, March 1985, National Aeronautical Establishment, Ottawa, Ontario, Canada

The phenomenon of vortex breakdown, also known as vortex core bursting, is introduced. The first part of the report presents some important elements of basic vortex theory. The second part reviews the research that was done on vortex breakdown. An overview of the historical development of vortex breakdown research and a summary of the current state of knowledge on the subject are also included.

Hall, M. G.

"A NEW APPROACH TO VORTEX BREAKDOWN"

Proceedings of 1967 Heat Transfer and Fluid Mechanics Institute, edited by P. Libby, D. Olfe and C. Van Atta, Stanford Univ. Press, 1967, pp. 319-340

Comparison between a practical example of vortex breakdown and a computed failure of the quasi-cylindrical approximation, and description of evidence that failure corresponds to breakdown. The theory for viscous axisymmetric quasi-cylindrical flows including the governing equations and boundary conditions, and the numerical method of solving the equations, is outlined. A simple model of a vortex core is set up which depends on only two parameters, representing the magnitude of the swirl and the shape of the bounding stream surface.

Hall, M. G.

"VORTEX BREAKDOWN"

Annual Review of Fluid Mechanics, Vol. 4, Ann. Rev. Inc., Palo Alto, CA, 1972, pp. 195-218

A study was made of the breakdown feature of the vortex core. The vortex core was set up by drawing fluid through a duct and imparting swirl with a set of vanes at entry. The spiral was followed along the duct and it was found that the structure of the vortex varied slowly in the axial direction, and then, unexpectedly, there is an abrupt change in the structure with a very pronounced retardation of the flow along the axis and a corresponding divergence of the stream surfaces near the axis.

Hall, M. G.

"A NUMERICAL METHOD FOR SOLVING THE EQUATIONS FOR A VORTEX CORE"

ARC-R&M-3467, May 1965, Royal Aircraft Establishment, Farnborough, England

A method is presented for calculating steady axially symmetric spiraling motions of an incompressible fluid at large Reynolds numbers. By making approximations of the boundary-layer type the Navier-Stokes equations are reduced essentially to a pair of non-linear parabolic equations. Initial conditions are specified on some upstream cross-section, and boundary conditions on the axis of symmetry and on some bounding surface of revolution.

Hall, M. G.

"THE STRUCTURE OF CONCENTRATED VORTEX CORES"

Progress in the Aeronautical Sciences, Vol. VII, edited by D. Kucheman, Pergamon Press, 1966, pp. 53-110

In a vortex we often observe an approximately axially symmetric core of spiraling fluid in which the vorticity is high. A review is given of recent work on the structure of such vortex cores. It begins with a discussion of the equations of motion and the appropriate boundary conditions, and continues with a description in general terms of the vigorous but highly responsive character of the flow, of the effects of compressibility and turbulence and of the phenomenon of energy separation. A discussion is given of the phenomenon of stagnation in the axial flow, spiral instability, and finite transition, any of which may destroy the typical core of high vorticity or prevent its maintenance.

Hall, M. G.

"A THEORY FOR THE CORE OF A LEADING-EDGE VORTEX"

J. Fluid Mech., Vol. 11, Part 2, September 1961, pp. 209-228

In the flow past a slender delta wing at incidence one can observe a roughly axial symmetric core of spiraling fluid, formed by the roll-up of the shear layer that separates from a leading edge. The aim of this paper is to predict the flow field within this vortex core, given appropriate conditions at its outside edge. A sample calculation yields results which are in good qualitative and fair quantitative agreement with experimental measurements.

Hall, T. and Soares, M.

"ANALYSIS OF LOCALIZER AND GLIDE SLOPE FLIGHT TECHNICAL ERROR"

27th Digital Avionics Systems Conf., St. Paul, Minn., Oct. 2008

A new wake turbulence procedure has been developed that permits two dependent arrival traffic streams during instrument meteorological conditions (IMC) to runways with centerline separations less

than 2500 ft. For the proposed procedure, aircraft approaching both runways of a closely-spaced pair under limited ceiling/visibility conditions utilize Instrument Landing System (ILS) localizer and glide slope guidance. A critical safety analysis building block was to quantify the risk posed by aircraft Flight Technical Error (FTE), a measure of the deviations from the localizer/glide slope centerlines, under ceiling/visibility conditions when non-visual ILS approaches are normally performed. Flight track data from Lambert-St. Louis International Airport (STL) under severe IMC conditions, when strict adherence to navigation aide guidance would most likely occur, were used to quantify the aircraft dispersion characteristics. The position sensors were the STL Airport Surface Detection Equipment, Model X (ASDE-X), the on-airport Surface Measurement Radar, multi-lateration subsystem sensors, and by Riegl laser range-measurement sensors near the runway thresholds. In general, the FTE found in this analysis were significantly tighter than the International Civil Aviation Organization navigation tolerances commonly used in safety simulations.

Hall, T., Mackey, S., Lang, S. and Tittsworth, J.

"LOCALIZER FLIGHT TECHNICAL ERROR MEASUREMENT AND UNCERTAINTY"

2011 IEEE/AIAA 30th Digital Avionics Systems Conference, October 2011, Seattle, WA.

Recent US Federal Aviation Administration wake turbulence research conducted at the John A. Volpe National Transportation Systems Center has continued to monitor the representative localizer Flight Technical Error (FTE) associated with ILS arrivals. This work complements, extends, and improves on previously published localizer ILS results by calculating FTE from more recent Airport Surface Detection Equipment -- Model X (ASDE-X) datasets with improved data quality characteristics, as well as providing a quantification of the FTE measurement uncertainty due to the geometry of the Remote Unit sensor array that provides the analysis data. This paper presents additional FTE results and improved uncertainty calculations for ILS arrivals at John F. Kennedy International Airport and Detroit Metropolitan Wayne County Airport, as well as comparisons with previous documented FTE results from Lambert-St. Louis International Airport.

Haller, G.

"AN OBJECTIVE DEFINITION OF A VORTEX"

J. Fluid Mech., Vol. 525, 2005, pp. 1-26

The most widely used definitions of a vortex are not objective: they identify different structures as vortices in frames that rotate relative to each other. Yet a frame-dependent vortex definition is essential for rotating flows and for flows with interacting vortices. Here we define a vortex as a set of fluid trajectories along which the strain acceleration tensor is indefinite over directions of zero strain. Physically, this objective criterion identifies vortices as material tubes in which material elements do not align with directions suggested by the strain eigenvectors. We show using examples how this vortex criterion outperforms earlier frame-dependent criteria. As a side result, we also obtain an objective criterion for hyperbolic Lagrangian structures.

Hallermeyer, A., Dolfi-Bonteyre, A., Valla, M., Le Brusquet, L., Fleury, G., Thobois, L., Carion, J. P., Duponcheel, M. and Winckelmans, G.

"DEVELOPMENT AND ASSESSMENT OF A WAKE VORTEX CHARACTERIZATION ALGORITHM BASED ON A HYBRID LIDAR SIGNAL PROCESSING"

AIAA Paper 2016-3272, June 2016, Washington, DC.

Since air traffic is in constant expansion, a more efficient optimization of the airports' capacity is expected. In this context, the characterization of aircraft hazardous turbulence known as wake vortices with an operational vortex LIDAR is one of the major issues for the dynamic distances' separation. A study has been probed to develop a hybrid vortex algorithm, i.e. that uses both the velocity envelopes and a parametric estimator in the purpose of estimating accurately and precisely the circulations with a processing time as short as possible. The aim is to make this algorithm exploitable for operational projects. That is why a methodology has been set up to evaluate the precision and its robustness. The results of tests on simulated scenarios of different aircraft vortices and different weather conditions including analytical simulations and Large Eddy Simulations show that this algorithm is able to localize precisely wake vortices and to estimate accurately their circulation since the root mean square error is below 20 percent even in the LES case when the vortices have been distorted sometime after the passage of the aircraft.

Hallock, J. N.

"VORTEX ADVISORY SYSTEM SAFETY ANALYSIS, VOLUME III: SUMMARY OF LASER DATA COLLECTION AND ANALYSIS"

FAA-RD-78-68,III, August 1979, DOT Transportation Systems Center, Cambridge, MA.

A Laser-Doppler Velocimeter was used to monitor the wake vortices shed by 5300 landing aircraft at a point 10,000 feet from the runway threshold. The data were collected to verify the analysis in Volume I of the safety of decreasing interarrival separations to three nautical miles between the outer marker and the runway threshold. Such reduced spacings would only be used when the Vortex Advisory System (VAS) indicated that wake vortices would not pose a threat to a following aircraft. The data show that vortex behavior, during times identified by the VAS, is commensurate with the goal of using uniform three-nautical miles separations from the outer marker to touchdown regardless of leader or follower aircraft type.

Hallock, J. N.

"VORTEX ADVISORY SYSTEM SAFETY ANALYSIS, VOLUME I: EFFECTIVENESS FOR SELECTED AIRPORTS"

FAA-RD-80-62,I, May 1980, DOT Transportation Systems Center, Cambridge, M.

The Vortex Advisory System (VAS) is based on a wind criterion; when the wind near the runway end is outside of the criterion, all interarrival IFR aircraft separations can be set at 3 nautical miles. Five years of wind data have been obtained for 20 airports. By comparing the VAS wind criterion to the 5 years of wind data, the percentages of time that interarrival separations can be reduced at the 20 airports have been found. The percentages are given on an hourly and a monthly basis.

Hallock, J. N.

"ANALYSIS OF THE WAKE VORTEX IMPLICATIONS FOR THE PROPOSED LDA/DME APPROACH AT LAMBERT/ST. LOUIS"

FAA-427-PM-84-1, December 1983, DOT Transportation Systems Center, Cambridge, MA

The proposed simultaneous use of ILS approaches to runway 12R and LDA/DME approaches to runway 12L at St. Louis International (Lambert Field) is analyzed from a wake turbulence perspective. Although the two runways are only 1300 feet apart, their staggered thresholds mitigate the wake turbulence problem. To preclude a vortex encounter, certain restrictions must be imposed: all Heavy-category aircraft must be confined to runway 12R, all Small-category aircraft must be confined to runway 12L, no aircraft larger than a B-727 may use runway 12L, and an MDA must be established for the 3-nm DME fix on runway 12L.

Hallock, J. N.

"AIRCRAFT WAKE VORTICES: AN ASSESSMENT OF THE CURRENT SITUATION"

DOT-FAA-RD-90-29, January 1991, DOT Volpe National Transportation Systems Center, Cambridge, MA

The state of knowledge about aircraft wake vortices in the summer of 1990 is summarized. With the advent of a new FAA wake vortex program, the current situation was assessed by answering five questions: (1) what do we know about wake vortices, (2) what don't we know about wake vortices, (3) what are the requirements and limitations for operational systems to solve the wake vortex problems, (4) where do we go from here, and (5) why do we need to collect more wake vortex data.

Hallock, J. N.

"AIRCRAFT WAKE VORTICES: AN ANNOTATED BIBLIOGRAPHY (1923 - 1990)"

DOT-FAA-RD-90-30, January 1991, DOT Volpe National Transportation Systems Center, Cambridge, MA

This annotated bibliography consists of abstracts of publications on aircraft wake vortices. The material is arranged alphabetically by author(s) and then by month and year of publication. Experimental and theoretical articles are included and consider the formation, structure, motion, and decay of vortices and their effect on penetrating aircraft.

Hallock, J. N.

"AIRCRAFT WAKE VORTICES: THEIR MOTION AND DECAY"

AIAA Seminar, Boston University, Boston, MA, January 1973

A review of the physics of aircraft wake vortices was presented considering the formation of vortices and their subsequent motion and decay. The experimental and analytical research programs of the Department of Transportation were reviewed; particular emphasis was given to the effects of meteorology on aircraft wakes.

Hallock, J. N.

"MONITORING THE MOVEMENT OF WAKE VORTICES AT KENNEDY AND STAPLETON AIRPORTS"

Proceedings of the Fifth Annual Symposium of the Society of Flight Test Engineers, SFTE, Anaheim, CA, 1974, pp. 4/7-4/12.

During the summer and fall of 1973, the Transportation Systems Center collected an extensive amount of data on the motion of aircraft wake vortices. Two test sites were instrumented: the John F. Kennedy International Airport in New York and the Stapleton International Airport in Denver, Colorado. The vortices from over 10,000 landing aircraft were recorded and the motion of the vortices correlated with the ambient meteorological conditions. The results of these measurements coupled with user requirements lead to the description of three basic vortex avoidance systems.

Hallock, J. N.

"WAKE VORTEX MODELING AND DETECTION"

Proceedings of the AFFDL/NASA/FAA Wake Turbulence Work Shop, Air Force Flight Dynamics Laboratory, AFFDL-TM-75-16-FGC, 1974, pp. 59-63

The FAA program in wake vortices was reviewed and included: the development of reliable vortex prediction methods in terms of meteorological conditions and generator aircraft characteristics, the determination of a hazard criterion regarding how close an aircraft can approach a vortex without experiencing an unacceptable disturbance, and the development of effective vortex detection equipment. The results of over 10,000 vortex observations recorded at Kennedy and Stapleton International Airports were presented as well as possible techniques for eventually decreasing current separation criteria.

Hallock, J. N.

"WAKE VORTEX DECAY NEAR THE GROUND"

AIAA Paper No. 1975-0882, Hartford, CT, June 1975

The strength of wake vortices is being measured for aircraft landing on runway 31R at JFK International Airport using monostatic acoustic radars. By range-gating and Doppler processing the backscattered acoustic energy from several sensors, measurements are made of vortex height, strength or circulation, vertical velocity field, translational velocity, and the circulation distribution within the vortex. Possible decay mechanisms and correlations with meteorological conditions are presented.

Hallock, J. N.

"AIRCRAFT WAKE VORTICES - AN ANNOTATED BIBLIOGRAPHY (1923-1975)"

FAA-RD-76-43, January 1976, DOT Transportation Systems Center, Cambridge, MA

This annotated bibliography consists of 570 abstracts of publications on aircraft wake vortices. The material is arranged alphabetically by year of publication and covers the time period through 1975. Experimental and theoretical articles are included (except for helicopter vortices) and consider the formation, structure, motion, and decay of vortices and their effect on penetrating aircraft.

Hallock, J. N.

"MONITORING WAKE VORTEX STRENGTH DECAY NEAR THE GROUND"

Journal of Aircraft, Vol. 13, No. 10, October 1976, pp. 830-832

The strength of aircraft wake vortices is being measured for aircraft landing on runway 31R at the John F. Kennedy International Airport using monostatic acoustic radars. By range-gating and Doppler processing the backscattered acoustic energy from a number of sensors, measurements are made of vortex height, strength or circulation, vertical velocity field, translational velocity, and the circulation distribution within the vortex. Possible decay mechanisms and correlations with meteorological conditions are described.

Hallock, J. N.

"VORTEX ADVISORY SYSTEM SAFETY ANALYSIS, VOLUME I: ANALYTICAL MODEL"

FAA-RD-78-68,I, September 1978, DOT Transportation Systems Center, Cambridge, M.

An analysis was conducted to examine the safety of decreasing landing aircraft separations to three nautical miles between the outer marker and the runway threshold. Such reduced separations would only be used when the Vortex Advisory System indicated that wake vortices would not pose a threat to a following aircraft. Based on state-of-the-art models of vortex and aircraft behavior, the analysis indicates that such reduced interarrival separations may be used safely by Large and Heavy aircraft following Heavies. When the analysis is expanded to include a yet unproven crosswinds aloft model, the results indicate that reduced separations may be used by all aircraft regardless of leader/follower aircraft type.

Hallock, J. N.

"PRESSURE MEASUREMENTS OF WAKE VORTICES NEAR THE GROUND"

Journal of Aircraft, Vol. 9, No. 4, April 1972, pp. 311-312

A simple barocel pressure sensor was tested to determine whether it could detect the presence of aircraft wake vortices. Pressure differentials more than 0.1 millibars were consistently measured when the vortices from DC-7, B-747, B-707, DC-8, C-141, and DC-3 aircraft were below 100 feet in altitude.

Hallock, J. N.

"DIFFERENCES BETWEEN LANDING AND TAKEOFF WAKE VORTICES"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 81-82

Data on wake vortex behavior from over 70,000 landing and 30,000 departures have been collected and analyzed. This presentation will examine the differences in vortex behavior (motion and decay) between these two regimes. The differences, in some cases, are not what one might expect at first glance. The effects of the winds and vortex altitude on vortex motion (persistence near the runway centerline as well as long distance movement in ground effect) and decay will be presented.

Hallock, J. N. and Burnham, D. C.

"DECAY CHARACTERISTICS OF WAKE VORTICES FROM JET TRANSPORT AIRCRAFT"

AIAA Paper No. 1997-0060, Reno, NV, January 1997

For more than two decades cw doppler lidars have been used to study the decay of wake vortices generated by jet transport aircraft. With appropriate scan and data processing strategies, the vortex tangential velocity profile can be measured every few seconds. Under low turbulence conditions conducive to long vortex persistence the observed decay process is contrary to that predicted by classical theory and observed at low Reynolds numbers in wind tunnels and for small aircraft; namely, that the core grows in size and the maximum tangential velocity decreases while the total circulation remains roughly constant. For full-sized jet transport aircraft, the vortex core often remains stable while the outer portion of the vortex decays, thereby reducing the total circulation. Data are presented from B-747 alleviation flight tests conducted in the 1970s and for other aircraft collected in the early 1990s. The stability of the core is consistent with the essentially laminar core flow observed via flow visualization.

Hallock, J. N. and Burnham, D. C.

"ANALYSIS OF WAKE VORTEX MEASUREMENT DATABASES"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

Many wake vortex databases have been collected and analyzed over the past three decades. Most of these tests were conducted at airports. The early tests examined the safety of the separation standards. As a result, in 1976 the separations were increased for Small or Light following aircraft. Then, the tests examined potential means to increase airport capacity or throughput. Examples include the Vortex Advisory System (VAS), the German Wake Vortex Warning System (WVWS), the French Systeme Anticipatif de Gestion des Espacements (SYAGE), and the NASA Aircraft Vortex Spacing System (AVOSS). Now, the tests are oriented toward studies of potential operational solutions, such as closer-spaced independent parallel runways, LDA approaches, and the Simultaneous Offset Instrument Approach (SOIA). The presentation will document what measurements were made in the many test programs and summarize the status of the raw and processed data. These datasets may be useful in new studies or as initial datasets for the development of new processing and analysis methods that will be used in future tests.

Hallock, J. N. and Eberle, W. R., editors

"AIRCRAFT WAKE VORTICES: A STATE-OF-THE-ART REVIEW OF THE UNITED STATES R&D PROGRAM"

FAA-RD-77-23, February 1977, DOT Transportation Systems Center, Cambridge, MA

The report summarizes the current state-of-the-art understanding of the aircraft wake vortex phenomenon and the results of the United States program to minimize the restrictions caused by aircraft wake vortices in the terminal environment. The vortex phenomenon, vortex avoidance systems, and vortex alleviation techniques are discussed.

Hallock, J. N. and Goldstone, L.

"US/UK VORTEX MONITORING PROGRAM AT HEATHROW AIRPORT"

Proceedings of 20th Symposium of Guidance and Control Panel, Plans and Developments for Air Traffic Systems, AGARD, 1975, pp. 24-1 to 24-9

Vortices shed from aircraft landing on Runway 28R at Heathrow Airport are being monitored in a joint US/UK program. Over 9100 vortex pairs have been recorded and analyzed and their motion correlated with the ambient meteorological conditions. It is shown that if the crosswind component measured near the runway threshold exceeds five knots, vortices linger near the extended runway centerline for a time more than one minute for less than 0.5 percent of the landings. This small percentage is almost entirely due to vortices from the heavy wide-body jets - the B-747, DC-10, and L-1011.

Hallock, J. N. and Holzaepfel, F.

"A REVIEW OF RECENT WAKE VORTEX RESEARCH FOR INCREASING AIRPORT CAPACITY"

Progress in Aerospace Sciences, Vol. 98, 2018, pp. 27-36.

This paper is a brief review of recent wake vortex research as it affects the operational problem of spacing aircraft to increase airport capacity and throughput. The paper addresses the questions of what do we know about wake vortices and what we do not know about wake vortices. The introduction of Heavy jets in the late 1960s stimulated the study of wake vortices for safety reasons and the use of pulsed lidars and the maturity of computational fluid dynamics in the last three decades have led to extensive data collection and analyses which are now resulting in the development and implementation of systems to safely decrease separations in the terminal environment. Although much has been learned about wake vortices and their behavior, there is still more to be learned about the phenomena of aircraft wake vortices.

Hallock, J. N. and Soares, M. A.

"COMPARISON OF TAKEOFF WAKE VORTICES OF HEAVY AND NON-HEAVY B-757"

DOT-VNTSC-FA27-PM-08-15, July 2008, Volpe Center, Cambridge, MA

In July 1996, a new wake vortex category was created for the B757-200 which placed it between revised Large and Heavy categories. Shortly thereafter, the B757-300, stretched version of the B757-200, was placed in service and soon was treated by Air Traffic Control as a Heavy aircraft due to its maximum certificated takeoff weight. Later, a Heavy version of the B757-200, the B757-200H, was also built. This is the third study examining the behavior of vortices from B757 aircraft; the first two examined landings and this study examines takeoffs. This study shows that the current Heavy versions of the B757 behave, from a wake vortex perspective, nearly identically to the non-Heavy version and all versions of the B757 can be treated the same on takeoff.

Hallock, J. N. and Soares, M. A.

"COMPARISON OF THE WAKE VORTICES OF HEAVY AND NON-HEAVY B757"

DOT/VNTSC-FAA-07-06, June 2007, DOT Volpe National Transportation Systems Center, Cambridge, MA

In July 1996, a new wake vortex category was created for the B757-200 which placed it between revised Large and Heavy categories. Shortly thereafter, the B757-300, stretched version of the B757-200, was placed in service and soon treated by Air Traffic Control as a Heavy aircraft due to its maximum certificated takeoff weight. This study examines the behavior of vortices from both aircraft during landing operations, and shows little difference between the vortices of the two B757 series. In fact, both measurements and theory indicate that B757-300 vortices decay somewhat faster than B757-200 vortices. Therefore, the B757-300 is being penalized by an unneeded increased wake vortex spacing during landing operations.

Hallock, J. N. and Soares, M. A.

"IS THE B757 REALLY A 'HEAVY' AIRCRAFT?"

AIAA Paper No. 2007-288, Reno, NV, January 200.

In July 1996, a new wake vortex category was created for the B757 which placed it between revised Large and Heavy categories. Shortly thereafter, the B757-300, stretched version of the B757-200, was placed in service and soon was treated by Air Traffic Control as a Heavy aircraft due to its maximum certificated takeoff weight. This study examines the behavior of vortices from both aircraft during approach/landing operations and shows little difference between the vortices of the two B757 series. In fact, both measurements and theory indicate that B757-300 vortices decay somewhat faster than B757-200 vortices. Therefore, the B757-300 is being penalized by unneeded increased wake vortex spacing during approach/landing operations.

"SUMMARY RESULTS FROM LONG-TERM WAKE TURBULENCE MEASUREMENTS AT SAN FRANCISCO INTERNATIONAL AIRPORT"

DOT-VNTSC-FA27-PM-04-13, July 2004, Volpe National Transportation Systems Center, Cambridge, MA

This report summarizes the results of an extensive wake turbulence data collection program at the San Francisco International Airport (SFO). Most of the landings at SFO are conducted on closely spaced parallel runways that are spaced 750 feet between centerlines (runways 28R and 28L). The purpose of the measurement program was to provide data to support the safety assessment of future enhancements to the Simultaneous Offset Instrument Approach procedure that permits continued use of both runways in deteriorating weather. The data collection was focused on wake behavior in the critical near-ground region where a wake encounter might be most hazardous. Limited measurements were also made at a glide slope altitude of about 530 feet to confirm prior results.

Hallock, J. N. and Winston, B. P.

"RUNWAY CONFIGURATION ANALYSIS FOR CHICAGO O'HARE AIRPORT USING VORTEX ADVISORY SYSTEM DATA"

FA186-PM-81-37, May 1981, DOT Transportation Systems Center, Cambridge, MA.

Based on an analysis of 14 months of data collected at O'Hare International Airport, it was found that decreased separations between runway threshold and outer marker would be permitted about 25 percent of the time. This figure assumes that the landing runways are selected as they are today without any input from the VAS. On the other hand, if the VAS were used to guide the decision on which runways should be used for landings, decreased separations would have been permitted about 40 percent of the time. This 15 percent increase would lead to large delay-dollar savings; \$150 to \$200

million in total IFR annual delay savings (1976 dollars) could be saved if VAS standards are applied instead of today's standards at the top 20 airports. The escalation of fuel prices certainly will increase these delay savings dollars.

Hallock, J. N. and Wood, W. D.

"STATUS OF THE WAKE VORTEX AVOIDANCE SYSTEM"

EASCON '74 Record, IEEE Electronics and Aerospace Systems Conference, 1974, pp. 250-256

The Federal Aviation Administration is pursuing a dual thrust program toward the solution of the wake vortex problem to be able to increase capacity to meet the air traffic density demands of the future while maintaining a high level of safety. One approach being investigated by NASA is to prevent the generation of a dangerous vortex via modification of the aircraft. The alternate approach, to be discussed herein and being undertaken by the Transportation Systems Center, is the design and development of a wake vortex avoidance system which will be used in the terminal airspace to detect and/or predict the presence of wake vortices, evaluate whether a threat of hazard exists, and command the hazard avoidance action. The status of the Wake Vortex Avoidance System is presented by briefly examining each of the modules making up a system: the predictive model and data base, vortex detecting and tracking subsystems, the hazard model, and the system concepts.

Hallock, J. N. and Wood, W. D.

"IMPACT OF WAKE TURBULENCE"

19th Annual Meeting and Technical Program, Air Traffic Control Association, Las Vegas, NV, October 1974

The paper presented the status of the Wake Vortex Avoidance System program by briefly reviewing what is known about vortices and the ability to predict their transport and demise; vortex detection and tracking sensors development; hazard definition; vortex data collection at Kennedy, Stapleton, and Heathrow International Airports; and various system concepts.

Hallock, J. N. and Wood, W. D.

"JOINT US/UK VORTEX TRACKING PROGRAM AT HEATHROW INTERNATIONAL AIRPORT, VOLUME I: EXECUTIVE SUMMARY"

FAA-RD-76-58.1, March 1976, DOT Transportation Systems Center, Cambridge, MA

From May 1974 through June 1975 the approach region to Runway 28R at Heathrow International Airport was equipped with aircraft wake vortex tracking equipment. The vortices from approximately 13000 aircraft were monitored along with the attendant meteorological conditions. The joint US/UK project represents a major step in learning how vortices move and die in the terminal environment. An overview of the Heathrow project is given and it is shown how the project has significantly contributed

to the capability to develop a vortex advisory system promising increased capacity through decreased aircraft separations.

Hallock, J. N., Burnham, D. C. and Sigona, J. J.

"ANALYSIS OF STALLED VORTICES AT DFW AIRPORT"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

Separation standards for final approach must account for the possibility that a wake vortex generated by a preceding aircraft may, because of interaction with the ground and the ambient crosswind, stall in the glide path. A ground-based array of anemometers was used extensively in the 1970s to detect stalled vortices. An array also gives measurements of the ambient wind close to the location where the vortices lateral motion is measured. Data recently collected at Dallas-Ft. Worth Airport are analyzed and compared to the 1970s results. The analysis concentrates on the arrivals when atmospheric turbulence was low to optimize the vortex detection and to select conditions when long vortex lifetimes can be expected.

Hallock, J. N., Burnham, D. C. and Wang, F. Y.

"AN INVENTORY OF VOLPE CENTER WAKE MEASUREMENTS"

DOT-VNTSC-FA27-PM-07-12, Oct. 2007, Volpe National Transportation Systems Center, Cambridge, MA.

The Volpe Center became involved with the subject of aircraft wake turbulence in late 1970, soon after the Center was established. The first test site was set up at the John F. Kennedy International Airport (JFK) in early 1971. Since that time many test programs have been initiated to collect wake vortex behavior. This report provides an overview of the state of the data from that first test site on runway 31R at JFK to October 2007. It includes just the test programs (or portions thereof) for which the Volpe Center was responsible.

Hallock, J. N., Burnham, D. C., Jenkins, J., Konopka, J. and Rudolph, R.

"WAKE VORTEX TRACKING USING FRANKFURT WINDLINE"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

The space between the Frankfurt parallel runways (518 m apart) is instrumented with 10 sonic anemometers (25-Hz measurement rate), which are used to measure the ambient crosswind. One-second averaged data have been processed to track the motion and strength of wake vortices travelling

between the two runways. Future work will (a) determine vortex location in real time and (b) study turbulence levels inside wake vortices using 25-Hz data.

Hallock, J. N., Burnham, D. C., Tombach, I. H., Brashears, M. R., Zalay, A. D. and Barber, M. R.

"GROUND-BASED MEASUREMENTS OF THE WAKE VORTEX CHARACTERISTICS OF A B747 AIRCRAFT IN VARIOUS CONFIGURATIONS"

AIAA Paper No. 1977-0009, Los Angeles, CA, January 1977

A Boeing 747 aircraft flew 54 passes at low level over ground-based sensors. Vortex velocities were measured by a laser-Doppler velocimeter, an array of monostatic acoustic sounders, and an array of propeller anemometers. Flow visualization of the wake was achieved using smoke and balloon tracers. Preliminary results were obtained on the initial downwash field, the time for merging of the multiple vortices, the velocity fields, vortex decay, and the effects of spoilers and differential flap settings on the dissipation and structure of vortices.

Hallock, J. N., editor

"PROCEEDINGS OF THE AIRCRAFT WAKE VORTICES CONFERENCE"

FAA-RD-77-68, June 1977, DOT Transportation Systems Center, Cambridge, MA

This volume contains the proceedings of a conference on aircraft wake vortices held at the DOT Transportation Systems Center on March 15-17, 1977. The contributed papers discuss technological advances in the knowledge of the phenomenon, its effects on aircraft, alleviation techniques, and vortex avoidance systems designed to permit decreases in delays at major airports.

Hallock, J. N., editor

"PROCEEDINGS OF THE AIRCRAFT WAKE VORTICES CONFERENCE"

DOT/FAA/SD-92/1.1 and 1.2 (Volumes 1 and 2), June 1992, DOT Volpe National Transportation Systems Center, Cambridge, MA.

These volumes contain the proceedings of the international conference of Aircraft Wake Vortices held at the Quality Hotel Capitol Hill, Washington, DC, on October 29-31, 1991. The contributed papers discuss technological advances in the knowledge of the phenomenon, its effect on aircraft and airport capacity, detection techniques, and vortex avoidance schemes.

"MONITORING OF AIRCRAFT WAKE VORTICES AT HEATHROW AIRPORT"

Proceedings Int. Conf. on Future of Aircraft All-Weather Operations, Inst. Electrical Engineers, London, November 1976, pp. 38-41

Aircraft separation to avert entrainment in wake vortices is weighed against loss of traffic capacity at airports, and meteorological conditions unfavorable to the formation of wake vortices and their attendant hazards are examined; the organization of vortex data collection sites is discussed. Experience with vortex data collection sites at London, New York, and Denver is surveyed. Anemometer baselines and an acoustic Doppler system are described. Delineation of safety zones and determination of the rate at which shed vortices leave the safety zone are discussed.

Hallock, J. N., Greene, G. C. and Burnham, D. C.

"WAKE VORTEX RESEARCH -- A RETROSPECTIVE LOOK"

Air Traffic Control Quarterly, Vol. 6, No. 3, September 1998, pp. 161-178

During the 1970's and the early 1980's, the FAA and NASA conducted extensive wake vortex research programs with the goal of safely increasing airport capacity. The FAA program focused on developing an extensive data base, the technology for predicting and/or detecting the presence of a vortex, and advising controllers when aircraft separations could be safely reduced. The NASA program emphasized reducing the wake hazard through changes to the aerodynamic characteristics of the aircraft. Both programs made significant technical progress, even though neither program resulted in an implementable solution. Research in the 1990's has the same goal and many of the same challenges as the earlier research. However, now both the FAA and NASA programs are focused on wake detection/avoidance. The primary difference between the FAA and NASA programs is the time scale, with the NASA program emphasizing technology for a future automated ATC system and the FAA program emphasizing enhancements to today's system. This paper discusses the most important lessons learned from prior research by both the FAA and NASA, and in particular, how prior research has shaped the issues, requirements, and constraints which will affect any proposed solution.

"USE OF SIMPLE MODELS TO DETERMINE WAKE VORTEX CATEGORIES FOR NEW AIRCRAFT"

AIAA Paper 2015-3172, June 2015, Dallas, TX.

The paper describes how to use simple models and, if needed, sensitivity analyses to determine the wake vortex categories for new aircraft. The methodology provides a tool for the regulators to assess the relative risk of introducing new aircraft into the current fleet.

Hallock, J. N., Osgood, S. P. and Konopka, J.

"WAKE VORTEX EFFECTS ON PARALLEL RUNWAY OPERATIONS"

AIAA Paper No. 2003-0379, Reno, NV, January 2003

Aircraft wake vortex behavior in ground effect between two parallel runways at Frankfurt/Main International Airport was studied. The distance and time of vortex demise were examined as a function of crosswind, aircraft type, and a measure of turbulence. Vortex decay in ground effect is little influenced by ambient turbulence and is seen to be a stochastic process.

Hallock, J. N., Sigona, J. J. and Burnham, D. C.

"MEASUREMENTS OF VORTICES STALLED NEAR EXTENDED RUNWAY CENTERLINE ON FINAL APPROACH"

AIAA Paper No. 1998-0591, Reno, NV, January 1998.

Longitudinal separation standards for final approach must account for the possibility that a wake vortex generated by the preceding aircraft may, because of interaction with the ground and the ambient crosswind, remain stalled in the glide path. A ground-based array of anemometers was used extensively in the 1970s to detect such stalled vortices. Recent developments in the capabilities of such arrays have permitted completely automatic operation and estimates of vortex height and circulation. The array also gives measurements of the ambient wind close to the location where the vortex lateral motion is measured. Data collected over 10 months in 1994-95 at Kennedy Airport are analyzed and compared to the 1970s results and to a mathematical model for the probability of encountering a wake vortex in the absence of vortex decay. The analysis concentrates on the arrivals when atmospheric turbulence was low (1) to optimize the vortex detection sensitivity of the array and (2) to select conditions where long vortex lifetimes can be expected.

"COMPARISON OF THE WAKE VORTICES OF HEAVY AND NON-HEAVY B-757 ON APPROACH"

DOT-VNTSC-FA27-PM-08-14, June 2008, Volpe Center, Cambridge, MA

In July 1996, a new wake vortex category was created for the B757-200 which placed it between revised Large and Heavy categories. Shortly thereafter, the B757-300, stretched version of the B757-200, was placed in service and soon was treated by Air Traffic Control as a Heavy aircraft due to its maximum certificated takeoff weight. Later, a Heavy version of the B757-200, the B757-200H, was also built. This is the second study examining the behavior of vortices from B757 aircraft during landing operations, and shows little difference between the Heavy and non-Heavy vortices of the B757. Both measurements and theory indicate that the Heavy B757 vortices decay somewhat faster than B757-200 vortices. Therefore, the current Heavy B757 is being penalized by an unneeded increased wake vortex spacing during landing operations.

"VORTEX ADVISORY SYSTEM"

Patent 4,137,764, February 1979, DOT Transportation Systems Center, Cambridge, MA

The invention relates to determining the appropriate spacing between fixed-wing aircraft arriving at runways so as to permit the minimum separation commensurate with safe operation as a function of the atmospheric conditions. More specifically, this invention is directed to a vortex advisory system which will enable flight controllers to vary the separation between aircraft as a function of the accurately predicted motion of wake vortices produced by the aircraft.

Hallock, J. N., Tung, C. and Sampath, S.

"CAPACITY AND WAKE VORTICES"

ICAS-2002-7.9.1, Toronto, Canada, September 2002

Vortex separation standards preclude hazardous encounters, but are oftentimes very conservative. A key to increasing airport capacity is to know when vortices are not a hazard so that aircraft can land and take off with closer intervals. This paper provides an overview of the highlights of a conference held in London to address the capacity and wake vortices issue.

"WAKE VORTEX MEASUREMENTS TO SUPPORT SAFETY ASSESSMENT OF THE SIMULTANEOUS OFFSET INSTRUMENT APPROACH PROCEDURE AT SFO"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

This paper summarizes the results of an extensive wake turbulence data collection program at the San Francisco International Airport (SFO). Most of the landings at SFO are conducted on closely spaced parallel runways that are spaced 750 feet between centerlines (runways 28R and 28L). The purpose of the measurement program was to provide data to support the safety assessment of the Simultaneous Offset Instrument Approach (SOIA) procedure that permits continued use of both runways in deteriorating weather. The data collection was focused on wake behavior in the near-ground region where a wake encounter might be most hazardous. Limited measurements were also made at a glide slope altitude of about 160 meters (530 feet). The specific objective was to more accurately measure wake vortex behavior to refine FAA flight procedure development and analysis tools. These tools will be used to develop safety and procedural requirements for closely spaced parallel runway operations. Wake turbulence data were collected for over 260,000 landing aircraft near the thresholds of Runways 28L and 28R where the glide slope height is approximately 20 meters (65 feet). The wake turbulence data were taken over all seasons and all-weather conditions, 24 hours per day, 7 days per week. The SOIA procedure, as currently designed for SFO, will be used when the cross-runway component of the total wind is 10 knots or less. 'SOIA conditions' at SFO typically occur in the morning or late evening and are often characterized by a fog or marine layer with low cloud ceilings and light surface winds. Stronger winds typically occur in the afternoon after the fog or marine layer has burned off and visibility and cloud ceiling conditions would support visual approach operations. Accordingly, the wake

data were analyzed and categorized relative to the cross-runway component of the total wind, as measured by the Automated Surface Observing System (ASOS), to better correlate wake transport and decay times to conditions when SOIA operations would be conducted. The vortex wake data support the conclusion that when the stagger between aircraft on adjacent approach courses is relatively small (approximately 1 nm for an approach speed of 130 kts), it is not possible for the wake from one aircraft to be blown by the wind into the path of the other aircraft quickly enough to create a hazard. The data are consistent with typical observed aircraft pairings during current SFO visual approach operations as well as proposed SOIA operations.

"WIND CRITERIA TO RELIEVE WAKE VORTEX EFFECTS ON DEPARTURE"

AIAA Paper No. 1999-3420, Norfolk, VA, June 1999

Aircraft wake vortices from departing aircraft represent one impediment on the throughput of an airport. To preclude a hazardous wake encounter, separation standards are employed to separate aircraft so that the vortices from a lead aircraft can translate away or decay sufficiently to permit a following aircraft to safely traverse the same airspace of the lead aircraft. Wind is a primary influence on vortex behavior. This study examined the behavior of the wake vortices of over 16,000 takeoffs at O'Hare International Airport to determine if wind criteria could be used to permit closer spacings on departure. Both a crosswind and a total wind criterion were developed.

"JOINT US/UK VORTEX TRACKING PROGRAM AT HEATHROW INTERNATIONAL AIRPORT, VOLUME II: DATA ANALYSIS"

FAA-RD-76-58,II, November 1977, DOT Transportation Systems Center, Cambridge, M.

From May 1974 through June 1975, the approach region to runway 28R at Heathrow International Airport was equipped with aircraft wake vortex tracking equipment. The vortices from approximately 13,000 aircraft were monitored along with the attendant meteorological conditions. The joint US/UK project represents a major step in learning how vortices move and die in the terminal environment. Volume II describes the entire project from the workings and locations of the equipment to the analysis of the data.

Hallock, J. N., Winston, B. P., Sullivan, T. E. and Burnham, D. C.

"TSC WAKE VORTEX DATA BASE AND APPLICATIONS"

Proceedings of the Aircraft Wake Vortices Conf., FAA-RD-77-68, DOT Transportation Systems Center, June 1977, pp. 67-80.

An extensive data base is being compiled on the motion and decay of wake vortices near the ground. To date, data for over 40,000 vortex pairs have been recorded, analyzed, and entered into the data base. The rationale for the data collection program at each site is presented along with a description of the entries into the data base and the results of some preliminary studies using the data base.

Hallock, J. N., Wood, W. D. and Spitzer, E. A.

"THE MOTION OF WAKE VORTICES IN THE TERMINAL ENVIRONMENT"

Proceedings of the Sixth Conference on Aerospace and Aeronautical Meteorology, American Meteorology Society, 1974, pp. 393-398

A Wake Vortex Avoidance System (WVAS) is being designed and developed for use in the terminal airspace to detect and/or predict the presence of vortices, to evaluate the threat, and to command the hazard avoidance action. The WVAS will consist of a predictive model and data base, a vortex detection and tracking subsystem, a hazard model, and a data processing and display subsystem. The paper describes the vortex detection and tracking systems (a pulsed acoustic, a Doppler acoustic, a ground wind, and a laser Doppler system), the JFK Vortex Test Site and its extensive meteorological network, and several WVAS concepts ranging from a very simple meteorological system to a complex and fully-automated system.

Hallock, J. N., Wood, W. D. and Spitzer, E. A.

"PREDICTIVE TECHNIQUES FOR WAKE VORTEX AVOIDANCE"

Proceedings of 20th Symposium of Guidance and Control Panel, Plans and Developments for Air Traffic Systems, AGARD, 1975, pp. 23-1 to 23-11

Aircraft wake vortices represent a major impediment to increasing runway capacity. Separation criteria are conservative most of the time and thus traffic is unnecessarily delayed by always adhering to the present inflexible regulations. Systems which employ vortex tracking sensors and/or meteorological sensors to determine safe reduced spacings are being designed. Any wake vortex avoidance strategy relies upon the ability to predict vortex transport and decay. The paper discusses vortex behavior, preliminary predictive models based upon the tracking of vortices from over 24,000 landing aircraft and systems and their implementation to provide the capability of using adaptive separations.

Hallock, J. N., Wood, W. D. and Spitzer, E. A.

"THE WAKE VORTEX ADVISORY SYSTEM"

Proceedings Int. Conf. on Electronic Navigational Aid Systems for Aircraft, Federation des Industries Electriques et Electroniques, November 1977, Paris, France, pp. 269-273

The vortices from over 50,000 landing aircraft have been monitored at Kennedy, Stapleton, O'Hare, and Heathrow International Airports. Using this data base, a wind criterion has been defined which can be used as a vortex condition indicator; by measuring the wind velocity in the runway approach zone and comparing the velocity with the wind criterion, the times when the aircraft spacing may be reduced safely to three nautical miles for all aircraft are delineated. A Vortex Advisory System has been implemented at the Chicago O'Hare International Airport and will be fully operational in December 1977.

"AERODYNAMIC OPTIMIZATION AND EVALUATION OF KC-135R WINGLETS, RAKED WINGTIPS, AND A WINGSPAN EXTENSION"

AIAA Paper 2010-0057, January 2010, Orlando, FL.

The ability of winglets and raked wingtips to reduce the drag of an aircraft are fairly well known. In 2008, the Air Force Research Laboratory and Air Mobility Command tasked the US Air Force Academy to examine the effect that winglets would have on the KC-135 Stratotanker. This investigation focused on finding an optimized configuration for the winglets. Wind tunnel tests were run on a range of Mach numbers (0.2, 0.3, 0.4), winglet sizes, cant angles (5-25 deg), and toe out angles (0-8 deg). An optimized winglet was found, but further testing with raked wingtips and a wingspan extension configuration were found to offer similar aerodynamic performance. While the optimal winglet offered increases in endurance and range potential of 5.62 and 3.55 percent respectively, a raked wingtip with 20 deg of additional leading-edge sweep offered increases of 8.32 and 4.69 percent. Meanwhile, the wingspan extension offered increases of 7.02 and 4.21 percent. Depending on the wingtip modification implemented and actual mission analysis evaluated, the KC-135 could see increases in range from 6-12 percent and increases in endurance from 6-13 percent. With set missions, the different wingtip modifications could decrease fuel burn by up to 8 percent. In addition, the stability analysis found that the static stability changes on the aircraft are very small.

Halsey, N. G. J.

"THE PREDICTION OF VERY SHORT PERIOD CROSSWIND SPEED USING STATISTICAL TECHNIQUES"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

Any future wake vortex advisory system needs to have the capability to predict the strength of the crosswinds affecting aircraft in the vicinity of the runway. Wind measurements are routinely taken at all airports and these measurements are available to the pilot through air traffic control. This is problematic since it is unlikely that the measured wind speed would be appropriate to the precise time and location of the aircraft on either final approach or after take-off. It is known that the use of persistence gives a reasonable forecast of wind speed over short time periods or short distances although the use of predictive statistical techniques can reduce forecast errors quite markedly. This

paper describes the use of various techniques for crosswind prediction as applied to a large sample of one-minute readings taken at Memphis airport during 1995. Results are presented showing the improvements in forecast accuracy that can be gained using these techniques.

Halsey, N. G. J.

"THE PREDICTION OF CROSSWIND COMPONENTS OVER VERY SHORT PERIODS IN THE CONTEXT OF WAKE VORTEX AVOIDANCE"

Technical Report No. 244, May 1998, Meteorological Office, Berkshire, UK

This paper describes attempts to predict one-minute mean crosswind components over short periods of at most twenty minutes. This work has been carried out in the context of research into the prediction and avoidance of aircraft wake vortices. It is known that the use of persistence (assuming that the wind speed will remain constant from one minute to the next) gives a useful forecasting technique over such short periods. However, it has been demonstrated that the level of accuracy from such forecasts is only marginally useful when attempting to predict the motion and decay of aircraft wake vortices. The prediction techniques used are purely statistical in nature although some meteorological knowledge is applied to some of the outcomes, i.e., results are not applied unless they are sensible in a meteorological context. The main method used is that of an autoregressive, integrated, moving average (ARIMA) process of which several alternatives are suggested and compared. The results of the study show that a straightforward ARIMA process can reduce the standard error of a prediction using persistence by around 15% with the possibility of future enhancements increasing this figure to 25%.

Ham, N. D.

"SOME CONCLUSIONS FROM AN INVESTIGATION OF BLADE-VORTEX INTERACTION"

Journal of American Helicopter Society, Vol. 10, No. 2, pp. 1-5.

Selected experimental spanwise airload harmonics are presented for single and rear tandem rotor configurations for various rotor shaft angles, advance ratios, and thrust loadings.

Hama, F. R.

"PROGRESSIVE DEFORMATION OF A CURVED VORTEX FILAMENT BY ITS OWN INDUCTION"

Phys. Fluids, Vol. 5, No. 10, October 1962, pp. 1156-1162

Progressive three-dimensional deformation of an initially parabolic, plane curved vortex due to its own induction is numerically obtained in this paper using the localized-induction concept instead of through the full Biot-Savart law. It is shown that, after the region near the vortex rises up from the plane of the initial orientation, a helical deformation takes place on the legs of the parabola. The helix, which rotates in the direction opposite to the circulatory rotation around the vortex filament, is found

to travel away toward the far ends of the parabola as the vortex keeps rising, while increasing the amplitude and extent of the helical deformation. Similar computations also carried out with a hyperbolic initial shape resulted in essentially the same conclusions as the parabola but with much better numerical stability, as well as with an exponential initial configuration, which grew into somewhat more complicated patterns, yet maintained the essential feature of the helical deformation.

Hamilton, D. W. and Proctor, F. H.

"WAKE VORTEX TRANSPORT IN PROXIMITY TO THE GROUND"

19th Digital Avionics Systems Conference, Philadelphia, PA, October 2000

A sensitivity study for aircraft wake vortex transport has been conducted using a validated large eddy simulation model. The study assumes neutrally stratified and nonturbulent environments and includes the consequences of the ground. The numerical results show that the nondimensional lateral transport is primarily influenced by the magnitude of the ambient crosswind and is insensitive to aircraft type. In most of the simulations, the ground effect extends the lateral position of the downwind vortex about one initial vortex spacing in the downstream direction. Further extension by as much as one vortex spacing occurs when the downwind vortex remains 'in ground effect' for relatively long periods of time. Results also show that a layer-averaged ambient wind velocity can be used to bound the time for lateral transport of wake vortices to insure safe operations on a parallel runway.

Hammarlund, H., Hillgren, R. and Karlsson, F.

"REDUCTION OF WAKE VORTEX TRANSIENTS IN THE JAS 39 GRIPEN"

AIAA Paper 2007-6765, August 2007, Hilton Head, SC.

JAS 39 Gripen is a modern aerodynamically unstable multi role combat fighter. It has delta canard configuration with all moving canards. It has very high demands on agility, precision, flying qualities and carefree maneuvering. For high precision and performance during demanding control tasks a blend of pure angle of attack vane signal and a complementary filtered angle of attack was selected for feedback at a cost of some sensitivity for wake vortex transients at high load factor and high angle of attack. The very robust carefree maneuver limit function enables the pilot to sustain max commands and thus expose the aircraft to wake vortex passages and their transients. After several wake vortex related incidents in the Swedish Air Force service a flight control system control law change was necessary. A wake vortex model was developed and validated with available flight test data from earlier wake vortex passages. The wake vortex model was then used to find the actual problem areas in terms of flight conditions, load factor and angle of attack at the wake vortex passage. The flight control system change was implemented and flight tested. The flight control laws update is implemented in the JAS 39 Gripen Flight Control System and it will significantly reduce the risk for wake vortex related incidents.

Hammer, J.

"SAFETY ANALYSIS OF AN APPROACH SPACING FOR INSTRUMENT APPROACHES (ASIA) APPLICATION USING ADS-B"

Air Traffic Control Quarterly, Vol. 11, No. 3, 2003, pp. 203-224.

This paper illustrates new techniques being adopted by some members of industry for analysis of the safety of aircraft surveillance applications. The techniques are illustrated using the example flight deck application of Approach Spacing for Instrument Approaches (ASIA). The techniques include analysis of the operational procedures, conducting a hazard analysis, and treating identified hazards in a fault-tree analysis. The fault-tree analysis in turn results in system requirements on various subsystems that support the operational application. The specific analysis of the approach spacing application results in a requirement that the probability of presenting hazardously misleading information be held to less than 0.00001 per operation. The 0.00001 value represents 'major' system criticality, and is a criticality that is considered by avionics vendors to be achievable within reasonable cost constraints. If the benefits of reduced spacing that are offered by the approach spacing concept are significant enough to justify the cost, users may find that it is worthwhile to equip their aircraft with such a capability.

Hammer, J.

"CASE STUDY OF PAIRED APPROACH PROCEDURE TO CLOSELY SPACED PARALLEL RUNWAYS"

Air Traffic Control Quarterly, Vol. 8, No. 3, 2000, pp. 223-252

This paper analyzes a new procedure called paired approach which has been proposed for use with very closely spaced parallel runways (less than 2500 ft. between runway centerlines). The intent of the procedure is to make better use of runways during instrument meteorological conditions. The analysis includes consideration of wake turbulence and collision avoidance. We find that for very closely spaced parallel runways, an angled, offset approach is necessary to simultaneously avoid wake turbulence and collision risk.

Han, C. and Cho, J.

"UNSTEADY TRAILING VORTEX EVOLUTION BEHIND A WING IN GROUND EFFECT"

Journal of Aircraft, Vol. 42, No. 2, March-April 2005, pp. 429-434

The unsteady evolution of trailing vortex sheets in ground effect is simulated by the use of a discrete vortex method. The ground effect is included by image method. Two cases of unsteady vortex evolution behind lifting lines (an elliptic loading and a fuselage/flap-wing configuration) are simulated for several ground heights. The present method is validated by comparison of the simulated wake roll-up shapes to published numerical results. For a lifting line with an elliptic loading, the ground has the effect of moving the wingtip vortices laterally outward and suppressing the development of the vortex. An increase in the wing loading has the effect of moving the wingtip vortex more laterally outward. The rotation of the wake vortices behind a fuselage/part-span flap configuration in ground effect is less than the case of flight out of the ground effect.

Han, C. and Mason, W. H.

"INVISCID WING-TIP VORTEX BEHAVIOR BEHIND WINGS IN CLOSE FORMATION FLIGHT"

Journal of Aircraft, Vol. 42, No. 3, May-June 2005, pp. 787-788

This study demonstrates the inviscid near-wake behavior behind aircraft flying in close formation. The prediction of the wake behavior shows that the distance between the wings has the effect of moving the wake vortices up behind wing tips facing each other. The relative heights between aircraft cause a large asymmetric evolution of wake vortices, which will result in a change of aerodynamic characteristics. Although the present results are obtained based on potential flow theory, it can be concluded that the prediction of the wake roll-up behavior behind aircraft in formation flight might be of considerable importance in the prediction of the aerodynamic performance.

Han, C., Cho, L. and Cho, J.

"WAKE SHAPES BEHIND WINGS IN CLOSE FORMATION FLIGHT NEAR THE GROUND"

Journal of Mechanical Science and Technology, Vol. 19, No. 2, 2005, pp. 674-681.

The unsteady evolution of trailing vortex sheets behind wings in close formation flight near the ground is simulated using a discrete vortex method. The ground effect is included by an image method. The method is validated by comparing computed results with other numerical results. For a lifting line with an elliptic loading, the ground has an effect of moving wingtip vortices laterally outward and suppressing the development of vortex evolution. The gap between wings in close formation flight has an effect of moving up wingtip vortices facing each other. For wings flying in parallel, the ground effect causes the wingtip vortices facing each other to move up, and it makes the opposite wing tip vortices to move laterally outward. When there is a relative height between the wings in ground effect, right-hand side wingtip vortices from a mothership move laterally outward.

Han, J.

"LARGE EDDY SIMULATIONS OF AIRCRAFT WAKE VORTICES IN A HOMOGENEOUS ATMOSPHERIC TURBULENCE (CROW INSTABILITY, VORTEX LIFESPAN)"

Ph.D. Thesis, 1998, North Carolina State University, Raleigh, NC.

This dissertation is composed of two separate papers where atmospheric turbulence effects on the behavior of aircraft wake vortices are studied using a validated large eddy simulation model. Information from this study may contribute to the development of a predictor algorithm for the National Aeronautics and Space Administration's (NASA) Aircraft Vortex Spacing System (AVOSS), which will determine safe operating spacing between arriving and departing aircraft and provide a safe reduction in separation of aircraft compared to the now-existing flight rules. In the first paper, the development of Crow instability in a homogeneous field of turbulence is studied. The Crow instability

becomes well developed in most atmospheric turbulence levels, but in strong turbulence the vortex pair deforms more irregularly due to turbulence advection. The maximum Crow instability wavelength decreases with increasing nondimensional turbulence intensity (ti) while it increases with increasing turbulence integral length scale. The vortex lifespan is controlled primarily by ti and decreases with increasing ti , while the effect of integral scale of turbulence on vortex lifespan is of minor importance. The lifespan of vortex in our numerical simulations is estimated to be about 40% larger than the theoretically predicted value. This larger lifespan compared with an analytic theory agrees very well with the data from laboratory experiments and is caused by slower growth in the middle of the vortex lifespan. The maximum deviation in lifespan from the average value due to ambient turbulence alone is about 7% of the mean for small ti and about 20% of the mean for large ti , showing much less scatter in lifespan compared with atmospheric observations. In the second paper, the vortex decay and descent in a homogeneous field of turbulence is investigated. The decay rate of the vortex circulation increases clearly with increasing ambient turbulence level but decreases with increasing radial distance, which is consistent with field observations. Simple vortex decay models are proposed as functions of ti and radial distance. A Gaussian type of vortex decay model can be applied at larger radial distances, while an exponential type of vortex decay model can be applied at smaller radial distances near the core, but the latter can be extended up to a radial distance of about half of the initial vortex separation distance for strong turbulence. The circulation averaged over radial distance, which is related to the rolling moment of an encountering aircraft, shows a Gaussian decay for weak and moderate turbulence and an exponential decay for strong turbulence. A model for the vortex descent based on the vortex decay model is also proposed as a function of ti and dimensionless time.

Han, J., Lin, Y.-L., Arya, S. P. and Kao, C.-T.

"LARGE EDDY SIMULATION OF AIRCRAFT WAKE VORTICES: ATMOSPHERIC TURBULENCE EFFECTS"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 131-144

Ambient atmospheric turbulence effects on aircraft wake vortices have been studied using a validated large eddy simulation model. The results show that the Crow instability becomes well developed in most atmospheric turbulence levels, but in strong turbulence the vortex pair deforms more irregularly due to turbulence advection. Strong ambient turbulence tends to accelerate the instability growth, while the maximum instability wavelength tends to decrease with increasing dimensionless turbulence intensity. Compared with two-dimensional simulation results, a decrease in circulation with time is significantly enhanced by three-dimensional ambient turbulence.

Han, J., Lin, Y.-L., Arya, S. P. and Proctor, F. H.

"NUMERICAL STUDY OF WAKE VORTEX DECAY AND DESCENT IN HOMOGENEOUS ATMOSPHERIC TURBULENCE"

AIAA Journal, Vol. 38, No. 4, April 2000, pp. 643-656.

Numerical simulations are performed to isolate the effect of ambient turbulence on the wake vortex decay rate within a neutrally stratified atmosphere. Simulations are conducted for a range of turbulence intensities by injecting wake vortex pairs into an approximately homogeneous and isotropic turbulence field. Consistent with field observations, the decay rate of the vortex circulation increases clearly with increasing levels of ambient turbulence. Based on the results from the numerical simulations, simple decay models for the vortex pair are proposed as functions of nondimensional ambient turbulent intensity, nondimensional radial distance, and nondimensional time. For strong atmospheric turbulence, the model predictions are in reasonable agreement with the observational data. For weak turbulence with stable stratification, the model, based on turbulence dissipation alone, underestimates circulation decay with consistent overestimation of vortex descent, unless stratification effects are included.

Han, J., Lin, Y.-L., Arya, S. P. and Proctor, F. H.

"LARGE EDDY SIMULATION OF AIRCRAFT WAKE VORTICES IN A HOMOGENEOUS ATMOSPHERIC TURBULENCE: VORTEX DECAY AND DESCENT"

AIAA Paper No. 1999-0756, Reno, NV, January 1999

The effects of ambient turbulence on decay and descent of aircraft wake vortices are studied using a validated, three-dimensional, large-eddy simulation model. Numerical simulations are performed to isolate the effect of ambient turbulence on wake vortex decay rate within a neutrally-stratified atmosphere. Simulations are conducted for a range of turbulence intensities, by injecting wake vortex pairs into an approximately homogeneous and isotropic turbulence field. The decay rate of the vortex circulation increases clearly with increasing ambient turbulence level, which is consistent with field observations.

Han, J., Lin, Y.-L., Schowalter, D. G. and Arya, S. P.

"LARGE EDDY SIMULATION OF AIRCRAFT WAKE VORTICES WITHIN HOMOGENEOUS TURBULENCE: CROW INSTABILITY"

AIAA Journal, Vol. 38, No. 2, February 2000, pp. 292-300

Ambient atmospheric turbulence effects on aircraft wake vortices are studied using a validated large eddy simulation model. Our results confirm that the most amplified wavelength of the Crow instability and the lifetime of wake vortices are significantly influenced by ambient turbulence. The Crow instability becomes well developed in most atmospheric turbulence levels, but in strong turbulence the vortex pair deforms more irregularly due to turbulence advection. The most amplified wavelength of the instability decreases with increasing dimensionless turbulence intensity n , although it increases with increasing turbulence integral length scale. The vortex lifespan is controlled primarily by n and decreases with increasing n , whereas the effect of integral scale of turbulence on vortex lifespan is of minor importance. The lifespan is estimated to be about 40% larger than Crow and Bate's predicted value but in agreement with Sarpkaya's recent modification to Crow and Bate's theory. This larger

lifespan is also supported by data from water tank experiments and direct numerical simulations. There appears to be a possibility that the scatter in vortex lifespans due to ambient turbulence alone decreases with increasing Reynolds number, whereas larger scatter of lifespans in flight tests may result from other factors such as stratification, wind shear, and inhomogeneous ambient turbulence.

Han, J., Lin, Y.-L., Schowalter, D. G., Arya, S. P. and Proctor, F. H.

"LARGE EDDY SIMULATIONS OF AIRCRAFT WAKE VORTICES: ATMOSPHERIC TURBULENCE EFFECTS"

12th Symposium on Boundary Layers and Turbulence, 1997, pp. 237-238

Large eddy simulations (LES) of a vortex pair induced by aircraft with a homogeneous atmospheric turbulence are performed. Vortex decay and deformation, onset, and development of mutual induction sinusoidal instability (Crow instability), and vortex bursting are investigated as functions of turbulence parameters.

Han, J., Lin, Y.-L., Schowalter, D. G., Arya, S. P. and Proctor, F. H.

"LARGE EDDY SIMULATION OF AIRCRAFT WAKE VORTICES WITHIN HOMOGENOUS TURBULENCE: CROW INSTABILITY"

AIAA Journal, Vol. 38, No. 2, February 2000, pp. 292-300.

Ambient atmospheric turbulence effects on aircraft wake vortices are studied using a validated large eddy simulation model. Our results confirm that the most amplified wavelength of the Crow instability and the lifetime of wake vortices are significantly influenced by ambient turbulence. The Crow instability becomes well developed in most atmospheric turbulence levels, but in strong turbulence the vortex pair deforms more irregularly due to turbulence advection. The most amplified wavelength of the instability decreases with increasing dimensionless turbulence intensity n , although it increases with increasing turbulence integral length scale. The vortex lifespan is controlled primarily by n and decreases with increasing n , whereas the effect of integral scale of turbulence on vortex lifespan is of minor importance. The lifespan is estimated to be about 40% larger than Crow and Bate's predicted value but in agreement with Sarpayka's recent modification to Crow and Bate's theory. This larger lifespan is also supported by data from water tank experiments and direct numerical simulations. There appears to be a possibility that the scatter in vortex lifespans due to ambient turbulence alone decreases with increasing Reynolds number, whereas larger scatter of lifespans in flight tests may result from other factors such as stratification, wind shear, and inhomogeneous ambient turbulence.

Han, Y. O.

"DIFFUSED TIP VORTEX STRUCTURE GENERATED BY A SLOTTED TIP ROTOR BLADE"

AIAA Paper No. 2005-0057, Reno, NV, January 2005

An experiment was conducted to understand the flow field surrounding a slotted helicopter rotor blade that directs a part of its incident flow along the spanwise direction. Flow visualization and 3-component LDV measurements were made on tip vortices trailing from the slotted blade for four different slot configurations to quantify the swirl and axial velocity components, mean kinetic energy, core development and its turbulent properties at a fixed wake age of 145 degrees. The presence of the slots created a flow velocity in the spanwise direction that resulted in much diffused vortex structure at very early wake ages. An increase in number of slots was shown to increase the diffusion of the tip vortices. However, the slot optimization study indicated that the slotted blade with two slots showed sufficient vortex diffusion, and as much as the blade with four slots. The axial velocity of tip vortices generated by the slotted blade was found to increase with more slots, which is different to the baseline case. Also, the convection swirl of the slipstream about the hub axis was found to be higher for the slotted blade case. This results in an increased mean kinetic energy of the tip vortices explaining the increased power requirement of the slotted blade rotor.

Han, Y. O. and Leishman, J. G.

"INVESTIGATION OF HELICOPTER ROTOR-BLADE-TIP-VORTEX ALLEVIATION USING A SLOTTED TIP"

AIAA Journal, Vol. 42, No. 3, March 2004, pp. 524-535

A slotted tip was developed to modify the characteristics of the strong vortex trailed from the tip of a small-scale helicopter blade. Forward-facing slots directed a slight amount of the incident flow in the spanwise direction, which was vented at the side edge of the blade tip. This caused the tip vortex to detach from the blade tip face, and introduced turbulent vortlets into the laminar core of the developing vortex. The resulting wake flow field was investigated using flow visualization and laser Doppler velocimetry. Measurements were conducted to quantify the vortex swirl velocity components, the inner core development, and the overall vortical flow inside the vortex trails. The results were then compared to a baseline blade with a standard unmodified rectangular tip. It was found that the slotted blade reduced the peak value of the swirl velocity components in the tip vortex by up to 60% relative to those of the baseline blade. The core growth of the tip vortices from the slotted blade suggested a much higher rate of diffusion, up to as much as three times that of the baseline case. Measurements of rotor power showed only a 3% increase relative to the baseline tip. Based on the overall results, the slotted blade is considered a highly effective design in diffusing vorticity and reducing the flow high field velocities that would otherwise be induced by a rotor tip vortex.

Han, Y. O. and Leishman, J. G. and Coyne, A. J.

"MEASUREMENTS OF THE VELOCITY AND TURBULENCE STRUCTURE OF A ROTOR TIP VORTEX"

AIAA Journal, Vol. 35, No. 3, March 1997, pp. 477-485

The turbulent flow structure of a tip vortex generated by a hovering rotor was investigated with the use of three-dimensional laser Doppler velocimetry. The velocity field was measured at five wake ages, with the three components of turbulence being measured at the three earliest ages. The tangential

(swirl) velocity component inside the tip vortex was found to have a self-similar behavior for all wake ages. The viscous core size was estimated to be approximately 2.5% of the blade chord just after formation, growing with the square root of vortex age to about 13% of blade chord at one rotor revolution. At early wake ages, radially symmetric peaks in the turbulence intensities were measured inside the vortex core, whereas only a single peak appeared in the turbulence distribution at later ages. The radial component of turbulence was found to be the most dominant, with the axial component being the smallest. Additional turbulence quantities, such as Reynolds' stress, were also measured. Finally, the evolutionary features of the turbulent kinetic energy production are discussed.

Hancock, G. J.

"A REVIEW OF THE AERODYNAMICS OF A JET IN A CROSS FLOW"

Aeronautical Journal, May 1987, pp. 201-213.

The aerodynamics of a circular jet emerging normally from a wall into a cross flow is critically assessed. Some general trends are obtained when viscous effects are neglected. Attempts to predict these real effects are reviewed and their anomalies highlighted. The importance of understanding and specifying the jet exit conditions is stressed, which is relevant to complete numerical solutions.

Hancock, G. J.

"AERODYNAMIC LOADING INDUCED ON A TWO-DIMENSIONAL WING BY A FREE VORTEX IN INCOMPRESSIBLE FLOW"

The Aeronautical Journal of the Royal Aeronautical Society, Vol. 75, June 1971, pp. 413-416.

Practical problems often arise in which the aerodynamic loadings on wings and fins, due to nearby free vortices, are required. For example, aerodynamic loads on helicopter blades are affected by the tip vortices which are continuously being shed and which lie beneath the rotor plane. And vortices shed from the nose of an aircraft fuselage can induce significant side loads on a fin. The estimation of the aerodynamic load distribution on a moving wing in the neighborhood of a free vortex (whose axis is primarily in the free stream direction) is an interesting problem which, as far as the author is aware, has not been discussed previously in the literature. Standard techniques for conventional linearized wing theory cannot be applied directly to this problem because the trailing vorticity shed from the wing trailing edge is affected by the flow field of the free vortex and so the mathematical application of the Kutta trailing edge condition is more complex. In this note the loading is estimated on a two-dimensional wing at zero incidence at low speeds due to a free line vortex, lying above the wing, whose axis is primarily in the free stream direction. The problem is three-dimensional. The loading on the wing is due to two primary effects. First the circulatory motion about the free vortex induces an asymmetric distribution of downwash (i.e. upwash on one side of the free vortex, downwash on the other side) which in turn induces an asymmetric spanwise load distribution, the loading will tend asymptotically to zero at large spanwise distances from the vortex. Second, the sidewash velocities induced on the wing upper surface by the free vortex will induce a 'suction' loading, this loading will be

symmetric on either side of the free vortex, and, in general, it will be a local effect. It is assumed that the rate of change of spanwise loading is small so that a 'lifting line' approximation can be made. A series solution, based essentially on a power series in terms of the strength of the free vortex, is set up which incidentally satisfies the trailing edge Kutta condition. Assuming that the velocities induced by the free vortex in the neighborhood of the wing are small, the first two terms in the series solution are sufficient to indicate the loading. The solution for a free vortex very close to the wing is not obtained. There are mutual interference effects between the free vortex and the wing vorticity. The wing vorticity will induce a flow field in the neighborhood of the free vortex, so the free vortex will curve to follow the local streamline direction. An estimation of this effect is given.

Hancock, G. J.

"ON THE ROLLING UP OF A TRAILING VORTEX SHEET"

Aero. Journal, Vol. 74, No. 717, September 1970, pp. 749-752

This paper looked at the rollup of two vortices behind a wing with an elliptical spanwise load distribution when the standard linear model becomes less valid, for example, at higher wing lift coefficients. The paper assumed that a continuous trailing vortex sheet rolls up into two discrete vortices, and this rolling up process takes place far downstream of the finite wing which generates the trailing vorticity.

Hancock, P. E., Zhang, S., Pascheke, F. and Hayden, P.

"WIND TUNNEL SIMULATION OF A WIND TURBINE WAKE IN NEUTRAL, STABLE AND UNSTABLE WIND FLOW"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012047-1 - 012047-11.

Measurements of mean velocity, Reynolds stresses, temperature and heat flux have been made in the wake of a model wind turbine in the EnFlo meteorology wind tunnel, for three atmospheric boundary layer states: the base-line neutral case, stable and unstable. The full-to-model scale is approximately 300:1. Primary instrumentation is two-component LDA combine with cold-wire thermometry to measure heat flux. In terms of surface conditions, the stratified cases are weak, but there is a strong 'imposed' condition in the stable case. The measurements were made between 0.5D and 10D, where D is the turbine disk diameter. In the stable case the velocity deficit decreases more slowly; more quickly in the unstable case. Heights at which quantities are maximum or minimum are greater in the unstable case and smaller in the stable case. In the stable case the wake height is suppressed but the width is increased, while in the unstable case the height is increased and the width (at hub height) reaches a maximum and then decreases. The turbulence in the wake behaves in a complex way. Further work needs to be done, to cover stronger levels of surface condition, requiring more extensive measurements to properly capture the wake development.

Handley, W. A.

"TWO NEXTGEN AIR SAFETY TOOLS: AN ADS-B EQUIPPED UAV AND A WAKE TURBULENCE ESTIMATOR"

MS Thesis, 2016, University of Washington, Seattle, WA.

Two air safety tools are developed in the context of the FAA's NextGen program. The first tool addresses the alarming increase in the frequency of near-collisions between manned and unmanned aircraft by equipping a common hobby class UAV with an ADS-B transponder that broadcasts its position, speed, heading and unique identification number to all local air traffic. The second tool estimates and outputs the location of dangerous wake vortex corridors in real time based on the ADS-B data collected and processed using a custom software package developed for this project. The TRansponder based Position Information System (TRAPIS) consists of data packet decoders, an aircraft database, Graphical User Interface (GUI) and the wake vortex extension application. Output from TRAPIS can be visualized in Google Earth and alleviates the problem of pilots being left to imagine where invisible wake vortex corridors are based solely on intuition or verbal warnings from ATC. The result of these two tools is the increased situational awareness, and hence safety, of human pilots in the National Airspace System (NAS).

"PULSED DOPPLER LIDAR FOR TERMINAL AREA MONITORING OF WIND AND WAKE HAZARDS"

AMS Conference, Hyannis, MA, October 2004.

CLR has made significant improvements in its solid-state 2-micron pulsed Doppler lidar systems over the past decade. For the past two years, one of our Doppler lidars has been operating at the Hong-Kong International Airport for windshear and turbulence detection. Another dedicated unit has been installed for more than a year at the St. Louis International Airport for FAA-sponsored, long-term wake vortex monitoring. These installations demonstrate significantly different means by which the same technology can benefit airport operations.

Hannon, S. M.

"TRACK FORMAT DESCRIPTION FOR PULSED DOPPLER LIDAR MEASUREMENTS OF WAKE VORTICES AT DENVER INTERNATIONAL AIRPORT"

Report, April 2004, CLR Photonics, Inc., Lafayette, CO.

This document describes the format for the ASCII wake vortex track output produced by the WindTracer pulsed Doppler lidar at the 2003 NASA-sponsored Denver International Airport Wake Acoustic Tests. The Wake Acoustic Tests were conducted on the north end of Denver International Airport (DIA) in August and September, 2003. This document comprises five sections. Section 2 provides a concise description of the lidar used during the test and an overview of the real-time wake vortex detection and tracking algorithm. Various parameters are defined. The lidar coordinate system for the measurements is illustrated in Section 3. Section 4 summarizes the database. Section 5 provides

representative plots of the vortex attributes (positions and circulation) along with the associated lidar-measured crosswind profiles.

"AUTONOMOUS INFRARED DOPPLER RADAR: AIRPORT SURVEILLANCE APPLICATIONS"

Proceeding First European Conference on Radar Meteorology, September 2000, Bologna, Italy, pp. 1-7.

Infrared Doppler radar (Doppler lidar) sensors provide a unique capability to generate high resolution, three-dimensional distributions of wind and aerosol data. Appropriately processed, these data can be used in the airport terminal area to map hazardous wind shear and turbulence levels, detect and track wake vortices, and monitor slant path visibility. The benefit of the infrared radar relative to its microwave counterparts is the ability to sense clear air hazards, especially those in and around local terrain features. The fact that the infrared radar beam is quite narrow significantly reduces, if not eliminates, artifacts associated with sidelobe-induced ground clutter. Continued rapid developments in the arena of solid-state infrared Doppler radar have yielded substantial advancements in terms of autonomous, stand-alone operation. Such developments have made possible the ability to deploy compact and robust systems that are unattended. This paper summarizes our autonomous pulsed lidar developments and reviews sample results.

Hannon, S. M.

"DETECTION AND TRACKING OF WAKE VORTICES WITHIN APPROACH AND DEPARTURE CORRIDORS"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001.

Pulsed infrared Doppler radar (Doppler lidar) sensors provide a unique capability to generate high resolution, three-dimensional distributions of wind data. Appropriately processed, these data can be used in the airport terminal area to map hazardous wind shear and turbulence levels and to detect and track wake vortices. Within the past five years, continued rapid developments in the arena of solid-state infrared Doppler radar have yielded substantial advancements in terms of autonomous, stand-alone operation. Such developments have made possible the ability to deploy compact and robust systems that are unattended. For certain operational scenarios and procedures designed to improve capacity, the lidar can provide needed wake vortex detection and tracking observations within the approach and departure corridors. This presentation summarizes autonomous pulsed lidar developments and reviews results from recent relevant deployments.

"WIND MEASUREMENT APPLICATIONS OF COHERENT LIDAR"

The Review of Laser Engineering, Vol. 23, No. 2, February 1995, pp. 124-130

Pulsed solid-state coherent laser radar (lidar) systems are rapidly evolving as useful sensors for a variety of ground-based and airborne measurement applications. This paper describes such measurement applications and sample demonstration measurement results associated with wake vortex detection and tracking, windshear and gust front detection, and wind field monitoring in support of Space Shuttle operations.

Hannon, S. M. and Pelk, J. V.

"PULSED DOPPLER LIDAR MEASUREMENTS OF WAKE VORTICES AT THE SAN FRANCISCO INTERNATIONAL AIRPORT"

Report CTI-TR-2002-04, February 2002, Coherent Technologies, Inc., Lafayette, CO.

This report summarizes results of a September 2001 program in which a WindTracer 2-m pulsed coherent Doppler lidar was deployed to the San Francisco International Airport (SFO). For historical reference, this was the first large scale pulsed lidar based wake turbulence dataset of the Federal Aviation Administration (FAA) Wake Turbulence Research Program. The focus of the wake vortex measurements was to collect data that can be used for comparison with other sensors (e.g., the Volpe windline and sodar) and/or model predictions (ASAT, the Airspace Analysis Tool). In a more general sense, the program supports the FAA Wake Turbulence Research Program which endeavors to improve airport capacity by addressing various issues associated with aircraft wake vortices.

Hannon, S. M. and Pelk, J. V.

"PULSED DOPPLER LIDAR MEASUREMENTS OF WAKE VORTICES AT THE SAN FRANCISCO INTERNATIONAL AIRPORT"

CTI-TR-2002-04, February 2002, Coherent Technologies, Inc., Lafayette, CO

A Wind Tracer pulsed coherent Doppler lidar has been used to generate a large, high-quality database of wake vortex behavior at the San Francisco International Airport. More than 2400 vortex track files have been generated. Vortex behavior out of ground effect (OGE) and in ground effect (IGE) was observed during a 2.5-week period in September 2001. In addition to the vortex track files, the database includes 420 PPI wind scans and 438 vertical wind profiles. These data can be used to significantly enhance the meteorological database at SFO and, in particular, to quantify turbulence level and overall wind variability. The SFO deployment was successful in demonstrating several key firsts for pulsed Doppler lidar: Simultaneous detection and tracking of aircraft vortices for paired approaches, Simultaneous observation of wake vortices along multiple points on the approach glide slope, and Unattended (i.e., no operator) detection and tracking of wake vortices.

"WAKE VORTEX DETECTION AT DENVER STAPLETON AIRPORT WITH A PULSED 2-MICRON COHERENT LIDAR;"

Airborne Windshear Detection and Warning Systems - Fifth and Final Combined Manufacturers' and Technologists' Conference, DOT/FAA/RD-94/14-II, Langley Research Center, Hampton, VA, July 1994, pp. 62.

This report describes the effort undertaken to relate aircraft wake history to the local environment. This involved the monitoring of the embedded wind field, monitoring of local meteorological parameters, a high-resolution velocity field analysis in vertical scan planes and measurement of the axial velocity signature. A flashlight pumped 2.09- micron solid state coherent laser radar system was used to detect and track wake vortices. Strong wake vortex signatures were measured for moderate to large aircraft at Denver's Stapleton airport and a large vortex database was compiled.

Hannon, S. M. and Thomson, J. A.

"AIRCRAFT WAKE VORTEX DETECTION AND MEASUREMENT WITH PULSED SOLID-STATE COHERENT LASER RADAR"

J. Modern Optics, Vol. 41, No. 11, November 1994, pp. 2175-2196

Pulsed solid-state coherent laser radar (lidar) systems can measure radial wind velocity to precision well below 1 m/s at spatial scales on the order of 30-50 m and to ranges of several kilometers. This capability is appropriate for a variety of measurement objectives in the airport terminal area. Wake vortex detection and tracking is one of the primary objectives currently being evaluated by regulatory agencies in the United States and elsewhere. Up to now, noninvasive measurement of wake vortex properties as been limited to short-range continuous-wave lidar systems. This paper discusses this application and presents theoretical analysis and experimental results for 21m coherent lidar. Detection, tracking, and measurement results are presented for sample DC-10, 757, and 727 aircraft landings from a laser radar wake vortex database compiled in 1993 at Denver Stapleton International Airport.

"APPLICATION OF PULSED DOPPLER LIDAR IN THE AIRPORT TERMINAL AREA"

Proceedings of SPIE, Vol. 5653, 2005, pp. 186-197

Pulsed coherent Doppler lidar systems have matured rapidly, especially at solid-state wavelengths. Turnkey systems are commercially available and are being deployed for various aviation applications. Doppler lidar data is used in the airport terminal area to map hazardous wind shear and turbulence levels and to detect and track wake vortices. Future applications could include slant path visibility monitoring. Several permanent installations and rapidly deployable instrument configurations have been achieved. The benefit of the infrared Doppler lidar relative to its microwave counterparts is the ability to sense clear air hazards, especially those in and around local terrain features. The fact that the lidar beam is quite narrow eliminates artifacts associated with sidelobe-induced ground clutter. This paper summarizes our autonomous pulsed lidar developments and reviews sample results.

"INDUCED MOMENT EFFECTS OF FORMATION FLIGHT USING TWO F/A-18 AIRCRAFT"

NASA/TM-2002-210732, August 2002, NASA Dryden Flight Research Center, Edwards, CA.

Previous investigations into formation flight have shown the possibility for significant fuel savings through drag reduction. Using two F/A-18 aircraft, NASA Dryden Flight Research Center has investigated flying aircraft in autonomous formation. Positioning the trailing airplane for best drag reduction requires investigation of the wingtip vortex effects induced by the leading airplane. A full accounting of the vortex effect on the trailing airplane is desired to validate vortex-effect prediction methods and provide a database for the design of a formation flight autopilot. A recent flight phase has mapped the complete wingtip vortex effects at two flight conditions with the trailing airplane at varying distances behind the leading one. Force and moment data at Mach 0.56 and an altitude of 25,000 ft and Mach 0.86 and an altitude of 36,000 ft have been obtained with 20, 55, 110, and 190 ft of

longitudinal distance between the aircraft. The moments induced by the vortex on the trailing airplane were well within the pilot's ability to control. This report discusses the data analysis methods and vortex-induced effects on moments and side force. An assessment of the impact of the nonlinear vortex effects on the design of a formation autopilot is offered.

Hanses, C., Knabe, F. and Korn, B.

"DESIGNING AND EVALUATING ADVANCED APPROACH PROCEDURES FOR THE CONCEPT OF SEGMENTED INDEPENDENT PARALLEL APPROACHES"

AIAA Paper 2015-2431, June 2015, Dallas, TX.

From the perspective of flight guidance, the development of laterally segmented or curved approach procedures that allow for rerouting around congested areas is a promising strategy for coping with noise issues. At major airport-hubs with parallel runway systems, airport capacity needs to be considered as well; for those airports, an increased capacity can be reached when runways are operated independently. This, however, requires straight precision approaches according to current guidelines issued by the International Civil Aviation Organization (ICAO). To help pave the way for independent operations of segmented approaches at airports with parallel runway systems, an elementary safety concept is summarized in this work. Moreover, a procedure design developed to participate from benefits of laterally segmented approach procedures will be presented and evaluated with respect to capacity implications.

Hanson, C. E.

"AN INVESTIGATION OF THE NEAR WAKE PROPERTIES ASSOCIATED WITH PERIODIC VORTEX SHEDDING FROM AIRFOILS"

AVL Report 76234-5, September 1970, Mass. Institute of Technology, Cambridge, MA

An investigation of the near wake of airfoils with various trailing edge configurations including splitter plates reveals properties which are conducive to wake periodicity. The frequency of the shedding process is found to scale with the new wake momentum thickness and a wake velocity simply related to the base pressure coefficient. Computer results suggest that the frequency and bandwidth of the vortex shedding process can be predicted by a solution of the complete Orr-Sommerfeld equation.

Hanson, C., Andrade, S. and Pable, J.

"EXPERIMENTAL MEASUREMENTS OF PASSENGER RIDE QUALITY DURING AIRCRAFT WAKE SURFING"

AIAA Paper 2018-3561, June 2018, Atlanta, GA.

The National Aeronautics and Space Administration (NASA) Armstrong Flight Research Center completed a series of research flights to better understand the challenges of aircraft wake surfing using civilian airplanes and commercial avionics. Airlines and air cargo carriers have identified uncertainty

about increased passenger/crew discomfort due to noise and vibrations as a potential obstacle to the widespread adoption of aircraft wake surfing. To measure the effects of wake surfing on passenger ride quality, NASA instrumented a business jet with cabin noise and vibration sensors. The airplane was then flown under control of an experimental autopilot at multiple locations within the wake of a similar airplane. This paper presents a summary of the measurements collected on these flights, an assessment of passenger discomfort correlated with wake surfing performance benefits, and qualitative evaluations collected from passengers aboard during the research flights.

Hanson, C., Pahle, J., Reynolds, J., Andrade, S. and Brown, N.

"EXPERIMENTAL MEASUREMENTS OF FUEL SAVINGS DURING AIRCRAFT WAKE SURFING"

AIAA Paper 2018-3560, June 2018, Atlanta, GA.

The National Aeronautics and Space Administration (NASA) Armstrong Flight Research Center (Edwards, California) completed a series of research flights to better understand the challenges of aircraft wake surfing using civilian airplanes and commercial avionics. The research flights sought to demonstrate significant fuel savings by a pair of business jets engaged in automated wake surfing using commercial off-the-shelf avionics to the fullest extent possible, including a 1090-MHz Automatic Dependent Surveillance - Broadcast (ADS-B) data link. A NASA Gulfstream C-20A airplane (Gulfstream Aerospace, Savannah, Georgia) was flown as the trail airplane within the wake of a NASA Gulfstream III (G-III) airplane. This paper presents a summary of the fuel savings measured during these flights.

Hanson, H. M. and Hanson, D. M.

"A REEXAMINATION OF THE FORMATION OF EXHAUST CONDENSATION TRAILS BY JET AIRCRAFT"

Journal of Applied Meteorology, Vol. 34, November 1995, pp. 2400-2405.

With the end of World War II, it became apparent that a study should be undertaken to identify the factors controlling the production of aircraft condensation trails (contrails). This early work provided a theoretical prediction of the critical temperature at which the values of the relative humidity and pressure are such that the formation of the contrail phenomenon will occur. As empirical data were obtained, the general agreement at increased altitude was not precise and several studies were made to obtain both theoretical and empirical fits that would provide a 'yes/no' decision. These modifications did allow a better decision for the formation of contrails but were found to be increasingly inaccurate at greater altitudes. This study provides an improved algorithm that yields a theoretical prediction that is in general agreement with the available empirical data at all altitudes. It demonstrates that there is a need for additional effort in the identification and precision of relative humidity and pressure that are input to this computation.

Hanson, H.-E.

"JAS 39 GRIPEN. WAKE VORTEX PENETRATION FLIGHT TESTING"

Proceedings of the 17th SFTE Symposium, Amsterdam, The Netherlands, June 2006

JAS 39 Gripen is basically a highly unstable aircraft in pitch in the subsonic Mach region. Pitch static stability is obtained by means of AoA vane feedback. For optimum control during demanding control tasks, a blend of proportional vane signal and complementary filtered AoA was selected. However, the good control characteristics were achieved at the cost of some sensitivity to vortex transients. The very robust AoA MLL function in the control laws entice pilots to sustained max commands below corner speed and thereby expose the aircraft to a vulnerable condition for Wake Vortex disturbances. After a number of Wake Vortex Related incidents in SwAF service there was an obvious need for a new control law. A new flight control system edition was developed and tested in large batch simulations of more than 12000 wake vortex passages to prove that the new flight control system edition had significant effect on transient reduction during a Wake Vortex passage. This paper describes the Gripen Vortex penetration and propwash flight test program performed during 2005 and 2006 at Saab in Linkoping, Sweden.

"AIRCRAFT WAKE VORTEX DETECTION USING CONTINUOUS-WAVE RADAR"

Johns Hopkins APL Technical Digest, Vol. 18, No. 3, 1997, pp. 348-357.

The Applied Physics Laboratory designed and constructed a bistatic continuous-wave radar system for experiments in aircraft wake vortex detection. Acoustic pumping was evaluated as a possible technique to enhance overall performance. The radar and acoustic systems were installed at the Baltimore-Washington International Airport in the fall of 1996. Controlled experiments using a NASA C-130 aircraft are discussed, and some preliminary results are presented.

Hanson, T.

"A WAY OUT OF THE WAKE"

Professional Pilot, Vol. 30, No. 6, June 1996, pp. 54-59.

The search for an affordable wake-turbulence-avoidance system.

Hardin, J. C.

"THE VELOCITY FIELD INDUCED BY A HELICAL VORTEX FILAMENT"

Physics of Fluids, Vol. 25, No. 11, November 1982, pp. 1949-1952.

An exact analytical solution for the velocity field, both interior and exterior, induced by an infinite right-handed helical vortex filament is derived. Due to the way the variables combine in this solution, the paper also shows that it is possible to derive a stream function for this non-axisymmetric flow. Sample calculations of these expressions are included.

Hardin, J. C.

"NOISE RADIATION FROM THE SIDE EDGES OF FLAPS"

AIAA Journal, Vol. 18, No. 5, May 1980, pp. 549-552.

The recently observed phenomenon of high noise radiation from the side edges of flaps in flow is investigated by way of a simple two-dimensional model problem. The model is based upon a physical picture of boundary layer vorticity being swept around the edge by spanwise flow on the flap. The model problem is developed and solved and the resulting noise radiation calculated. Further, a mathematical condition for the vortex to be captured by the potential flow and swept around the edge is derived. The results show that the sound generation depends strongly upon the strength of the vorticity and distance from the edge and that it can be more intense than the more common trailing edge noise source in agreement with the experimental observations.

Hardin, J. C. and Wang, F. Y.

"SOUND GENERATION BY AIRCRAFT WAKE VORTICES"

NASA-CR-2003-212674, December 2003, NASA Langley Research Center, Hampton, VA.

This report provides an extensive analysis of potential wake vortex noise sources that might be utilized to aid in their tracking. Several possible mechanisms of aircraft vortex sound generation are examined based on discrete vortex dynamic models and characteristic acoustic signatures calculated by application of vortex sound theory. It is shown that the most robust mechanisms result in very low frequency infrasound. An instability of the vortex core structure is discussed and shown to be a possible mechanism for generating higher frequency sound bordering the audible frequency range. However, the frequencies produced are still low and cannot explain the reasonably high-pitched sound that has occasionally been observed experimentally. Since the robust mechanisms appear to generate only very low frequency sound, infrasonic tracking of the vortices may be warranted.

Hardin, J. C., Gilinsky, M. and Khaikine, V.

"ESTIMATION OF THE LOCATION OF A FARFIELD ACOUSTIC SOURCE"

J. Acoustical Soc. America, Vol. 118, July 2005, pp. 45-50

A backward integration method for estimating the location of a source of sound waves in the atmosphere is presented. This geometric acoustics method is based upon the analysis of microphone array measurements to determine the incoming ray direction in three dimensions. The equations governing the propagation of the ray are then integrated backward in time. The sound source lies somewhere along the calculated ray path. The intersection of such loci from more than one array would provide an estimate of the source location. The method appears to be very rapid to implement

and, assuming the time delays to be accurately measured, limited in accuracy only by the timeliness of the input sound speed and velocity profiles in the atmosphere.

"SOUND GENERATION BY AIRCRAFT WAKE VORTICES INTERACTING WITH THE GROUND PLANE"

AIAA Paper No. 2004-2881, Manchester, UK, May 2004

This paper examines the acoustic radiation produced by the interaction of aircraft wake vortices with the ground plane. The wake vortices are modeled as vortex filaments of finite length and the theory of vortex sound is applied to calculate the resulting noise generation. A new expression for evaluating the retarded time integrals in this geometry is developed. An example is presented which illustrates that the sound generation by this source for commercial aircraft is generally infrasonic. In addition, a comparison of the sound pressure time histories with and without taking retarded time differences into account is presented. It is determined that, for the case of wake vortex-ground interaction, retarded time differences can be ignored, thereby allowing more efficient computation.

Hardy, G. H. and Lewis, E. K.

"COCKPIT DISPLAY OF TRAFFIC AND WAKE INFORMATION FOR CLOSELY SPACED PARALLEL APPROACHES"

AIAA Paper No. 2004-5106, Providence, RI, August 2004.

A preliminary study of a Cockpit Display of Traffic and Wake Information for closely spaced parallel approaches was conducted at the NASA Ames Research Center. With the advent of the navigational precision of the Global Position System, data-link, and the operational procedures of Required Navigational Performance, the possibility exists for simultaneous instrument operations to runways with separations approaching those used for simultaneous visual operations. In addition, new algorithms for predicting wake vortex movement may allow these instrument operations to be conducted with greater safety than for present visual operations. The study developed a cockpit display for traffic and wake information and developed operational procedures for a mix of conventional and runway independent aircraft to closely spaced landing areas. Results showed that very small Total System Errors were obtained using pursuit displays and manual flight control. For aircraft with different approach speeds, a small increase in paired aircraft approach spacing was found to be necessary for wake separation over that for aircraft with similar approach speeds. Performance at decision height was compatible with CAT II/IIIA operations.

Hariharan, N.

"ROTARY-WING WAKE CAPTURING: HIGH-ORDER SCHEMES TOWARD MINIMIZING NUMERICAL VORTEX DISSIPATION"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 822-829

The use of high-order, first-principles-based Euler/Navier-Stokes methodologies for rotary-wing wake capturing is assessed. Fifth/seventh-order spatially accurate essentially non-oscillatory methodologies were implemented and their benefits in capturing wake vortices were addressed. The use of high-order solution reconstruction, in conjunction with the use of overset grids to resolve selectively regions of interest such as concentrated vorticity, was also explored. The tip vortex off of a NACA0015 wing was captured using this methodology, and the tip vortex characteristics are compared with experiments. The relative merits of fifth- and seventh-order schemes are assessed for capturing wake vorticity.

Hariharan, N. and Sankar, L.

"UNIFORMLY HIGH-ORDER ESSENTIALLY NONOSCILLATORY SCHEMES FOR VORTEX CONVECTION ACROSS OVERSET INTERFACES"

J. Aircraft, Vol. 45, No. 2, March-April 2008, pp. 546-559

The construction of uniformly high-order accurate numerical schemes based on an essentially non-oscillatory methodology was considered in this work. In particular, the accuracy of essentially non-oscillatory scheme implementations near the interface boundaries for overset grids was analyzed. Essentially non-oscillatory schemes use large stencil support for constructing progressively high-order accuracy spatial schemes. The handling of such schemes near overset boundaries influences the overall solution accuracy for large-scale computations. An essentially non-oscillatory based 5th/7th order spatially accurate Euler/Navier-Stokes overset solver was used to study the convection of vortices across overset interfaces. Three different numerical formulations near the boundary interfaces were studied. Two overlapping Cartesian meshes were generated, and a Lamb's vortex was convected across the overset interface between the two meshes. The fidelity of the vortex as it crossed the interface was analyzed, and the results were compared for the three near-boundary formulations. It was found that the preservation of the vortex strength crucially depended upon the correct formulation and interpolation of high-order fluxes within the essentially non-oscillatory framework near the overset interface.

"A REVIEW OF COMPUTATIONAL TECHNIQUES FOR ROTOR WAKE MODELING"

AIAA Paper No. 2000-0114, Reno, NV, 2000

This paper discusses existing techniques for modeling the rotor wake in hover and in forward flight. It also briefly reviews extensions of these methods for modeling complete rotorcraft. The review is followed by results from promising high order overset methods for wake capturing, and efficient hybrid near field Navier-Stokes wake capturing/far-field potential flow wake convecting methodologies. The paper concludes with some speculations on the likely advances in rotorcraft flow field modeling in the forthcoming years.

Hariharan, N. and Sankar, L. N.

"HIGH-ORDER ESSENTIALLY NONOSCILLATORY SCHEMES FOR ROTARY-WING WAKE COMPUTATIONS"

Journal of Aircraft, Vol. 41, No. 2, March-April 2004, pp. 258-267

The use of fifth-seventh-order spatially accurate, essentially non-oscillatory (ENO) schemes for capturing vortices using Euler/Navier-Stokes equations is discussed. These schemes are constructed to minimize numerical dissipation and are evaluated for their application to flow fields laden with vorticity. The fifth-order ENO scheme is compared with a commonly used third-order MUSCL scheme for a two-bladed rotor in hover. Based on the results, the fifth- and seventh-order ENO schemes are evaluated for their ability to convect a vortex generated from a wing tip. The relative merits of these schemes for capturing vortex wakes arising from wings and rotor blades are summarized.

Hariharan, N. S.

"A HIGH ORDER OVERSET REFINEMENT METHODOLOGY FOR VORTEX-DOMINATED FLOWFIELD STUDIES"

AIAA Paper No. 2002-0965, Reston, VA, April 2002

A high order methodology with vortex-tracking overset refinement for the use in vorticity dominated flow fields is explored in this effort. The stimulus for this work arises from efforts to capture the tip vortex of a rotor-blade using first-principles based Euler/Navier-Stokes methods. High order solution reconstruction in conjunction with moving 'tracking' overset grid is used to selectively resolve required regions of interests such as concentrated vorticity. Vortex capturing using a wing grid-vortex grid overset system was undertaken using a baseline fifth/seventh order spatial/third order temporal ENO scheme. A system to automatically re-shape the vortex grid to conform to the vortex shape as the solution evolves was developed and tested. The methodology was found to work well when the vortex system is well defined, i.e., rotor-blade, wing tip vortex system.

"SIMULATION OF ROTOR IN HOVER: CURRENT STATE AND CHALLENGES"

AIAA Paper 2014-0041, January 2014, National Harbor, MD.

A helicopter is subjected to a wide variety of flight conditions with disparate objectives; these include efficient cruise and hover, and high-performance maneuvering. The hover condition remains a very important design consideration because it represents the true value of the helicopter, and it is a limiting design point in terms of power requirements. Accurate numerical prediction of rotor-blade aerodynamic parameters such as thrust, torque and efficiency, requires an accurate modeling of the vortex wake. Despite tremendous advancements in the ability to preserve the tip vortex from first principles, the capability to consistently and reliably predict performance parameters for a new rotor-

blade has still been elusive. These challenges provide the motivation for the AIAA Applied Aerodynamics Technical Committee Rotorcraft Simulation Working Group's efforts to evaluate hover simulation capabilities across government organizations, industry, and academia. The AIAA Applied Aerodynamics Rotor Simulation Working Group aims to bring together government, industry, and academic participants to evaluate and further rotor-in-hover performance predictions. The invited session at SciTech 2014 is the first step to assess different approaches for the prediction of baseline S-76 rotor planform. Future plans include a full workshop at SciTech 2015 to evaluate prediction of performance for S-76 planforms with various tip-shapes.

Hariharan, N., Wissink, A. and Steffen, M.

"TIP VORTEX FIELD RESOLUTION USING AN ADAPTIVE DUAL-MESH COMPUTATIONAL PARADIGM"

AIAA Paper No. 2011-1108, January 2011, Orlando, FL.

This paper describes the efforts to model vorticity laden flow fields using the CREATE-AV Helios platform. Helios employs a dual-mesh paradigm: near body unstructured grids, and high order accurate off-body Cartesian grids, and information exchange is facilitated by an automated, implicit hole cutting method. Further, an automatic mesh refinement capability is employed to refine regions of intense vorticity. Two different scenarios are considered: (a) the vortical flow field off a high-angle-of-attack aircraft, (b) the helical wake of a model rotor in hover. The ease of use, efficiency, and power of the Helios dual-mesh paradigm is demonstrated through high fidelity solutions for the aforementioned unsteady vortical fields.

"A HAZARD DEFINITION FOR WAKE TURBULENCE ENCOUNTER DURING TERMINAL AREA OPERATIONS"

RE-81, March 1973, Mass. Institute of Technology, Cambridge, MA

A six-degree-of-freedom vortex encounter simulation has been developed for use on a hybrid computer to determine the hazard potential for terminal area operations. Complete trajectory data for landing, horizontal flyby, and climbing flights are presented and conclusions are drawn from these results. A hazardous condition is defined as having the roll angle exceed ten degrees and/or the flight path angle become steeper than -4.5 degrees at any point along the flight path with the aircraft under autopilot control. A simplified sensitivity analysis shows that the controllability of an aircraft is about twice as sensitive to changes in vortex proximity than to changes in wingspan, but if the near wingtip proximity is chosen to be the independent variable, controllability is nearly independent of aircraft size.

Harrington, R. F.

"FEASIBILITY OF DETECTING AIRCRAFT WAKE VORTICES USING PASSIVE MICROWAVE RADIOMETERS"

NASA-CR-191553, December 1993, Old Dominion Univ., Norfolk, VA

The feasibility of detecting the cold core of the wake vortex from the wingtips of an aircraft using a passive microwave radiometer was investigated. It was determined that there is a possibility that a cold core whose physical temperature drop is 10 C or greater and which has a diameter of 5 m or greater can be detected by a microwave radiometer. The radiometer would be a noise injection balanced Dicke radiometer operating at a center frequency of 60 GHz. It would require a noise figure of 5 dB, a pre-detection bandwidth of 6 GHz, and an integration time of 2 seconds resulting in a radiometric sensitivity of 0.018 K. However, three additional studies are required. The first would determine what are the fluctuations in the radiometric antenna temperature due to short-term fluctuations in atmospheric pressure, temperature, and relative humidity. Second, what is the effect of the pressure and temperature drop within the cold core of the wake vortex on its opacity. The third area concerns the possibility of developing a 60 GHz radiometer with a radio metric sensitivity an order of magnitude improvement over the existing state of the art.

"INSTABILITY OF SECONDARY VORTICES GENERATED BY A VORTEX PAIR IN GROUND EFFECT"

Journal of Fluid Mechanics, Vol. 700, 2012, pp. 148-186.

In this work we investigate the approach of a descending vortex pair to a horizontal ground plane. As in previous studies, the primary vortices exhibit a rebound, due to the separation of secondary opposite-sign vortices underneath each primary vortex. On each side of the flow, the weaker secondary vortex can become three-dimensionally unstable, as it advects around the stronger primary vortex. It has been suggested in several recent numerical simulations that elliptic instability is the origin of such waviness in the secondary vortices. In the present research, we employ a technique whereby the primary vortices are visualized separately from the secondary vortices; in fact, we can mark the secondary vortex separation, often leaving the primary vortices invisible. We find that the vortices are bent in a Crow-type displacement mode, and, by keeping the primary vortices invisible, we can see both sides of the flow simultaneously, showing that the instability perturbations on the secondary vortices are antisymmetric. Triggered by previous research on four-vortex aircraft wake flows, we analyze one half of the flow as an unequal-strength counter-rotating pair, noting that it is essential to consider the angular velocity of the weak vortex around the stronger primary vortex in the analysis. In contrast with previous results for the vortex-ground interaction, we find that the measured secondary vortex wavelength corresponds well with the displacement bending mode, like the Crow-type instability. We have analyzed the elliptic instability modes, by employing the approximate dispersion relation of Le Dizès and Laporte in our problem, finding that the experimental wavelength is distinctly longer than predicted for the higher-order elliptic modes. Finally, we observe that the secondary vortices deform into a distinct waviness along their lengths, and this places two rows of highly stretched vertical segments of the vortices in between the horizontal primary vortices. The two rows of alternating-sign vortices translate towards each other and ultimately merge into a single vortex row. A simple point vortex row model can predict trajectories of such vortex rows, and the net result of the model's orbital or passing modes is to bring like-sign vortices, from each secondary vortex row, close to each other, such that merging may ensue in the experiments.

"A SHORT WAVE INSTABILITY CAUSED BY THE APPROACH OF A VORTEX PAIR TO A GROUND PLANE"

Physics of Fluids, Vol. 22, 2010, p. 091106-1.

In the present work, we study the approach of a counter-rotating vortex pair to a ground plane. Between the vortices and the ground, a boundary layer forms, which can separate, to generate secondary vortices of opposite sign (originally discovered by Harvey and Perry). We have developed a novel technique to study this flow in which we pool dye on a horizontal ground plane prior to forming the primary vortex pair, allowing us to principally visualize the secondary vorticity. The secondary vortices begin to develop a three-dimensional instability in the presence of the strain rate field of the primaries. The work here provides a clear visualization of such a periodic phenomenon from experiment, and indicates a distinct phase relationship between the instabilities in the two secondary vortices, leading to interesting subsequent vortex dynamics.

"UNIFORM DOWNWASH WITH ROTORS HAVING A FINITE NUMBER OF BLADES"

J. American Helicopter Society, Vol. 21, No. 1, January 1976, pp. 9-20

This paper deals with factors that influence the hovering performance of helicopter rotors. First, a discussion is presented on the short comings of the classical blade element-momentum theory when it is used to define the optimum rotor with a finite number of blades. Fixed-wing aerodynamics theory is used to demonstrate that the loading on a single blade is better represented by treating the rotor blade as a wing in a linearly varying spanwise velocity field. A comparison between experimentally obtained loading on a single blade and the loading calculated from fixed-wing theory is presented. An approximation for the velocity induced by a rolled-up vortex is suggested and comparison of this approximation with a measured velocity distribution near the core region of a tip vortex is shown to be very good.

Harris, M.

"CHALLENGES PAST, PRESENT AND FUTURE FOR LIDAR IN WIND ENERGY"

19th Coherent Laser Radar Conference (CLRC), Paper Th1, June 2018, Okinawa, Japan.

Lidar made its first tentative steps in 2003 towards becoming an accepted tool in the wind industry; significant efforts were needed initially to understand the requirements and establish lidar methods. Important questions were raised, including: is lidar reliable and does it work in all conditions, particularly low backscatter? Is the accuracy sufficient? Can costs be reduced? Today, lidar is used onshore, offshore and on the turbine itself for a range of important activities including resource assessment, power performance evaluation, turbine optimization and active control. The level of acceptance has steadily increased to the point where lidar is now considered mainstream in the growing wind industry, with the development of international standards and roadmaps to bankability.

Remaining challenges include better understanding of complex terrain, wakes and turbulence, and greater acceptance by way of certification and standards. In future new applications may emerge as the technology improves with further cost reductions.

Harris, M.

"FIELD TRIAL MEASUREMENTS OF AIRCRAFT WAKES USING COHERENT LASER RADAR"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Coherent laser radar (or lidar) is a powerful technique for the detection and evaluation of full-scale aircraft wake vortices. The technique measures the Doppler shift of light scattered from atmospheric particles, and hence infers the line-of-sight flow velocity allowing a picture of vortex flow to be built up. Detection and monitoring of vortices at ranges exceeding a few hundred meters is best carried out using pulsed lidar; in contrast, detailed measurements at short range are better obtained with continuous-wave (CW) lidar. This presentation concentrated on characterization of wake vortices by CW lidar measurements; the work has potential to aid low-vortex wing design, and for quantifying the vortex hazard from existing aircraft. Data will be presented from several trials conducted by DERA/QinetiQ at Heathrow, Toulouse and Munich. Analysis techniques will be outlined for obtaining vortex characteristics such as circulation and trajectory. The influence of atmospheric conditions and local topography on vortex measurements will be discussed.

Harris, M., Vaughan, J. M., Huenecke, K. and Huenecke, C.

"AIRCRAFT WAKE VORTICES: A COMPARISON OF WIND-TUNNEL DATA WITH FIELD TRIAL MEASUREMENTS BY LASER RADAR"

Aerospace Science and Tech., Vol. 4, 2000, pp. 363-370

A method is presented for comparison of measurements on aircraft wake vortices obtained using two very different techniques: 1) five-hole probe measurements on a 1/13.6 (7.35%) scale half-model of an Airbus A321 were made in a wind tunnel, and 2) coherent laser radar (lidar) measurements were made in full-scale field trials at Toulouse Blagnac Airport. The lidar measurements provide line-of-sight tangent velocities across the vortex pair to over half the peak core velocity, whereas the wind tunnel measurements cover the full core region, extending nearly to the mid-point. Measurements from the two systems may thus be compared over the overlap region of the vortex profile. Over this range the measured tangent velocity profiles show good agreement for vortices of comparable age. Vortex disturbance is brought about by atmospheric turbulence, and the effects are evident in the lidar data, leading to significant distortion of older vortices. Some implications of the results are discussed together with points of comparison for the two measurement systems. The complementary character of the information that may be derived from the two techniques is emphasized.

Harris, M., Young, R. I. and Vaughan, J. M.

"MEASUREMENTS OF AIRCRAFT WAKE VORTEX STRUCTURE BY CW COHERENT LASER RADAR"

Tenth Biennial Coherent Laser Radar Technology and Applications Conference, November 1999, pp. 203-206

The laser sensors group at DERA Malvern has a long history of detailed measurements of aircraft wake vortices. The equipment used has recently been upgraded to achieve improved accuracy in determining the core separation. The use of direction-sensing lidar giving the ability to distinguish the sign (direction) of wind velocity allows the acquisition of superior data compared to earlier DERA trials. The increased ability to define the position of the core vortex gives greater accuracy in measurements of the circulation. The gathering of a large database allows the potential to build a comprehensive picture of vortex evolution and decay. The upgraded equipment was deployed on a trial for Airbus Industrie at Toulouse Blagnac during March 1998, with the aim of making measurements of wake turbulence from aircraft on the final approach to the runway. Laser radar has proved a useful tool for examining vortices and hence determining the necessary separation distances between landing aircraft. Laser radar has a further role to play in the negation of vortices. Detailed measurement of the vortex core may allow for the optimization of aircraft wing design to ameliorate vorticity and enhance decay. The possibility of making high-quality measurements has been demonstrated on full-scale aircraft in the real atmosphere. Such measurements are thus complementary to the information provided by wind tunnel studies. However, to achieve optimum and reproducible results, the lidar measurements must be made under stringent atmospheric conditions.

"TIP VORTEX DEVELOPMENT ON A PITCHING-PLUNGING LOW ASPECT RATIO FLAT PLATE"

AIAA Paper No. 2011-3580, June 2011, Honolulu, Hawaii.

Many natural flyers utilize low-aspect-ratio wings to harness unsteady flow features which enhance their flight characteristics in the low Reynolds number regime. This study investigates the tip vortices' development and interaction with the leading edge (LE) circulation regions on a low-aspect-ratio, flat plate subjected to a pitch-plunge motion. Stereoscopic Particle Image Velocimetry is used to measure the flow field over a flat plate throughout the downstroke of a pitch-plunge kinematic motion with varying phase lags and a pure plunge kinematic motion. Phase averaged velocity fields are calculated along various streamwise locations centered at the tip of the flat plate. The strength of the tip vortex is shown to increase in the streamwise direction, except for when the plate is at a low effective angle of attack. The slope of the tip vortex core separation from the upper surface of wing in the chordwise direction remains relatively constant. The initial displacement of the tip vortex structure is shown to be dependent upon the plunge velocity. Also, it is seen that two different flow mechanisms exist between the tip vortex and LE circulation region based upon their transient development throughout the downstroke. Outward spanwise flow from the LE circulation region exists in the absence of existing, inward spanwise velocity over the wing tip. This occurs for the pure plunge and pitch-plunge kinematic motion with a phase lag of 30 degrees. The outward flow provides added momentum to the tip vortex structure thereby strengthening it downstream.

Hart, D. P.

"CAVITATION AND WAKE STRUCTURE OF UNSTEADY TIP VORTEX FLOWS"

PhD Thesis, December 1992, California Institute of Technology, Pasadena, CA.

Unsteady flows are prevalent in virtually every fluid application yet, because of their intrinsic complexity, few attempts have been made to measure them or explain their behavior. This thesis presents an experimental study of one of the simplest unsteady flow-induced effects, the periodic change in angle of attack of a lifting surface. Of particular interest is the influence this effect has on the

tip vortex structure of a finite aspect ratio hydrofoil and the part it plays in the inception of cavitation. An aspect ratio 2.3 hydrofoil was reflection-plane mounted to the test section floor of the Caltech Low Turbulence Water Tunnel and harmonically oscillated in pitch near its center of pressure. Observations of the growth and collapse of surface and tip vortex cavitation were made along with detailed observations of the interaction of the tip vortex formation with the spanwise wake structure. Measurements of the cavitation inception number for surface cavitation and tip vortex cavitation were made relative to the phase of the hydrofoil and the reduced frequency, k , of oscillation. Studies of the oscillation-induced spanwise trailing vortex structures and the Karman vortex street generated by the boundary layer were made of a two-dimensional hydrofoil. Laser Doppler Velocimetry measurements were taken of the tip vortex velocity profile and the flow at the trailing edge of both the two- and the three-dimensional hydrofoils at reduced frequencies ranging from 0.5 to 2.0. Dynamic changes in bound circulation and shed vorticity in the streamwise and spanwise directions relative to the freestream were calculated from these measurements at three locations along the span of the foil. The results of these measurements are compared to theoretical flow calculations and related to measurements of the cavitation inception number in the tip vortex region of the three-dimensional foil.

Hartman, R. J. and Lewis, H. W.

"WAKE COLLAPSE IN A STRATIFIED FLUID: LINEAR TREATMENT"

J. Fluid Mech., Vol. 51, Part 3, 1972, pp. 613-618

The linear initial-value problem of a partially mixed cylindrical wake in a uniformly stratified fluid is formulated and exact solutions are given for the density and velocity fields inside and just outside the original cylinder. An asymptotic expression for the far-field internal wave radiation is given and the corresponding solutions for a spherical wake geometry are noted. The treatment emphasizes the inadequacy of the usual linear Boussinesq approximation to describe the detailed nature of similar problems, in particular, the fully mixed wake-collapse problem.

Harvey, J. K.

"SOME OBSERVATIONS OF THE VORTEX BREAKDOWN PHENOMENON"

J. Fluid Mech., Vol. 14, Part 4, December 1962, pp. 585-592

This paper describes an experiment in which a cylindrical vortex, formed in a long tube, was used to study the 'vortex breakdown' that has been previously reported in investigations of the flow over slender delta wings. By varying the amount of swirl that was imparted to the fluid before it entered the tube, it was found that the breakdown was the intermediate stage between the two basic types of rotating flows, that is, those that do and those that do not exhibit axial velocity reversal. In addition, it was shown that an unusual flow pattern was established after the breakdown and that certain features of this pointed to it being a 'critical' phenomenon. The tests were concluded by measuring the swirl angle distribution a short distance ahead of the breakdown and comparing these results with the prediction of Squire's theory.

Harvey, J. K. and Fackrell, J. E.

"OBSERVATION OF A MECHANISM CAUSING A TRAILING VORTEX TO BREAK UP"

IC-AERO-70-08, December 1970, Imperial College, London, England.

Simple flow visualization experiments have been performed to identify a new form of vortex breakdown which is characterized by the disturbance appearing somewhere near the edge of the core and not on the vortex center line. There is a marked similarity between the disc observed and those seen in condensation trails. In the experiments a towing tank was used which enabled the vortices to

be studied within a frame of reference which was stationary with respect to the undisturbed fluid and so their total history could be observed.

Harvey, J. K. and Perry, F. J.

"FLOWFIELD PRODUCED BY TRAILING VORTICES IN THE VICINITY OF THE GROUND"

AIAA Journal, Vol. 9, No. 8, August 1971, pp. 1659-1660

Vortices have been noted to rise again after having descended close to the ground. To attempt to explain this phenomenon, a series of total-head surveys in planes across the flow were made in a wind tunnel with a single trailing vortex passing over a moving floor simulating the ground boundary condition. The vortex induces a cross flow on the floor with an attendant suction peak beneath the core. Consequently, the boundary layer resulting from the cross flow must negotiate an adverse pressure gradient once it has passed under the vortex. When the vortex is sufficiently near the ground, the pressure gradient is strong enough for separation to occur, and a bubble forms containing vorticity of opposite sense to the main vortex. Progressing downstream, the bubble detaches from the floor as a secondary vortex fed by a vortex sheet from the separation point. The subsequent motion of the two vortices is complicated but the secondary vortex can induce an upward velocity on the main vortex.

Harvey, J. K. and Steiner, T. R.

"DISPERSION IN THE WAKE OF AIRCRAFT: AN INVESTIGATION OF THE EFFECTS OF A GROUND PLANE ON TRAILING VORTICES: LITERATURE SURVEY"

IC-AERO-REP-86-04, June 1986, Imperial College of Science and Technology, London, England

Physical processes of trailing vortices are discussed, and the complexities and subtleties of aircraft wake flow are explored. A literature survey detects little work of direct relevance to the problem of dispersion of aircraft wake material, especially near the ground. However, problems and likely areas of useful research are identified.

Hasegawa, H., Matsuuchi, K. and Yamakami, J.

"THE MECHANISM OF ACTIVE BOUNDARY LAYER CONTROL USING VORTEX GENERATOR JETS"

ICAS-98-3.4.3, September 1998, Melbourne, Australia.

The vortex generator jet method is an active control of flow separation that can provide a time-varying control action to optimize performance under a wide range of flow conditions. Pitched and skewed jets issue into a free stream and the interaction between the jets and the free stream generates longitudinal (streamwise) vortices. The mechanism for suppressing flow separation was studied experimentally by making a comparison between two effects of steady and pulsed jets on generating longitudinal vortices. The suppression of flow separation is accomplished by the secondary flow of longitudinal vortices which transport high momentum fluid of the free stream to the lower wall.

However, if the vortex moves away from the lower wall, a counter-rotating vortex of nearly equal strength is induced, and thus an upwash region is produced by the effect of a vortex pair. The upwash makes ineffective the secondary flow toward the lower wall. Consequently, the boundary layer thickness is strongly distorted and is not uniform in the spanwise direction because streamwise velocity decreases near the outer edge of the boundary layer. Pulsed jets enhance the mixing process in comparison with steady jets and indicate effective separation control for the purpose of keeping the vortex near the lower wall.

Hashemabadi, H. K.

"AERODYNAMIC ANALYSIS OF HELICOPTER ROTOR USING FREE WAKE VORTEX LATTICE METHOD"

Journal of Faculty Engineering, , Vol. 40, Jan. 2007, pp. 895-906.

The accurate computation of helicopter rotor flow leads to an accurate calculation of rotor blade aerodynamic loads. The flow field around a rotor is difficult to model due to the presence of vortical wake. The complexity of the rotor flow field results from the effects of strong vortical wake and primary vortical structures that are convected away from the rotor disk at relatively low speeds. In the present work, a free wake vortex lattice method is used to accurately predict the vortical wake and blade loading of an isolated rotor in hover. In the vortex lattice method, the blades are modeled as flat plates with zero thickness and ring vortices are distributed on the surface of each blade. When the blades rotate, the vortices are shed into the wake and freely moved with a velocity induced by the effects of the vortices located on the blades and in the wake. The wake can freely deform over time to take its natural shape. The distribution of lift can be computed from the strength of each vortex on the blade. The aerodynamic analysis of a wing in oscillating motion for different reduced frequencies is performed to show the accuracy of the free wake vortex lattice method for unsteady calculations. Then, the aerodynamic calculations are performed for a hovering helicopter rotor for two operating conditions of subsonic and transonic tip Mach numbers (0.44, 0.88). To accurately compute the compressible flow case, the Prandtl-Glauert correction is applied to the Biot-Savart Law. The present calculations based on the free wake vortex lattice method are compared with available theoretical and experimental results. The effects of number of panels, vortex core radius, and computational time step on the aerodynamic results and wake structure are also studied. Finally, the capability of the free wake vortex lattice method for aerodynamic analysis of the rotor blades with twist is demonstrated.

"DEFINING VALID GEOMETRIC ALTITUDE ROUND 2: GEOMETRIC ALTITUDE VALIDITY FOR DO-317C"

DO-317C, RTCA, June 2019, RTCA, Washington, DC.

This working paper addresses an action from WG4 Meeting 314 to define valid geometric altitude . It also addresses actions taken from WG4 Teleconference on April 17th. The highlighted portions are what is being proposed to change.

Hastings, Jr., E. C. and Champine, R. A.

"RESULTS OF FULL-SCALE VORTEX ATTENUATION FLIGHT EXPERIMENTS"

Proceedings of the Fifth Annual Symposium of the Society of Flight Test Engineers, SFTE, 1974, pp. 4/26-4/46

Flight tests have been conducted to evaluate the effectiveness of a wing-tip vortex attenuating device called a spline. Vortex penetrations were made with a PA-28 behind a C-54 aircraft with and without wing-tip splines attached and the resultant rolling acceleration was measured and related to the roll acceleration capability of the PA-28.

"SIMULATED VORTEX ENCOUNTERS BY A TWIN-ENGINE COMMERCIAL TRANSPORT AIRCRAFT DURING FINAL APPROACH"

SAE Paper No. 800775, Cincinnati, OH, May 1980

Piloted simulations of encounters with vortices of various ages and degrees of attenuation were performed with the Visual Motion Simulator. In the simulations, a twin-engine, commercial transport on final approach encountered the modeled vortices of a four-engine, wide-body, commercial transport. The data in this report show the effect of vortex age and ground effect on the severity of the initial upset, as well as the effect of the vortex encounters on the landing capability.

Hastings, Jr., E. C. and Keyser, Jr., G. L.

"SIMULATOR STUDY OF VORTEX ENCOUNTERS BY A TWIN-ENGINE, COMMERCIAL, JET TRANSPORT AIRPLANE"

NASA TP-1966, February 1982, Langley Research Center, Hampton, V.

An investigation of vortex-induced upset and recovery characteristics was conducted by using a simulated twin-engine, commercial, jet transport airplane with fixed controls and with a conventional manual-control system. The piloted simulations were performed with the Langley Visual/Motion Simulator. Wake vortex encounters were simulated with the airplane in the final-approach configuration at altitudes between 76.2 m and 30.5 m. The investigation consisted of parametric studies of the effects of the lateral and vertical locations of the vortex center, vortex aging in and out of ground effect, approach speed of the simulated following airplane, lift coefficient of the vortex-generating airplane, and vortex attenuation by using the flight spoilers of the vortex-generating airplane. In addition, altitude-dependent bank angle and flight-path excursion criteria were used to evaluate the acceptability of the vortex-induced upsets.

Hastings, Jr., E. C., Holbrook, G. T. and Keyser, Jr., G. L.

"PRELIMINARY RESULTS OF SIMULATED VORTEX ENCOUNTERS BY A TWIN-ENGINE, COMMERCIAL AIRCRAFT DURING FINAL LANDING APPROACH"

NASA TM-81782, May 1980, Langley Research Center, Hampton, VA.

Piloted simulations of encounters with vortices of various ages and degrees of attenuation have been performed with the Visual Motion Simulator at the Langley Research Center. In the simulations, a twin-engine, commercial transport on final approach, encountered the modeled vortices of a four-engine, wide-body, commercial transport. Unattenuated vortices (in-and out-of-ground effect) and vortices attenuated by the spoilers of the generating aircraft were used in the simulations. The results show that the upset severity due to encounters with unattenuated vortices out-of-ground effect, decreased very little with vortex aging. The presence of ground effect, or the utilization of spoiler attenuation, had little effect on the upset severity for vortices near 45 seconds of age. The upset severity of the ground effect and 15-deg. spoiler vortex encounters however, diminished more rapidly as the vortices aged.

"DEVELOPMENT AND FLIGHT TESTS OF VORTEX ATTENUATING SPLINES"

NASA TN D-8083, November 1975, Langley Research Center, Hampton, VA

The report describes some of the ground test and full-scale flight test conducted by the Langley Research Center during development of the vortex-attenuating spline. The flight tests were conducted using a vortex generating aircraft with and without splines; a second aircraft was used to probe the vortices generated in both cases. The results showed that splines significantly reduced the vortex effects, but resulted in some noise and climb performance penalties on the generating aircraft.

Hastings, Jr., E. C., Shanks, R. E., Champine, R. A., Copeland, W. L., Latham, W. and Young, D. C.

"PRELIMINARY RESULTS OF FLIGHT TESTS OF VORTEX ATTENUATING SPLINES"

NASA TMX-71928, March 1974, NASA Langley Research Center, Hampton, VA

Flight tests have been conducted to evaluate the effectiveness of a wingtip vortex attenuating device, referred to as a spline. Vortex penetrations were made with a PA-28 behind a C-54 aircraft with and without wingtip splines attached and the resultant rolling acceleration was measured and related to the roll acceleration capability of the PA-28. Preliminary results indicate that the splines led to a significant reduction in the vortex induced roll acceleration experienced by the PA-28 probe aircraft.

Haussling, H. J.

"COMPUTATIONAL EXPERIMENTS ON THE TRACKING OF VORTICES; FINAL REPORT"

CARDIVNSWC TR-95/021, August 1995, Naval Surface Warfare Center, Carderock Division, Bethesda, MD

A general-purpose viscous flow code, DTNS3D, has been used to compute the strength and trajectories of an isolated vortex and a vortex pair. Analytic solutions and previous computations are used to judge the accuracy of the three-dimensional steady state results. It is possible to track, quite accurately, the decay and translation of these vortex structures. A byproduct of this study is some information on the limitations of the unsteady crossflow analogy and on the effect of axial velocity variations on vortex trajectories.

Haverdings, H.

"WAVENDA ALGORITHM AND PERFORMANCE TESTS"

CREDOS Report D2-2, February 2009, NLR, Amsterdam, The Netherlands.

A Wake Vortex Detection Algorithm (WAVENDA) was adapted for the detection of aircraft Wake Vortex Encounters (WVE) using Flight Data Recording (FDR) data. The algorithm is an improved, adapted version of an already existing algorithm NLR-VORTEX, developed by NLR, but has been made suitable to also process take-off data, and it has reduced false alert rate. Use has been made of discriminant analysis techniques to derive classification functions on Wake Vortex Encounter FDR data provided. This updated document (D2-2) gives both a detailed description of the algorithm as well as results on a performance test and an initial validation using simulated landing approach and take-off data on flights through a Wake Vortex as well as of an actual Wake Vortex Encounter that has occurred.

Haverdings, H.

"THE NLR-VORTEX ALGORITHM: DETECTION OF WAKE VORTEX ENCOUNTERS FROM FLIGHT DATA RECORDER DATA"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

In 1999 NLR began the development of an algorithm that allows wake vortex encounters to be detected from processing Flight Data Recorder (FDR) data. Initially, in cooperation with the National Air Traffic Services Ltd, from 1999 to 2000 the first part of the algorithm, the so-called WINDGRAD algorithm, was developed, which computes wind gradients from available inertial and aerodynamic data. Sophisticated data processing takes place to derive these quantities from basic FDR data. Among these are angle of attack calibrations performed on the data, computation of the sideslip angle from lateral accelerations, the application of Kalman filtering and smoothing to determine the inertial path (in 3D), and computation of a pseudo-vorticity, i.e. the rotation in the airflow through which the aircraft flew. For this process to be possible, estimates of the aircraft's stability derivatives were obtained from the same data set. Although the estimation process worked well, some values of derivatives are

questionable. In the S-wake project NLR developed the second part of the algorithm, the so-called VDC algorithm Vortex Detection and Classification. From the available wind gradients and other parameters (as a pre-cursor to the vorticity data) an initial detection logic was devised, assuming the data has a normal distribution. In this case signal-to-noise ratios were computed for several variables that were assumed to play a role in detecting the true occurrence of an encounter. Later NLR developed an alternative algorithm based on the use of the vorticity data. The NLR-VORTEX algorithm was applied to the Heathrow database built up in the S-Wake project. The final algorithm as it stands per 2002 works well and gave a wake vortex encounter alert for all those cases where, by visual inspection and through pilot reports, a valid encounter occurred in the Heathrow database. However, the NLR-VORTEX algorithm was sensitive to false alarms, in that it indicated more events to have occurred than really was the case. This relatively high false alarm rate was primarily due to lower-than-desired data quality, in terms of data dropouts, sampling rate, etc., and due to the use of non-validated values for aircraft's stability derivatives. This is evidenced by the fact that for the experimental test aircraft good results were obtained; from this aircraft all required data were known well. Future efforts will therefore focus on reducing the false alarm rate by introducing more filtering at the proper points in the algorithm as well as different kinds of standardization, and by replacing estimates of stability derivatives by values given by the airplane manufacturer (preferably per configuration, i.e. a function of flap setting, Mach, etc.).

"QUICK ACCESS RECORDER (QAR) DATA ANALYSIS SOFTWARE FOR STUDIES OF WINDSHEAR, TURBULENCE AND WAKE VORTEX"

NLR-TP-2010-435, April 2012, National Aerospace Laboratory, Amsterdam, The Netherlands.

For analysis of low-level windshear and turbulence events at the Hong Kong International Airport (HKIA), besides pilot reports routinely received from Air Traffic Control, Quick Access Recorder (QAR) data are obtained from the local airlines by the Hong Kong Observatory (HKO). Instead of using directly the wind data recorded on the aircraft by the flight management system, there has been a collaborative study between HKO and the National Aerospace Laboratory (NLR) in The Netherlands to develop a QAR data analysis software to calculate the meteorological quantities, such as the three components of the wind, windshear hazard factor, and turbulence intensity parameters, taking into account the aircraft's aerodynamic factors (e.g. sideslip angle, angle-of-attack). This paper describes the main features of the calculation software, named WINDSTURB, and illustrates its application to windshear and turbulence studies through selected cases at HKIA.

Haverdings, H. and Chan, P. W.

"QUICK ACCESS RECORDER (QAR) DATA ANALYSIS SOFTWARE FOR WINDSHEAR AND TURBULENCE STUDIES"

AIAA Paper 2009-3871, June 2009, San Antonio, Texas.

For analysis of low-level windshear and turbulence events at the Hong Kong International Airport (HKIA), besides pilot reports routinely received from Air Traffic Control, Quick Access Recorder (QAR) data are obtained from the local airlines by the Hong Kong Observatory (HKO). Instead of using directly the wind data recorded on the aircraft by the flight management system (FMS), there has been a collaborative study between HKO and the National Aerospace Laboratory (NLR) in The Netherlands to develop a QAR data analysis software to calculate the meteorological quantities, such as the three components of the wind, windshear hazard factor and turbulence intensity parameters, taking into account the aircraft's aerodynamic factors (e.g. sideslip angle, angle-of-attack). This paper describes the main features of the calculation software, named WINDSTURB, and illustrates its application to windshear and turbulence studies through selected cases at HKIA.

"ACTIVE AND PASSIVE VORTEX WAKE MITIGATION USING CONTROL SURFACES"

Aerospace Science and Tech., Vol. 9, 2005, pp. 5-18

Aircraft trailing vortices constitute a hazard to following aircraft and are therefore one of the main concerns for airport capacity constraints. At the Institute of Aerospace Engineering experiments on wake vortices are conducted in a towing tank using particle image velocimetry. The motivation behind the presented investigations is the alleviation of the rolling moment induced on following aircraft using control surfaces of the preceding aircraft. An unstable vortex system is generated using control surfaces. The instabilities lead to a mitigation of the vortex system. A variety of outboard flaps are used in preliminary studies to estimate the sizing and deflection of ailerons that lead to a vortex system with strong cooperative instabilities and thus to an alleviation of the rolling moment induced on following aircraft. In subsequent experiments a rectangular wing is equipped with preset ailerons, producing an unstable vortex system in its wake. The instabilities are excited by oscillating the ailerons. Each half-wing is equipped with two adjacent ailerons that oscillate in counter-phase in order to minimise fluctuations of the lift coefficient.

Haverkamp, S., Neuwerth, G. and Jacob, D.

"ACTIVE CONTROL OF AIRCRAFT VORTEX WAKES BY MEANS OF PRESET AILERONS"

AIAA Paper No. 2003-6823, Denver, CO, Nov. 2003

Aircraft trailing vortices constitute a hazard to following aircraft, and are therefore one of the main concerns for airport capacity constraints. At the Institute of Aerospace Engineering, experiments on wake vortices up to 50 spans behind the model of a rectangular wing are conducted in a towing tank. The motivation behind the presented experiments is the alleviation of the rolling moment induced on following aircraft by constructive means at wings and flaps of the preceding aircraft. It is shown that within 50 spans behind the wing a reduction of the induced rolling moment by approximately 50% can be achieved by an appropriate aileron preset alone. This is due to an increase of the effective vortex

size resulting from the counter-rotating vortex pairs produced by the ailerons. Oscillating the ailerons induces a sinusoidal perturbation of the vortices and accelerates the onset of rapid decay.

Haverkamp, S., Neuwerth, G. and Jacob, D.

"EXPERIMENTAL INVESTIGATION OF THE INFLUENCE OF WING GEOMETRY ON ITS WAKE IN A TOWING TANK"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

At the Institute of Aerospace Engineering experiments on wake vortices in the near far field up to 60 spans behind the model are conducted in a towing tank. The motivation behind the presented experiments is the alleviation of the induced rolling moment posed to following aircraft by constructive means at wings and flaps of the preceding aircraft. The influence of the geometry of outboard flap extensions on the wake of a rectangular wing is investigated. Towing tank experiments using Particle Image Velocimetry are conducted, and the induced rolling moment is calculated from the experimentally determined downwash. The idea is to trigger instabilities in the vortex wake by inserting counter-rotating secondary vortices. These secondary vortices are generated using outboard flap extensions of different shape. A significant reduction of the induced rolling moment by more than 50% can be achieved by inserting counter-rotating vortices into the wake.

Haverkamp, S., Neuwerth, G. and Jacob, D.

"STUDIES ON THE INFLUENCE OF OUTBOARD FLAPS ON THE VORTEX WAKE OF A RECTANGULAR WING"

Aerospace Science and Technology, Vol. 7, 2003, pp. 331-339

Aircraft trailing vortices constitute a hazard to following aircraft, and are therefore one of the main concerns for airport capacity constraints. At the Institute of Aerospace Engineering (ILR) experiments on wake vortices up to 60 spans behind the model of a rectangular wing are conducted in a towing tank. The motivation behind the presented experiments is the alleviation of the rolling moment induced on following aircraft by constructive means at wings and flaps of the preceding aircraft. Following the approach of Ortega et al., the influence of the geometry of outboard flap extensions on the wake of a rectangular wing is investigated. Towing tank experiments using Particle Image Velocimetry are conducted, and the induced rolling moment is calculated from the experimentally determined downwash. In addition, a stability analysis is performed for the experimentally investigated four-vortex configurations utilizing the linearized Biot-Savart law as proposed by Crow. It is assumed that the vortex system attunes to the most unstable eigenform. The theoretical results help giving an interpretation of the experimental data. It is shown that a significant reduction of the induced rolling moment by more than 50% can be achieved using outboard flap extensions. This is due to an increase of the effective vortex size resulting from the counter-rotating vortex pairs produced by the flaps.

Hawkes, J. W.

"A SIMPLE MODEL FOR THE VORTEX BREAKDOWN PHENOMENON"

M.S. Thesis, August 1969, Mass. Institute of Technology, Cambridge, MA

Previous experimental and theoretical investigations of vortex breakdown are reviewed. Considering past experimental results, a new model for the vortex breakdown is proposed. It is modelled as a transition from an upstream uniform vortex core to a downstream flow in which there exists a stagnant bubble on the axis. The conservation equations are applied across this transition under the constraint that the pressure jump in the breakdown be a maximum. Model results indicate that a pressure increase in the stagnant bubble of about 75% of the initial maximum swirl dynamic head is to be expected at swirl ratios comparable to those observed experimentally to involve a breakdown. Radii predicted for the breakdown bubbles are compared on a limited basis with experiments and reasonable agreement obtained.

Hay, G. C.

"FAA R&D OBJECTIVES REGARDING WAKE TURBULENCE"

FAA Symposium on Turbulence, Federal Aviation Administration, Washington, DC, March 1971, p. 26

The FAA breaks the wake vortices program into three parts, each being examined concurrently. One part is to eliminate or minimize the problem at its sources; NASA has been asked to pursue this effort. Second, real time detection and measurement concepts using present day technology is being examined; this includes system designs, the feasibility of a predictive system, and the identification of hazardous conditions. Third, in concert with the National Airspace System users, current operational procedures need to be updated.

Hayashi, H., Kodama, Y., Fukano, T. and Ikeda, M.

"RELATION BETWEEN WAKE VORTEX FORMATION AND DISCRETE FREQUENCY NOISE"

In: Separated and Complex Flows - 1995; Proceedings of the ASME/JSME Fluids Engineering and Laser Anemometry Conference and Exhibition, Hilton Head, SC, August 1995, pp. 107-114

The discrete frequency noise (DFN) generated by the wake vortex have been investigated for symmetrical NACA airfoils of three different thicknesses submerged in a uniform main flow. It was clarified that the airfoil thickness have influence on the flow characteristics of the near wake and the DFN in the case of low attack angles. The position of rolling up of the wake vortex was far from the trailing edge, the vortices did not have a strong effect on the flow around the airfoil. However, when rolling up took place in the vicinity of the airfoil, the interaction between the wake vortices and the surface flow was strong. The shear layers near the trailing edge were swinging with rolling up of the wake vortex and the DFN was generated by the pressure fluctuation with this swinging shear layer.

Hayashi, H., Sasaki, S., Kodama, Y. and Fukano, T.

"STUDY OF 3-DIMENSIONAL COHERENT STRUCTURE OF WAKE VORTICES AND AEROACOUSTIC SOURCE"

AIAA Paper No. 2000-1974, Lahaina, HI, June 2000

The coherent structure of the wake of a body was investigated to clarify the mechanism of aeolian tone from an isolated blade immersed in a uniform flow field. In the Reynolds number transition region, the sound power of the aeolian tone from an isolated blade is proportional to the sixth power of the main flow velocity; it is then well known that the sound is closely related to the wake characteristics. It was found that the Karman vortices shed from a symmetrical NACA blade have a multiple cell structure, whose phase is shifted at each span position. The authors propose a new correlation coefficient which considers the coherence function and the phase difference, and which was used to estimate the statistical length within which a pair of Karman vortices is shed. In an experiment on an isolated blade with bluff trailing edge, it was found that the span direction velocity fluctuation is an important parameter for relaxing the regulation of the wake vortex, and an empirical relationship between the correlation length and the velocity fluctuation is proposed. These phenomena were also verified by a 3-D numerical simulation. Lastly, prediction of the discrete frequency noise level by using this correlation length indicates ± 3 dB accuracy.

"EVALUATING THE RATIONALE FOR FOLDING WING TIPS COMPARING THE EXERGY AND BREGUET APPROACHES"

AIAA Paper 2017-0464, January 2017, Grapevine, TX.

The design and development processes for future aircraft aims to address the environmental and efficiency challenges needed to facilitate the engineering of concepts that are far more integrated and require a multidisciplinary approach. This study investigates the benefit of incorporating span extension wing tips onto future aircraft configurations as a method of providing improved aerodynamic efficiency, whilst allowing the extension to fold on the ground to meet airport gate size constraints. Although the actuated wing tips are not studied in detail, the focus of this study is to compare two different methods of analysis that can be used to identify the benefit and limitations of adding such devices. The two methods considered are a quasi-steady implicit energy analysis based on the Breguet Range Equation and an explicit energy analysis based on the first and second laws of thermodynamics known as Exergy Analysis. It has been found that both methods provide agreeable results and have individual merits. The Breguet Range Equation can provide quick results in early design, whilst the Energy Analysis has been found to be far more extensive and allows the complete dynamic behavior of the aircraft to be assessed through a single metric. Hence, allowing comparison of losses from multiple subsystems.

He, A. and Zheng, Z. C.

"AERODYNAMIC SIMULATION OF WAKE ENCOUNTER FOR AIRCRAFT CLOSE FORMATION OPERATIONS"

AIAA Paper 2015-3319, June 2015, Dallas, TX.

In this study, the rolling moment coefficient of a following unmanned aerial vehicle (UAV) induced by wake vortices from a leading UAV is analyzed and studied. Numerical simulation results are compared to the results from an analytical vortex lattice method. Then a complete UAV mesh is built and used to calculate the influence by a pair of wake vortices created by the leading UAV in real flight scenario. The paper provides an estimate of the vortex roll hazard assessment for the following UAV in close formation operations.

He, A., Tian, P., Zheng, Z. C., Chao, H. and Gu, Y.

"A STUDY ON UAS WAKE TURBULENCE ENCOUNTER USING COUPLED AERODYNAMICS AND FLIGHT DYNAMICS SIMULATION"

AIAA Paper 2016-3439, June 2016, Washington, DC.

In this paper, a new UAS wake encounter simulation platform with coupled modeling of aerodynamics and flight dynamics is presented. Two wake encounter scenarios with different lateral encounter angles are investigated as the examples. The influence of wake encounters on the follower aircraft during the cutting through is simulated and further discussed. In the 90-degree lateral encounter case, the unmanned aircraft can still go back to steady state after experiencing vortex wake disturbances without any controller compensation. However, vortex wakes generate observable rolling for the follower UAV undergoing a 30-degree lateral encountering angle. Results show that the wake encounter can cause significant influences to the follower aircraft.

He, C. and Zhao, J.

"MODELING ROTOR WAKE DYNAMICS WITH VISCOUS VORTEX PARTICLE METHOD"

AIAA Paper No. 2008-339, Reno, NV, January 2008

Rotor induced flow modeling and prediction has been one of the central issues for rotorcraft performance, control, and stability, and loads and vibration analysis for decades. Traditional singularity methods used in most of current comprehensive rotorcraft analysis codes are limited by the potential flow assumption and thus must rely on empirical formulation (e.g., vortex core size, etc.) for the solution. This paper discusses the development of a viscous vortex particle model for modeling the complicated rotor wake vorticity transportation and diffusion. Instead of solving the viscous vorticity equations through numerical discretization over the flow field grid, the vortex particle method addresses the solution via Lagrangian formulation where there is no artificial numerical dissipation involved. The Lagrangian approach also allows the application of hierarchical TreeCode and Fast Multipole Method that can dramatically improve the computational efficiency for the vortex particle method for practical and comprehensive rotorcraft analysis.

He, C. and Zhao, J.

"MODELING ROTOR WAKE DYNAMICS WITH VISCOUS VORTEX PARTICLE METHOD"

AIAA Journal, Vol. 47, No. 4, April 2009, pp. 902-915.

Rotor-induced-flow modeling and prediction has been one of the central issues for rotorcraft performance, control, stability, loads, and vibration analysis for decades. Traditional singularity-based methods used in most current comprehensive rotorcraft analysis codes are limited by the potential flow assumption and thus must rely on empirical formulations (e.g., vortex decay factor, vortex core size, etc.) to reach a solution. This paper discusses the development and validation of a viscous vortex particle model for modeling the complicated rotor wake vorticity transportation and diffusion. Instead of solving the viscous vorticity equations through numerical discretization over the flow field grid, the vortex particle method addresses the solution through a Lagrangian formulation in which there is no artificial numerical dissipation involved. The Lagrangian approach also allows the application of the hierarchical TreeCode and the fast multipole method. These methods can dramatically improve the computational efficiency of the viscous vortex particle simulation, which enables it to be used for practical and comprehensive rotorcraft analysis.

"STUDY ON EXPERIMENTS FOR SUPPRESSING WINGTIP VORTICES WITH PLASMA"

Engineering Mechanics, Vol. 30, No. 5, May 2013, pp. 277-281.

The wind tunnel experiment on suppressing wingtip vortices (WTV) through adding energy with DBD plasma has been conducted in the paper. The WTV flow field of a swept wing has been visualized by PIV and the aerodynamic forces of a rectangular wing have been measured, in the condition of using three different kinds of plasma actuators respectively. The results show that the WTV may be suppressed and the separation on the upper wingtip surface may be delayed because the energy of the vortex induced by the plasma (VIP) is added into the flow field, which increases the lift and the ratio of lift to drag at a small angle of attack (AOA) effectively. Even at large AOA, the effect of plasma still appears. The effects are related to the structures of the plasma actuators. It can obtain better results to suppress the WTV through optimizing the design of the plasma actuators and choosing the appropriate placement to install the actuators on wingtip surface. [In Chinese.]

"TURBULENCE DISSIPATION PROCESSES OF 2-D AND 3-D VORTICES IN NUMERICAL SIMULATIONS"

AIAA Paper No. 1989-0610, Reno, NV, January 1989

Using the spectral method, the three-dimensional time-dependent Navier-Stokes equations were solved for various initial vortex structures. The significant difference in lifetimes between the three-dimensional and the two-dimensional vortices indicates that the instability of two-dimensional flow is not enough to explain the turbulence development process. Analysis shows that (1) the transfer of kinetic energy from the large vortex to the smaller ones is active in the braid region of the large vortex, and (2) the transfer is mainly through the interaction with neighboring vortex sectors which have different orientation in space. This mechanism is supported by experimental observations.

Heaslet, M. A. and Lomax, H.

"THE CALCULATION OF DOWNWASH BEHIND SUPERSONIC WINGS WITH AN APPLICATION TO TRIANGULAR PLAN FORMS"

NACA Technical Note No. 1620, June 1948, Ames Aeronautical Lab., Moffett Field, CA.

A method is developed consistent with the assumptions of small perturbation theory, which provides a means of determining the downwash behind a wing in supersonic flow for a known load distribution. The analysis is based upon the use of supersonic doublets which are distributed over the plan form and wake of the wing in a manner determined from the wing loading. The first application of the method proves the equivalence in subsonic and supersonic flow of the downwash at infinity corresponding to a given load distribution. The principal application in this report is concerned with the downwash behind a triangular wing with leading edges swept back of the Mach cone from the vertex. A complete solution is given along the center line of the wake and an approximation provided for points in the vicinity of this line.

Heaton, C. J.

"OPTIMAL GROWTH OF THE BATCHELOR VORTEX VISCOUS MODES"

J. Fluid Mech., Vol. 592, 2007, pp. 495-505

We present calculations of optimal linear growth in the Batchelor (or q) vortex. The level of transient growth is used to quantify the effect of the viscous center modes found at large Reynolds number and large swirl. The viscous modes compete with inviscid-type transients, which are seen to provide faster growth at short times. Following a smooth transition, the viscous modes emerge as dominant in a different regime at later times. A comparison is drawn with two-dimensional shear flows, such as boundary layers, in which weak instability modes (Tollmien-Schlichting waves) also compete with inviscid transients (streamwise streaks). We find the competition to be more evenly balanced in the Batchelor vortex, because the inviscid transients are damped faster in a swirling jet than a two-dimensional shear flow, so that despite their weak growth rates the viscous modes may be relevant in some situations.

Heaton, C. J. and Peake, N.

"TRANSIENT GROWTH IN VORTICES WITH AXIAL FLOW"

J. Fluid Mech., Vol. 587, 2007, pp. 271-301

We investigate transient growth in high-Reynolds-number vortices with axial flow. Many cases of vortex instability are not fully explained by strong exponential instability modes, and transient growth could offer an alternative route to breakdown in such cases. Strong transient growth is found, in agreement with previous studies. We first discuss the problem by reference to ducted vortices which

model aeroengine flow. The transient growth is inviscid in character, and in this paper, we specifically interpret it as an effect of the inviscid continuous spectrum. The relevant inviscid theory explains new scalings which we find for the transient growth, which are generalizations of the quadratic scaling seen previously in two-dimensional flows and non-swirling pipe flows. We then turn to a second case, of interest for vortex breakdown, the Batchelor vortex, and present calculations of the transient growth. Large growth is possible, especially for the helical modes (with azimuthal wavenumber). The general trends are complicated by several issues, including a long-wavelength effect and a resonance effect, both of which were recently discovered for a vortex without axial flow and are found here to be present in the Batchelor vortex also. Overall, the results suggest that strong transient effects are present in the moderate- to high-swirl regime of practical interest. For axisymmetric and higher modes, however, transient effects are not found to be significant.

Heaton, C. J., Nichols, J. W. and Schmid, P. J.

"GLOBAL LINEAR STABILITY OF THE NON-PARALLEL BATCHELOR VORTEX"

Journal of Fluid Mechanics, Vol. 629, 2009, pp. 139-160.

Linear stability of the non-parallel Batchelor vortex is studied using global modes. This family of swirling wakes and jets has been extensively studied under the parallel-flow approximation, and in this paper we extend to more realistic non-parallel base flows. Our base flow is obtained as an exact steady solution of the Navier-Stokes equations by direct numerical simulation (with imposed axisymmetry to damp all instabilities). Global stability modes are computed by numerical simulation of the linearized equations, using the implicitly restarted Arnoldi method, and we discuss fully the numerical and convergence issues encountered. Emphasis is placed on exploring the general structure of the global spectrum, and in particular the correspondence between global modes and local absolute modes which is anticipated by weakly non-parallel asymptotic theory. We believe that our computed global modes for a weakly non-parallel vortex are the first to display this correspondence with local absolute modes. Superpositions of global modes are also studied, allowing an investigation of the amplifier dynamics of this unstable flow. For an illustrative case we find global non-modal transient growth via a convective mechanism. Generally, amplifier dynamics, via convective growth, are prevalent over short time intervals, and resonator dynamics, via global mode growth, become prevalent at later times.

Hecht, A. M., Bilanin, A. J. and Hirsh, J. E.

"TURBULENT TRAILING VORTICES IN STRATIFIED FLUIDS"

AIAA Journal, Vol. 19, No. 6, June 1981, pp. 691-698

The effects of stable atmospheric-density stratification, vortex core size, and turbulent scale on the descent of aircraft-trailing vortices are investigated using numerical solutions of a second-order closure turbulent model. A B-747 vortex descent is simulated numerically and compared to reported measurements of descent distance, velocity, and circulation profiles. It is concluded that the pair was halted in its descent by a diffuse region of countersign vorticity primarily outboard and above the

vortex cores. It is shown that the core size and turbulent macroscale have significant effects on vortex behavior through their influence on turbulence production, diffusion, and dissipation.

Hecht, A. M., Bilanin, A. J., Hirsh, J. E. and Snedeker, R. S.

"INVESTIGATION OF STABLE ATMOSPHERIC STRATIFICATION EFFECT ON THE DYNAMICS OF DESCENDING VORTEX PAIRS"

FAA-RD-79-4, February 1979, Aeronautical Research Assoc. of Princeton, Princeton, NJ

The physics of vortex flows in stratified fluids is studied with the objective of determining the influence of stable stratification on the descent of aircraft vortex pairs. Vortex rings descending into linear and discontinuous density stratifications are investigated experimentally and simulated numerically. The computer code used for this is based on a second-order closure turbulence model of the Reynolds stress equations in axisymmetric coordinates. Verification of the code is provided by the agreement found between the measured and calculated results. The two-dimensional version of the code is then used to simulate a measured Boeing-747 vortex descending in stable stratification. The strength and tightness of the measured vortex cores have necessitated development of a new method of numerically calculating strong vortex flows. The comparison of measured with calculated descent velocity, descent distance, swirl velocity, and circulation in the vortex agree. It is concluded that turbulence effects must be accounted for in the study of aircraft vortex behavior. It is found that unalleviated vortices remain strong during descent, that the vortices stop descending due to a diffuse region of countersign vorticity outboard and above the cores, and that core separation does not primarily control descent.

"TURBULENT VORTICES IN STRATIFIED FLUIDS"

AIAA Journal, Vol. 18, No. 7, July 1980, pp. 738-746

The effects of density stratification and turbulence on the behavior of vortex rings and vortex pairs is investigated. The results of a vortex ring experiment, in which rings were injected into linear and discontinuous density stratifications, are compared with calculations of ring behavior made using an axisymmetric, unsteady solution of the mean variable and the modeled Reynolds stress equations. Second-order closure of the equations is based upon the invariant modeling technique of Donaldson. Comparisons are made for ring trajectories, radius, and size of the recirculation cell carried along with the ring. Calculations of turbulent vortex pairs descending into a stably stratified atmosphere are presented. The vortex separation for the two-dimensional calculation is found to be very nearly constant with vortex pair descent, while both the experimental and numerical results for vortex rings give a sharply decreasing radius during descent.

Hedenstrom, A.

"VORTEX WAKES OF BIRD FLIGHT: OLD THEORY, NEW DATA AND FUTURE PROSPECTS"

WIT Transactions on State of the Art in Science and Engineering, Vol. 4, 2006, pp. 706-734.

Flying birds leave a vortex wake. Fluid dynamic theory in the form of Helmholtz' theorems dictate the allowable topologies, and Kelvin's circulation theorem requires that changes in wake circulation are directly proportional to force changes on the wing/airfoil that generated the wake. Much bird flight research has therefore been focused on the properties of trailing wake vortices behind birds, since an accurate quantitative description of these will reveal also the aerodynamics of bird wings. The first vortex theory of bird flight assumed the periodic shedding of discrete vortex loops, each one generated during a downstroke, while the upstroke was considered aerodynamically functionless. This view received some support from early visualization experiments of take-off flight or very low speeds, while experiments at a higher speed ($U = 7$ m/s) in one species showed undulating wing-tip vortices of similar circulation on both down and upstroke. The necessary force asymmetry between downstroke and upstroke was obtained by wing flexing during the upstroke. Then followed an almost 20-year drought, with no further quantitative experiments, until recently when digital particle imaging velocimetry (DPIV) was successfully deployed in a low-turbulence wind tunnel, and where the same small (30 g) bird could be studied across a large range of flight speeds (4-11 m/s). These new experiments revealed a much more complicated wake pattern than previous data suggested, mainly due to the improved experimental resolution. The bird generated structures most closely resembling vortex loops at slow speeds, which gradually transformed into something like a constant circulation wake at the highest speeds. However, the wakes were never as clean as the idealized cartoon models of the vortex theory of bird flight, and previous paradoxical results were shown to be attributable to the resulting difficulty in accounting for all wake components. New DPIV data on other species indicate that these findings are quite general.

"BAT FLIGHT GENERATES COMPLEX AERODYNAMIC TRACKS"

Science, Vol. 316, May 2007, pp. 894-898

The flapping flight of animals generates an aerodynamic footprint as a time-varying vortex wake in which the rate of momentum change represents the aerodynamic force. We showed that the wakes of a small bat species differ from those of birds in some important respects. In our bats, each wing generated its own vortex loop. Also, at moderate and high flight speeds, the circulation on the outer (hand) wing and the arm wing differed in sign during the upstroke, resulting in negative lift on the hand wing and positive lift on the arm wing. Our interpretations of the unsteady aerodynamic performance and function of membranous-winged, flapping flight should change modeling strategies for the study of equivalent natural and engineered flying devices.

Hedman, S. G.

"COMPUTATION OF VORTEX MODELS FOR WINGS AT HIGH ANGLE OF ATTACK IN INCOMPRESSIBLE FLOW"

FFA-AU-653, February 1973, Aeronautical Research Inst. of Sweden, Stockholm, Sweden

The vortex lattice method is applied in the solution of the thin wing lifting problem. The strength of the horseshoe vortices and a set of trailing vortex definition points are computed. The flow is required to be tangential at several collocation points on the wing and on the trailing vortices. This is expressed in a system of equations. It is shown how the system can be solved in two ways. In the first the system is partitioned into two subsystems, one where the boundary conditions of the wing are used for the determination of the vortex strengths, and one where the boundary conditions of the free vortices determine the positions of the vortices. In the second method the whole system is solved simultaneously by means of Newton-Raphson's rule.

Heffernan, K. G.

"TRAILING VORTEX ATTENUATION DEVICES"

M.S. Thesis, June 1985, Naval Postgraduate School, Monterey, CA

Trailing vortices generated by large aircraft pose a serious hazard to other planes. Numerous studies have been carried out to destroy them either before and/or after their formation. The present investigation is a survey and critical assessment of all the known active/passive devices and wingtip modifications proposed to achieve vortex attenuation. It is concluded that some devices, such as the wing tip sails, have promise in affecting the vortex roll-up in the vicinity of the aircraft. However, more data and analysis on this and other devices are needed before they can be incorporated into existing aircraft or future designs.

Heil, R. M.

"CHARACTERIZING THE WAKE VORTEX SIGNATURE FOR AN ACTIVE LINE OF SIGHT REMOTE SENSOR"

MS Thesis, August 1994, Clemson University, Clemson, SC.

A recurring phenomenon, described as a wake vortex, develops as an aircraft approaches the runway to land. As the aircraft moves along the runway, each of the wing tips generates a spiraling and expanding cone of air. During the lifetime of this turbulent event, conditions exist over the runway which can be hazardous to following aircraft, particularly when a small aircraft is following a large aircraft. Left to themselves, these twin vortex patterns will converge toward each other near the center of the runway, harmlessly dissipating through interaction with each other or by contact with the ground. Unfortunately, the time necessary to disperse the vortex is often not predictable, and at busy airports can severely impact terminal area productivity. Rudimentary methods of avoidance are in place. Generally, time delays between landing aircraft are based on what is required to protect a small aircraft. Existing ambient wind conditions can complicate the situation. Reliable detection and tracking of a wake vortex hazard is a major technical problem which can significantly impact runway

productivity. Landing minimums could be determined based on the actual hazard rather than imposed based on a worst-case scenario. This work focuses on using a wind field description of a wake vortex to generate line-of-sight Doppler velocity truth data appropriate to an arbitrarily located active sensor such as a high-resolution radar or lidar. The goal is to isolate a range Doppler signature of the vortex phenomenon that can be used to improve detection. Results are presented on use of a simplified model of a wake vortex pattern. However, the method of analysis can easily be applied to any vortex model used to generate a wind field snapshot. Results involving several scan strategies are shown for a point sensor with a range resolution of 1 to 4 meters. Vortex signatures presented appear to offer potential for detection and tracking.

"ON INSTABILITY CHARACTERISTICS OF ISOLATED VORTICES AND MODELS OF TRAILING-VORTEX SYSTEMS"

Computers & Fluids, Vol. 33, 2004, pp. 741-753

This paper demonstrates the applicability of a two-dimensional eigenvalue problem approach to the study of linear instability of analytically constructed and numerically calculated models of trailing-vortex systems. Chebyshev collocation is used in the 2D eigenvalue problem solution to discretize two spatial directions on which non-axisymmetric vorticity distributions are defined, while the third, axial spatial direction is taken to be homogeneous and is resolved by a Fourier expansion. The leading eigenvalues of the matrix discretizing the equations which govern small-amplitude perturbations superimposed upon such a vorticity distribution are obtained by Arnoldi iteration. The present approach has been validated by comparison of its results on the problem of instability of an isolated Batchelor vortex. Here benchmark computations exist, employing classic instability analysis, in which the azimuthal direction is also treated as homogeneous. Subsequently, the proposed methodology has been shown to be able to recover the classic long- (Crow) and short-wavelength instabilities of a counter-rotating vortex-pair basic flow obtained by direct numerical simulation. Finally, the effect on the eigen-spectrum of the isolated Batchelor vortex is documented, when the basic flow consists of a linear superposition of such vortices. The modifications of the eigen-spectrum of a single vortex point to the potential pitfalls of drawing conclusions on the instability characteristics of a trailing-vortex system by monitoring the constituent vortices in isolation.

"APPLICATION OF THREE-COMPONENT PIV TO A HOVERING ROTOR WAKE"

American Helicopter Society, 56th Annual Forum, May 2000, Virginia Beach, VA.

Three-component velocity measurements in the wake of a two-bladed rotor in hover were made using the Particle Image Velocimetry 'PIV' technique. The velocity fields were oriented in a plane normal to the rotor disk and were acquired for wake ages ranging from 0 to 270 degrees for one rotor thrust condition. The experimental setup and processing of the instantaneous images are discussed. Data averaging schemes are demonstrated to mitigate the smearing effects of vortex wander. The effect of vortex wander on the measured vortex core size is presented.

Heinrich, R.

"NUMERICAL SIMULATION OF WAKE-VORTEX ENCOUNTERS USING THE CHIMERA-TECHNIQUE"

In New Results in Numerical and Experimental Fluid Mechanics III, Notes on Numerical Fluid Mechanics, Vol. 77, Eds. Wagner, et al., Springer-Verlag, Berlin Heidelberg, 2002, pp. 74-81.

Within the EU-project WAVENC the block structured DLR-FLOWer code has been applied to the inviscid simulation of a wake vortex encounter of a generic aircraft. The incoming vortices of the preceding aircraft are prescribed at the inflow boundary of the computational domain. This allows to capture a mutual interaction between aircraft and incoming vortices. To transport the vortices without too big numerical losses from the inflow boundary to the aircraft, very fine Cartesian grids, so 'called vortex transport meshes', have been embedded into the grid structure. This is enabled by the Chimera technique implemented in the code. One main advantage of this strategy is, that no remeshing is

needed to perform a parametric study of the aircrafts position relative to the incoming vortices. Global forces and moments as well as pressure distributions obtained for different positions of the aircraft in the vortex disturbed flowfield show a good agreement to experimental data.

Heinrichs, R. M.

"WAKE VORTEX MEASUREMENTS WITH A CW 10.6-MICRON COHERENT LASER RADAR"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 235-246

CW coherent laser radar provides detailed vortex measurements at ranges less than or equal to 400 m. Lincoln Laboratory has collected simultaneous wake vortex and meteorological data at Memphis for validation of vortex behavior models. Vortex range estimated from the angular integral of velocity spectra versus velocity compare well with wind-line data. Vortex circulation is estimated from spectral maximum velocities. Circulations (especially of smaller aircraft) can be biased due to flow from neighboring vortex. Results agree well with theory when the bias is considered.

Heinrichs, R. M.

"OVERVIEW OF WAKE VORTEX DATA COLLECTION AND ANALYSIS AT MEMPHIS, JFK, AND DFW AIRPORTS"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Quebec, Canada, pp. 109-11.

Lincoln Laboratory has constructed and fielded a CW-coherent laser radar at the Memphis International Airport during November-December, and August, 1995, and more recently at Dallas/Ft. Worth in September, 1997. Wake vortex data were collected during these periods from a variety of aircraft, accompanied by simultaneous measurements of local meteorological conditions. These data have been used to correlate vortex behavior with local atmospheric parameters, such as winds, turbulence, and atmospheric stability. This presentation discusses the lidar configuration and data collection process. The basic configuration of the lidar and its performance capabilities are presented. The active vortex tracking capability of the lidar is also detailed along with algorithms developed for estimating vortex position and strength from lidar spectral data. Examples from the Memphis data set will be presented which demonstrate vortex behavior under various circumstances, such as out-of-ground effect and in-ground effect conditions.

Heinrichs, R. M. and Dasey, T. J.

"ANALYSIS OF CIRCULATION DATA FROM A WAKE VORTEX LIDAR"

AIAA Paper No. 1997-0059, Reno, NV, January 1997

The following paper presents the rationale and procedures used to estimate wake vortex circulation from data collected by a continuous-wave, 10.6-micron, coherent laser radar as well as selected results. These data have been collected during fielding at Memphis, TN in December 1994 and August 1995. Since the lidar measures line-of-sight (LOS) velocities, there is the potential for a bias of the circulation estimate of a vortex due to the velocity field of the neighboring, counter-rotating, vortex. An analytical expression is developed for the size of this effect for the case of the lidar looking straight up at a pair of vortices and a numerical model is developed for the case of the lidar observing a pair of equal altitude vortices at an arbitrary angle. The impact on LOS velocity determination from the spectral spreading of the lidar is also considered and an algorithm is developed which attempts to compensate for this effect. Comparisons of the averaged estimated vortex circulation for various individual aircraft are made with the initial theoretical circulation. Initial vortex circulations estimated from larger sets of aircraft measurements are also compared with theoretical expectations. As an independent confirmation of the circulation estimation procedure, 'virtual' lidar scans are numerically performed across vortex velocity fields generated from NASA computational models and the circulation estimates are compared with the actual circulations of the velocity field data. Finally, as an example of how the vortex circulation results can be analyzed, normalized circulation data is compared with the predictions from a model which accounts for atmospheric density profiles.

"MEASUREMENTS OF AIRCRAFT WAKE VORTICES AT MEMPHIS INTERNATIONAL AIRPORT WITH A CW CO₂ COHERENT LASER RADAR"

SPIE Paper No. SPIE-2737-20, Orlando, FL, April 1996

A CW-coherent laser radar using a 20-Watt CO₂ laser has been constructed and deployed for the measurement of wake-vortex turbulence. This effort is part of the NASA Terminal Area Productivity Program and has the goal of providing information to further the understanding of the motion and decay of wake vortices as influenced by the local atmospheric conditions. To meet this goal, vortex measurements are made with the lidar along with simultaneous measurements from a suite of meteorological sensors which include a 150' instrumented tower, a profiler/RASS, sodar and balloon soundings. The information collected also includes airline flight data and beacon data. The operation of the lidar during two field deployments at Memphis International Airport are described as well as examples of vortex motion and decay measurements in various atmospheric conditions.

"LASER SYSTEMS FOR CHARACTERIZATION AND MONITORING OF WAKE VORTICES"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 40-1 - 40-12

Adequate characterization of wake vortices by high-resolution (e.g., 30 cm downrange resolution), noninvasive, measurements in conjunction with measurements of local atmospheric conditions has been a long-standing requirement for operationally oriented studies. We describe a system to provide these high-resolution measurements based on a mode-locked, cavity-dumped, CO₂ laser. This system offers the capability of 1' x 1' spatial resolution along with 0.5 m/sec velocity resolution of a vortex. Such a system would also be able to extend the coherent integration time to measure velocities down to 5 - 10 cm/sec, thus enabling a measurement of the velocity turbulence in the ambient air towards which a vortex is heading. This measurement capability would provide input regarding the vortex structure and surrounding velocity turbulence for detailed modelling of vortex dynamics. Wake vortex monitoring as part of an advisory system can be accomplished with a coarser resolution than for characterization. For this application, long-term reliability and overall system cost are key issues. We suggest a system based on a diode-pumped cw solid-state laser at 2.1 microns because of its advantages of smaller optical aperture size, greater reliability, and lower cost over a CO₂ laser-based system. A set of these laser radars would be located beneath the glideslope to measure the average circulation and location of vortices at operationally relevant spatial scales. A point design based on existing solid-state laser technology is described.

"DEVELOPMENT AND PERFORMANCE OF A CW COHERENT LASER RADAR FOR DETECTING WAKE VORTICES"

Conference on Coherent Laser Radar, OSA, Keystone, CO, July 1995

A CW-coherent laser radar using a 20-Watt CO₂ laser has been constructed and deployed for the measurement of wake-vortex turbulence. This is part of a larger effort to understand the motion and decay of wake vortices as a function of local atmospheric conditions. The construction and operation of the lidar and the initial fielding at Memphis International Airport are described.

Heinrichs, R. M., Libby, J. C. and Dasey, T. J.

"WAKE VORTEX MEASUREMENTS WITH A CW COHERENT LASER RADAR OF THE XV-15 TILTROTOR AIRCRAFT"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Lincoln Laboratory, in coordination with Bell Helicopter Textron, has conducted measurements of the wake vortex characteristics of the XV-15 tiltrotor aircraft. Vortices generated in different forward flight configurations were detected and tracked by our mobile continuous-wave coherent CO₂ laser radar. This is the first time the wake of a tiltrotor aircraft has been measured using laser radar. The CW coherent laser radar was developed as part of the NASA AVOSS program. It has been employed over several measurement campaigns to collect wake-vortex data from fixed-wing landing aircraft while simultaneous measurements were performed to characterize the atmospheric state. The laser radar is

described along with examples of wake-vortex measurements of landing fixed-wing aircraft under the AVOSS program. Measurements made in August 2000 at the Bell Helicopter Test Flight Facility in Arlington, Texas are presented, along with an analysis of the vortex data.

"REALTIME-SIMULATION OF AIRCRAFT BEHAVIOUR IN WAKE VORTICES WITH RESPECT TO FLIGHT SAFETY"

Proceedings 19th ICAS Congress, Anaheim, CA, September 18-19, 1994, AIAA, Vol. 1, pp. 529-540

Interactions between an aircraft and the vortex flow shed by another aircraft are presently explored by means of a real-time-capable vortex model; the aircraft simulation employed in this effort uses an aerodynamic lifting surface/lifting-line algorithm to determine vortex-induced forces and moments exerted on the aircraft that encounters the vortex. Attention is given to the vortex angle, the wingspan of the encountering aircraft relative to the vortex-core extension, and the weight and size of both the encountering and the generating aircraft.

"THE COMPRESSIBLE VORTEX PAIR"

J. Fluid Mechanics, Vol. 220, 1990, pp. 339-354.

A numerical solution for the flow field associated with a compressible pair of counter-rotating vortices is developed. The compressible, two-dimensional potential equation is solved utilizing the numerical method of Osher et al for flow regions in which a non-zero density exists. Close to the vortex centers, vacuum 'cores' develop owing to the existence of a maximum achievable flow speed in a compressible flow field. A special treatment is required to represent these vacuum cores. Typical streamline patterns and core boundaries are obtained for upstream Mach numbers as high as 0.3, and the formation of weak shocks is observed.

Helmis, C. G., Kalogiros, J. A., Asimakopoulos, D. N. and Soilemes, A. T.

"ESTIMATION OF POTENTIAL-TEMPERATURE GRADIENT IN TURBULENT STABLE LAYERS USING ACOUSTIC SOUNDER MEASUREMENTS"

Quarterly Journal of the Royal Meteorological Society, Vol. 126, 2000, pp. 31-61.

The intensity of acoustic backscatter from a monostatic acoustic sounder is used to compute the profile of the temperature structure parameter $C_{\text{sub}} T^2$. The average value of $C_{\text{sub}} T^2$ in low-height turbulent stable layers (temperature inversions) is used to infer the local potential-temperature gradient. The estimates of temperature jump in the first height inversion at the top of the unstable atmospheric boundary layer (ABL) are compared with the direct measurements of the temperature profile by a tethered balloon, and the indirect estimation from the wave period of the

waves present on the inversion. The agreement of the estimations with the direct measurements is satisfactory (at least a 0.4 deg C accuracy). Also, the $-4/3$ similarity law of the $C_{sub T}$ squared profile in the unstable ABL is used to obtain estimates of the surface heat flux, $Q_{sub 0}$. The comparison of these estimates of $Q_{sub 0}$ with eddy correlation measurements shows the high accuracy of this method. This direct connection of the $C_{sub T}$ squared profile with $Q_{sub 0}$ can also be used to calibrate the backscatter intensity.

"TIME-BASED ARRIVAL MANAGEMENT FOR DUAL THRESHOLD OPERATION AND CONTINUOUS DESCENT APPROACHES"

Eighth USA/Europe Air Traffic Management Research and Development Seminar (ATM2009), June 2009, Napa, CA.

The paper deals with the successive application of time-based arrival management and automatic arrival-departure-coordination. DLR's arrival manager 4D-CARMA supports approach controllers with sequence and advisory information during two time-based human-in-the-loop experiments: First 4D-CARMA was used for dual threshold operation on a parallel runway system operated in mixed mode for arrivals and departures. The dual threshold operation was performed within the context of the OPTIMAL project of the European commission. Particular consideration is given in this paper to the validation exercises performed with three different European controller teams. An increase of the inbound flow of 3 to 4 arrivals per hour without negative impact on the outbound flow and on controller workload is possible if automatic arrival-departure-coordination together with advisory information is provided to the controllers. In an additional human-in-the-loop experiment 4D-CARMA supports the controllers to integrate unequipped aircraft into a stream of 4D equipped ones performing a user-preferred CDA approach.

"WAKE SENSING FOR AIRCRAFT FORMATION FLIGHT"

AIAA Paper No. 2012-4768, August 2012, Minneapolis, Minnesota.

It is well established that flying aircraft in formation can lead to improved aerodynamic efficiency. However, successfully doing so is predicated on having knowledge of the lead aircraft's wake position. Here, we develop a wake sensing strategy to estimate the wake position and strength in a two-aircraft formation. The wake estimator synthesizes wing-distributed pressure measurements, taken on the trailing aircraft, by making use of an augmented lifting line model in conjunction with both Kalman-type and particle filters. The various estimation algorithms are tested in a vortex-lattice simulation environment, thus enabling the effects of modeling error to be analyzed. It is found that biases in the position estimates no longer arise if a particle filter is used in place of the Kalman-type filters. Filter divergence is observed when the relative aircraft separations are held fixed. This divergent behavior can

be alleviated with the introduction of relative aircraft motions, for example in the form of a cross-track dither signal.

Hemati, M. S., Eldredge, J. D. and Speyer, J. L.

"WAKE SENSING FOR AIRCRAFT FORMATION FLIGHT"

Journal of Guidance, Control and Dynamics, Vol. 37, No. 2, March-April 2014, pp. 513-524.

It is well established that flying aircraft in formation can lead to improved aerodynamic efficiency. However, successfully doing so is predicated on having knowledge of the lead aircraft's wake position. Here, a wake-sensing strategy for estimating the wake position and strength in a two-aircraft formation is explored in a simplified proof-of-concept setting. The wake estimator synthesizes wing-distributed pressure measurements, taken on the trailing aircraft, by making use of an augmented lifting-line model in conjunction with both Kalman-type and particle filters. Simple aerodynamic models are introduced in constructing the filter to enable fundamental wake-sensing challenges to be identified and reconciled. The various estimation algorithms are tested in a vortex lattice simulation environment, thus allowing the effects of modeling error to be analyzed. It is found that biases in the position estimates no longer arise if a particle filter is used in place of the Kalman-type filters. Filter divergence is observed when the relative aircraft separations are held fixed. This divergent behavior can be alleviated with the introduction of relative aircraft motions, for example in the form of a cross-track dither signal.

Hemm, R.

"BUSINESS CASE ANALYSIS FOR NASA WAKE VORTEX TECHNOLOGY"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

This briefing summarizes a business case analysis for the Wake Vortex Advisory System (WVAS) technology being developed by NASA and related technologies being developed by the Federal Aviation Administration (FAA). The technologies modeled in the current task include simultaneous offset instrument approaches (SOIA), dependent (staggered) arrivals on closely-spaced parallel runways (CSPRs), and reduced arrival and departure miles-in-trail (MIT) separations. The briefing will summarize the analysis with a focus on the role of meteorological data. The use of SOIA avoids air traffic control wake vortex constraints by expanding the visual operating conditions under which aircrews, not controllers, are responsible for wake vortex separation. SOIA procedures allow visual operations under reduced, but not IFR, ceiling and visibility limits. SOIA benefits were estimated by including the appropriate SOIA ceiling and visibility in airport delay model meteorological condition selection rules. CSPR procedures allow dependent (staggered) approaches to parallel runways with centerline separations less than 2500 feet. Near-term FAA weather-independent CSPR procedures are limited to Small- and Large-class aircraft. Mid- and Far-term CSPR procedures are weather dependent and apply to all aircraft classes. Reduced MIT is also weather dependent. CSPR and reduced MIT benefits are

estimated by using airport capacity models to generate various CSPR and MIT configurations and selecting those configurations in airport delay models when specified conditions (e.g., wind limits) are met. The analysis includes three individual airport studies - San Francisco, St. Louis, and Dallas/Fort Worth. Two of the airports, San Francisco and St. Louis, suffer from significant delays and provide good models for examining the benefits of improved operating procedures for both CSPRs and MIT. While Dallas/Fort Worth benefits derive solely from reducing MIT, it was the demonstration site for the Aircraft Vortex Spacing System AVOSS in 2000, and the considerable data collected could potentially be used to corroborate assumptions made in predicting benefits.

Hemm, R. and Shapiro, G.

"TERMINAL AREA PRODUCTIVITY AIRPORT WIND ANALYSIS AND CHICAGO O'HARE MODEL DESCRIPTION"

NASA CR-207662, April 1998, NASA Langley Research Center, Hampton, VA

This paper describes two results from a continuing effort to provide accurate cost-benefit analyses of the NASA Terminal Area Productivity (TAP) program technologies. Previous tasks have developed airport capacity and delay models and completed preliminary cost benefit estimates for TAP technologies at 10 U.S. airports. This task covers two improvements to the capacity and delay models. The first improvement is the completion of a detailed model set for the Chicago O'Hare (ORD) airport. Previous analyses used a more general model to estimate the benefits for ORD. This paper contains a description of the model details with results corresponding to current conditions. The second improvement is the development of specific wind speed and direction criteria for use in the delay models to predict when the Aircraft Vortex Spacing system (AVOSS) will allow use of reduced landing separations. This paper includes a description of the criteria and an estimate of AVOSS utility for 10 airports based on analysis of 35 years of weather data.

Hemm, R. V., Eckhause, J. M., Long, D., Stouffer, V. and Hees, J.

"BUSINESS CASE ANALYSIS FOR NASA WAKE VORTEX TECHNOLOGY"

LMI-NS254T1, March 2004, Logistics Management Institute, McLean, VA

Building on the wake vortex technology developed under the Aircraft Vortex Spacing System (AVOSS) program in the 1990's, NASA is developing an updated system - the Wake Vortex Advisory System (WVAS). The Federal Aviation Administration is also pursuing ways to improve capacity at congested airports through reduction of overly conservative wake vortex separations. NASA and FAA have coordinated their wake vortex efforts through development and use of a joint Research Management Plan (RMP). This business case analysis addresses the procedures and technologies being pursued under the RMP. The analysis quantitatively estimates the impact on delay at three individual airports - San Francisco, St. Louis, and Dallas/Ft. Worth - and the delay impact of deploying WVAS at 18 airports in a network of 64 airports. The report includes estimates of WVAS life-cycle costs for all 18 airports, and benefit-to-cost and net present value results for the three individual airports.

Hemm, R., Shapiro, G., Lee, D. A., Gribko, J. and Glaser, B.

"BENEFIT ESTIMATES OF TERMINAL AREA PRODUCTIVITY PROGRAM TECHNOLOGIES"

NASA CR-1999-208989, January 1999, Logistics Mgmt. Inst., McLean, VA

This report documents benefit analyses for the NASA Terminal Area Technology (TAP) technology programs. Benefits are based on reductions in arrival delays at ten major airports over the 10 years from 2006 through 2015. Detailed analytic airport capacity and delay models were constructed to produce the estimates. The goal of TAP is to enable good weather operations tempos in all weather conditions. The TAP program includes technologies to measure and predict runway occupancy times, reduce runway occupancy times in bad weather, accurately predict wake vortex hazards, and couple controller automation with aircraft flight management systems. The report presents and discusses the estimate results and describes the models. Three appendixes document the model algorithms and discuss the input parameters selected for the TAP technologies. The fourth appendix is the user's guide for the models. The results indicate that the combined benefits for all TAP technologies at all 10 airports range from \$550 to \$650 million per year (in constant 1997 dollars). Additional benefits will accrue from reductions in departure delays. Departure delay benefits are calculated by the current models.

"CONNECTION BETWEEN LEADING-EDGE SWEEP, VORTEX LIFT, AND VORTEX STRENGTH FOR DELTA WINGS"

Journal of Aircraft, Vol. 27, No. 5, May 1990, pp. 473-475.

In this Note the difference between nonlinear lift and vortex lift has been distinguished. The nonlinear lift is the difference between the actual lift at a given angle of attack and that given by the product of the slope of the lift coefficient at zero angle of attack times the angle of attack. The vortex lift is the increment of lift above the zero leading-edge suction attached-flow lift and is due to the presence of the leading-edge vortex. Using similarity and several experimental and computational results, it has been possible to show that the effect of increasing leading-edge sweep for slender delta wings is to decrease vortex lift and leading-edge vortex strength. These results are useful for the development of future design strategies for high angle-of-attack wing performance when it is desired to tailor the growth of the leading-edge vortices using sweep, camber, and leading-edge shape.

"REVIEW OF FUNDAMENTAL CHARACTERISTICS OF COHERENT AND DIRECT DETECTION DOPPLER RECEIVERS AND IMPLICATIONS TO WIND LIDAR SYSTEM DESIGN"

17th CLRC, Review of Fundamental Characteristics of Coherent and Direct Detection Doppler Receivers, June 2013, Barcelona, Spain.

Coherent and direct detection lidar systems for wind measurement applications have many similarities but differ fundamentally in photon detection and frequency estimation sensitivity. In this paper we review the key characteristics of each receiver type and implications of these fundamental characteristics on the design of Doppler measurement lidar systems. Although signals from aerosol and molecular scattering are included in the discussion, the emphasis in this paper is on systems utilizing narrowband aerosol backscatter for the wind measurement. Simplified system designs and approximate equations are used to better illustrate the fundamental characteristics of each receiver type without being bogged down by fine design details of any given system. Of course more detail must be added, beyond what is presented here, in order to describe the performance of any specific real lidar system to a high level of fidelity.

"COHERENT LASER RADAR AT 2 MICRONS USING SOLID-STATE LASERS"

IEEE Transactions on Geoscience and Remote Sensing, Vol. 31, No. 1, January 1993, pp. 1-15.

Coherent laser radar systems using 2-micron Tm- and Tm, Ho-doped solid-state lasers are useful for the remote range-resolved measurement of atmospheric winds, aerosol backscatter, and DIAL measurements of atmospheric water vapor and CO₂ concentrations. Recent measurements made with a 2-micron coherent laser radar system, advances in the laser technology, and atmospheric propagation effects on 2-micron coherent lidar performance are described.

Hennemann, I.

"DEFORMATION UND ZERFALL VON FLUGZEUGWIRBELSCHLEPPEN IN TURBULENTER UND STABIL GESCHICHTETER ATMOSPHERE"

Dr.-Ing. Thesis, February 2010, University of Munich, Munich, Germany.

Aircraft wake vortices have been observed to often live much longer than expected. Following aircraft encountering the wake vortices experience a rolling moment which depends on the deformation of the vortices. With the help of Large-Eddy Simulations, this work investigates the dynamics of wake vortices in a turbulent and stratified atmosphere. Particularly, a method was developed which precisely determines the vortex core line. For the first time, the curvature of that line was analyzed in sections. The results show that the frequency of vortex ring formation is astonishingly high. The descent speed of vortex rings is reduced and the circulation changes from flight direction to span wise direction. Before linking, mean curvature radii of the vortices reduce to the size of one initial vortex spacing. After linking, they may grow again. The expected rolling moment of following aircraft is estimated. In particular, the comparison with field measurement data obtained within the EU project AWIATOR confirms the presented results. [In German.]

"LARGE-EDDY SIMULATION OF AIRCRAFT WAKE VORTEX DEFORMATION AND TOPOLOGY"

Proceedings of IMechE, Vol. 225, Part G, 2011, pp. 1336-1350.

On the one hand, it is known from visual observations, Lidar measurements, and numerical simulations that aircraft wake vortices may live longer than anticipated by today's standard regulations of air traffic control. On the other hand, the initially counter-rotating, parallel vortex pair deforms quickly, which reduces the impact time of adverse forces and moments on encountering aircraft. Therefore, large-eddy simulations of wake vortex evolution in different meteorological conditions are conducted to analyze the physics of vortex deformation. A new post-processing algorithm has been developed that at first determines the three-dimensional path of the vortex core line and then computes piecewise curvature radii as a measure of vortex deformation. It is found that larger turbulence levels and neutral to weakly stable temperature stratification particularly support vortex ring formation. The vortex ring regime is characterized by a reduced descent rate and by a surprising variability of its core radius. It is shown that the varying core size directly affects the evolution of radius-averaged circulation. Comparisons with field experiments indicate good agreement with the considerable life time of the vortex rings and topology.

"AIRCRAFT WAKE VORTEX DEFORMATION IN TURBULENT ATMOSPHERE"

5th International Symposium on Turbulence and Shear Flow Phenomena, Munich, August 2007

Large-scale distortion of aircraft wake vortices appears to play a crucial role for aircraft safety during approach and landing. Vortex distortion is investigated based on large eddy simulations of wake vortex evolution in a turbulent atmosphere. A vortex identification method is developed that can be adapted to the vortex scales of interest. Based on the identified vortex center tracks, a statistics of vortex curvature radii is established. These statistics constitute the basis for understanding, modeling, and exploiting mitigation effects of vortex distortion on wake vortex encounters.

Herder, A. J.

"AIRCRAFT WAKE TURBULENCE AWARENESS"

US Patent Application 2016/0328981 A1, November 2016.

An avionics wake-turbulence awareness system and method for use in an aircraft includes an ADS-B receiver that is adapted to be positioned in an equipped aircraft and receives ADS-B transmissions from other aircraft. A control system is responsive to the ADS-B receiver and determines an identity for each of the other aircraft and determines a movement of each of the other aircraft relative to the equipped aircraft. The control system determines a flight path history of each of the other aircraft from their respective identities and movements relative to the equipped aircraft. An output device is responsive to the control system to provide guidance to a pilot of the equipped aircraft to avoid an encounter with a wake turbulence caution area that is defined by a flight path history of another aircraft. The control

system evaluates the relative risk of the equipped aircraft encountering the respective wake turbulence caution areas of each of the other aircraft, and after selecting an aircraft of the other aircraft with a highest priority, provides guidance to the pilot of the equipped aircraft to avoid an encounter with a wake turbulence caution area of the selected aircraft.

"NUMERICAL STUDY IN WING TIP VORTEX FOR A MODIFIED COMMERCIAL BOEING AIRCRAFT"

Proceedings 2008 ASME International Mechanical Engineering Congress, IMECE2008-68149, Nov. 2008, Boston, MA.

Recent studies have shown that the use of winglets in aircrafts wing tips have been able to reduce fuel consumption by reducing the lift-induced drag caused by wing tip vortex. This paper presents a 3-D numerical study to analyze the drag and lift forces, and the behavior of the vortices generated in the wing tips from a modified commercial Boeing aircraft 767-300/ER. This type of aircraft does not contain winglets to control the wing tip vortex, therefore, the aerodynamic effects were analyzed adding two models of winglets to the wing tip. The first one is the vortex diffuser winglet and the second one is the tip fence winglet. The analyses were made for steady state and compressible flow, for a constant Mach number. The results show that the vortex diffuser winglet gives the best results, reducing the core velocity of the wing tip vortex up to 19%, the total drag force of the aircraft up to 3.6% and it leads to a lift increase of up to 2.4% with respect to the original aircraft without winglets.

"VORTEX BURST BEHAVIOR UNDER DYNAMIC FREESTREAM"

AIAA Paper No. 2005-63, Reno, NV, January 2005

A series of experiments on a 70-degree delta wing was conducted at Wichita State University to study the effect on the vortex burst position when simultaneous dynamic pitch and unsteady freestream velocity were used. The aim was to better understand the relationship between the freestream velocity and the time constants involved in the movement of the vortex burst point. Experiments indicated that a change in the freestream velocity resulted in a momentary pause in the forward progression of the vortex burst of the leading-edge vortex.

Heron, I. and Myose, R. Y.

"IMPINGEMENT OF A VON KARMAN VORTEX STREET ON A DELTA WING"

Journal of Aircraft, Vol. 42, No. 4, July-August 2005, pp. 1084-1087.

A series of experiments, where a von Karman vortex street wake was made to impinge upon a 70-deg delta wing, was conducted at Wichita State University using a towing mount. There was a temporal correlation to the burst location of the delta wing's leading edge (LE) vortices, which indicated

modulation of the burst location. The LE vortex burst location moved forward towards the apex with the passing of the filaments. This jump was most noticeable at lower angles of attack. It was also found that the average vortex-burst location remained approximately the same whether the freestream flow was clean or in the wake. Qualitatively, as the von Karman vortex filaments were entrained by the shear layer, they appeared to wrap themselves around the core. Additionally, there was a small-amplitude wave distortion of the LE core. Dye concentrations at regular intervals were also observed in the LE vortex core.

"NONPARALLEL LINEAR STABILITY ANALYSIS OF UNCONFINED VORTICES"

Physics of Fluids, Vol. 16, No. 10, Oct. 2004, pp. 3755-3764.

Parabolized stability equations have been used to study the stability of a family of swirling jets at high Reynolds numbers whose velocity and pressure fields decay far from the axis as r to $m-2$ power and r to $2(m-2)$ power, respectively; r is the radial distance and m is a real number in the interval $0 < m < 2$. Results show that the nonparallel effects of the basic flow play an important role in the development of both axisymmetric and non-axisymmetric unstable perturbations upstream of the vortex breakdown station. A complementary local nonparallel analysis shows the convective nature of these instabilities. Therefore, a criterion based on the transition from convective to absolute instabilities cannot be applied to predict the vortex breakdown of this kind of swirling jets. On the contrary, the failure of the quasi-cylindrical approximation used to compute the downstream evolution of the basic flow gives a clear breakdown criterion based on the catastrophic transition between slender and non-slender flows.

Herrada, M. A. and Shtern, V.

"CONTROL OF VORTEX BREAKDOWN BY TEMPERATURE GRADIENTS"

Physics of Fluids, Vol. 15, No. 11, November 2003, pp. 3468-3477

An axial gradient of temperature can either suppress or enhance vortex breakdown (VB). The underlying mechanism of such VB control is centrifugal or/and gravitational convection. An additional thermal-convection flow directed oppositely to the base flow suppresses VB while a co-flow enhances VB. Our numerical simulations of a compressible flow in a sealed cylinder induced by a rotating bottom disk clearly reveal these effects. We vary the temperature gradient, Mach (Ma), Froude (Fr), and Reynolds (Re) numbers, and the aspect ratio (h). As E increases ($E > 0$ corresponding to a temperature gradient parallel to the downward near-axis flow), the VB 'bubble' which occurs at $E = 0$, diminishes and then totally disappears. The opposite temperature gradient ($E < 0$) enlarges the VB bubble and makes the flow unsteady. These effects of centrifugal convection become more prominent with increasing Ma and Re . Density variations induced by the temperature gradients are more important for VB control than those induced by the increase in Ma . A new efficient time-evolution code for axisymmetric flows of an ideal gas has facilitated these simulations.

Herrada, M. A., Perez-Saborid, M. and Barrero, A.

"VORTEX BREAKDOWN IN COMPRESSIBLE FLOWS IN PIPES"

Physics of Fluids, Vol. 15, No. 8, August 2003, pp. 2208-2218

The effects of compressibility on vortex flows in pipes have been analyzed using both the axisymmetric Navier-Stokes (NS) equations and the quasi-cylindrical (QC) approximation. Numerical simulations of the full axisymmetric NS equations show that, for sufficiently large values of the Reynolds number, compressible flows present a multiplicity of steady-state solutions in a range of values of the swirl strength. The sensitivity of the vortex flow structure to the parameters of the problem: Mach number, Reynolds number, velocity profiles at the pipe entrance and pipe geometry has been also investigated. In particular, the critical swirl parameter necessary for the occurrence of vortex breakdown has been determined as a function of both the Mach number and the axial momentum of the flow at the pipe entrance. For large Reynolds number, the results of the QC approximation are found to be in good agreement with those of the full NS simulations. These results show that the upstream propagation of the sound waves seems to have a negligible influence on vortex breakdown and give support to the use of the QC approximation for the study of some aspects of the compressible swirling flows.

Herrema, F.

"TIME BASED SEPARATION COMPRESSION ON FINAL APPROACH AND TIME BASED SEPARATION FOR OPTIMIZED RUNWAY DELIVERY"

MS Thesis, December 2014, Delft University of Technology, Delft, The Netherlands.

For going over Distance Based Separation (DBS) and modelling a Time Based Separation (TBS) concept, a better characterization of the compression effect is required, which is the main goal of this report. Actual distance-based separations are to be replaced by time intervals, and/or speed compensation. The problem is that the aircraft pair (leader-follower) flying different point on final approach differs in its speeds, causing the separation between the two paired aircraft to increase or decrease. Decreasing separation below the minima increases the risk of wake turbulence encounters. In addition, the headwind conditions should be considered since these will reduce the groundspeed and as such the time to fly when no speed compensation is applied. This study will predominately focus on these headwind conditions. The characterization issues extracted in this study are needed to feed or support the TBS FFH tool for building an airspeed profile for the leader and follower aircraft on final approach. The tool can include the following characterization effects: Approach Speed (V_{app}), Deceleration and Stabilization Fix (DF & SF) and Glide Slope Speed. These performance parameters depend on the, aircraft type (wingspan/speed), wind profile, manufacturer (Airbus or Boeing), airline, part of the day and STAR. However, other challenging compression issues such as Time to Fly, current time separation, pilot/ATC practices and the Flight Management System (FMS) have also been analyzed in extensive detail and will act as recommendation for the future TBS studies. The data supporting the above conclusions is obtained from Charles De Gaulle (CDG) airport. To improve verification the results are compared with data from Vienna airport and show significant similarities, noting that DF and SF

standard deviations are higher compared to the TAS and time to fly due to local ILS and IAP procedures. A comparison of CDG approach speed profiles with the data used in RECAT-EU and Boeing data also shows significant similarities. In two case studies the new TBS FFH tool and the TBS OSED 1 tool are tested against real radar tracks. By comparing the performances of these two models, the best performances are extracted by looking at the least time separation error. In both studies the TBS FFH tool performed better. Finally, approach speeds, DF & SF and glide slope speeds resulting from this study have been used as input parameters in the SESAR Project 06.08.01 Validation Exercise for the TBS OSED Phase 2 model. Primarily results from this exercise indicate an improvement in runway throughput recovery applying the new TBS methodology when comparing low wind with high wind conditions.

Herrema, F. F., Zhao, W., Curran, R., Treve, V. and Graham, R.

"TIME BASED SEPARATION: COMPRESSION ON FINAL APPROACH AND TIME BASED SEPARATION FOR OPTIMIZED RUNWAY DELIVERY"

AIAA Paper 2015-2430, June 2015, Dallas, TX.

In this research, firstly individual characterization performances are examined, such as, the time to fly, the deceleration and stabilization fix, airspeeds, aircraft type and flight manual system. This will be done for a better understanding of the speed profile and the compression effect on final approach. Secondly, these performances will be verified with Vienna airport, RECAT-EU and Boeing data and incorporated into a DBS model. Thirdly, the model will be translated into a TBS FFH (Floris Friso Herrema) model by giving as input the most relevant extracted characterization issues. Finally, the report shows two case studies, in which TBS FFH and TBS OSED 1 models are tested in real radar tracks, using both Airbus and Boeing medium aircraft types. By comparing the performances of these two TBS models, the best performances will be extracted by looking at the least time separation error. The innovation of this study is that the aircraft performances, runway compression issues and air traffic control solutions for applying TBS are now, for the first time, captured mathematically in a model, to evaluate the system requirements and constraints to cater to compression. With this model the potential performance improvements and related compression issues by using a TBS methodology, can be predicted.

"A NOVEL MACHINE LEARNING MODEL TO PREDICT ABNORMAL RUNWAY OCCUPANCY TIMES AND OBSERVE RELATED PRECURSORS"

12th USA/Europe Air Traffic Management Research and Development Seminar (ATM2017), June 2017, Seattle, WA.

Accidents on the runway triggered the development and implementation of mitigation strategies. Therefore, the airline industry is moving toward proactive risk management, which aims to identify and predict risk precursors and to mitigate risks before accidents occur. For certain predictions Machine

Learning techniques can be used. Although many studies have explored and applied novel Machine Learning techniques on different aircraft Radar and operational Taxi data, the identification and prediction of abnormal Runway Occupancy Times and the observation of related precursors are not well developed. In our previous papers, three feasible methods were introduced: Lasso, Multi-Layer Perception and Neural Networks to predict the Taxi-Out Time on the taxiway and the Time to Fly and True Airspeed profile on final approach. This paper presents a new Machine Learning method, where we merge these feasible Machine Learning techniques for predicting the abnormal Runway Occupancy Times of unique radar data patterns. Additionally, we use in this study the Regression Tree method to observe key related precursors extracted from the top 10 features. Compared with existing methods, the new method no longer requires predefined criteria or domain knowledge. Tests were conducted using runway and final approach aircraft radar data consisting of 78,321 Charles de Gaulle flights and were benchmarked against 500,000 Vienna flights.

Herring, G. C.

"NONINVASIVE MEASUREMENT OF VELOCITY, PRESSURE, AND TEMPERATURE IN UNSEEDED SUPERSONIC AIR VORTICES"

Journal of Aircraft, Vol. 46, No. 3, May-June 2009, pp. 1074-1076.

In summary, novel nonintrusive time-averaged point measurements of velocity, pressure, and temperature have been demonstrated with vertical height profiles through the low-density vortex core from a supersonic delta wing. The present work illustrates the potential of the SRGS laser diagnostic for noninvasive and quantitative off-body flow measurements for many applications such as vortex and other flow field studies, wind-tunnel optimization, and validation of computational fluid dynamics.

Hess, R. A.

"ASSESSING WAKE VORTEX HAZARDS USING PILOT/VEHICLE ANALYSES"

In: Advances in Human Aspects of Aviation, edited by W. Karwowski, CRC Press, 2012, Chapter 55, pp. 581-592.

The development of a methodology that will allow the assessment of hazards associated with wake-vortex encounters by fixed and rotary-wing aircraft is presented. The methodology utilizes pilot/vehicle analyses and is intended to serve as a prelude to high-fidelity pilot-in-the-loop flight simulation. The pilot model, itself, has been introduced in the literature for flight simulator fidelity investigations. The analysis procedure provides an economical and time-saving tool for preliminary assessment of wake vortex hazards. The approach is exercised using a model of a small business jet as an in-trail aircraft interacting with a relatively simple vortex model assume generated by a large transport aircraft. Hazard metrics are proposed and employed in the analysis. The possibility of wake vortex-induced upsets providing triggering events for pilot-induced oscillations is emphasized.

Hesse, H. and Palacios, R.

"DYNAMIC LOAD ALLEVIATION IN WAKE VORTEX ENCOUNTERS"

Journal of Guidance, Control, and Dynamics, Vol. 34, No. 4, April 2016, pp. 801-813.

This paper introduces an integrated approach for flexible-aircraft time-domain aeroelastic simulation and controller design suitable for wake encounter situations. The dynamic response of the vehicle, which may be subject to large wing deformations in trimmed flight, is described by a geometrically nonlinear finite-element model. The aerodynamics are modeled using the unsteady vortex lattice method and include the arbitrary time-domain downwash distributions of a wake encounter. A consistent linearization in the structural degrees of freedom enables the use of balancing methods to reduce the problem size while retaining the nonlinear terms in the rigid-body equations. Numerical studies on a high-altitude, long-endurance aircraft demonstrate the reduced-order modeling approach for load calculations in wake vortex encounters over a large parameter space. Closed-loop results finally explore the potential of combining feedforward/feedback H_∞ control and distributed control surfaces to obtain significant load reductions.

Hesse, H. and Palacios, R.

"DYNAMIC LOAD ALLEVIATION OF FLEXIBLE AIRCRAFT IN WAKE VORTEX ENCOUNTERS"

International Forum on Aeroelasticity and Structural Dynamics, June-July 2015, Saint Petersburg, Russia.

This paper introduces an integrated approach for flexible-aircraft time-domain aeroelastic simulation and controller design suitable for wake encounter situations. The dynamic response of the vehicle, which may be subject to large wing deformations in trimmed flight, is described by a geometrically-nonlinear composite-beam finite-element model. The aerodynamics is modeled using the unsteady vortex lattice method and includes the arbitrary time-domain downwash distributions of a wake encounter. A consistent linearization in the structural degrees of freedom enables the use of balancing methods to reduce the problem size while retaining the nonlinear terms in the rigid-body equations. Numerical studies on a very flexible aircraft demonstrate the reduced-order modeling approach for load calculations in wake vortex encounters over a large parameter space. Closed-loop results finally explore the potential of combining feedforward/feedback H_∞ control and conventional control surfaces for load alleviation.

Hewitt, R. E. and Duck, P. W.

"LONG'S VORTEX REVISITED"

Journal of Fluid Mechanics, Vol. 634, 2009, pp. 91-111.

We consider exact solutions to the Navier-Stokes equations that describe a vortex in a viscous, incompressible fluid. This type of solution was first introduced by Long and is parameterized by an inverse Reynolds number ϵ . Long's attention (and that of many subsequent investigators) was centered

upon the 'quasi-cylindrical' (QC) case corresponding to $e = 0$. We show that the limit e going to 0 is not straightforward, and that it reveals other solutions to this fundamental exact reduction of the Navier-Stokes system (which are not of QC form). Through careful numerical investigation, supported by asymptotic descriptions, we identify new solutions and describe the full parameter space that is spanned by e and the pressure at the vortex core. Some erroneous results that exist in the literature are corrected.

Heyes, A. L. and Smith, D. A. R.

"MODIFICATION OF A WING TIP VORTEX BY VORTEX GENERATORS"

Aerospace Science and Tech., Vol. 9, 2005, pp. 469-475

The vortex wake hazard associated with transport aircraft is well known. One strategy for its alleviation is to alter the near field wake topology to distribute circulation over an increased area and reduce the consequent rolling moment on a following aircraft encountering the wake. The paper describes the results of an experimental investigation of the use of supplementary vortex generators to modify the tip vortex shed from a half-span airfoil. The experiments were conducted in a small low speed wind tunnel at a chord Reynolds number of $2.2 \times 100,000$ and the flow was characterized by measurement of the instantaneous and mean cross-stream flow field using particle image velocimetry. The results show that when the vortex generator is configured to produce a vortex that is co-rotating with respect to the wing-tip vortex, the two merge within five chord-lengths of the trailing edge resulting in a vortex with increased size relative to that of the baseline wake. Various vortex generator geometries were tested. A semi-circular generator produced an increase in core radius by a factor of five but the best shape was deemed triangular since generators of this shape produced substantial vortex enlargement with relatively low lift penalty. Low slenderness ratio generators were also deemed preferable since for a high slenderness generator it was shown that merging failed due to a negative vorticity buffer constrained to the region between the tip and generator vortex by the proximity of the generator vortex to the wing surface. Increasing the generator angle of attack was shown to increase the effectiveness of circulation redistribution. At the highest angles of attack increases occurred despite a decrease in VG vortex strength due to stalling. Unsteadiness in the stalled VG flow appears to enhance vorticity diffusion and it is hypothesized that it may also initiate cooperative instabilities in multiple vortex systems.

Heyes, A. L. and Smith, D. A. R.

"SPATIAL PERTURBATION OF A WING-TIP VORTEX USING PULSED SPAN-WISE JETS"

Experiments in Fluids, Vol. 37, 2004, pp. 120-127

The separation distance required between transport aircraft to avoid wake vortices remains a limiting factor on airport capacity. The dissipation of the wake can be accelerated by perturbing co-operative instabilities between multiple pairs of vortices. This paper presents the results of a preliminary experimental investigation into the use of pulsed span-wise air jets in the wing tip to perturb a single

tip vortex in the very near field. Velocity measurements were made using PIV and hot-wire anemometry. The results demonstrate that the vortex position can be modulated at frequencies up to 50 Hz and, as such, the method shows promise for forcing instability in multiple vortex wakes.

Heyes, A. L. and Smith, D. A. R.

"CHARACTERISATION AND MODIFICATION OF A VORTEX WAKE IN THE NEAR FIELD"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

The most attractive alleviation method from an operational point of view is to employ active or passive devices on the aircraft to hasten wake destruction, enabling a blanket decrease in aircraft separation. Premature destruction of the wake can be brought about by exciting co-operative instabilities, first described by Crow which amplify under mutual inductance of the vortex pair or pairs and lead to linking of the vortices, formation of vortex rings and subsequently a benign wake. These instabilities are naturally excited by atmospheric turbulence; however, the amplification rates are slow and the distance for the wake to become benign can be hundreds of spans. By forcing these instabilities by devices on the wing we seek to significantly reduce this distance. In this preliminary study a small wind tunnel, 0.45m x 0.3m test section, is used to study the wake from half span NACA 0012 models in the very near field. By using this modest facility, methods for perturbing the vortex, which are ineffective, can be quickly discounted. If a perturbation does not persist in the near-field then it is very unlikely there will be any far field effect either. Planer measurements and velocity profiles through the center of the vortex from a variety of half span-models have been made. These confirmed that the vortex core is formed from the separated flow around the tip and the subsequent roll up of the shear layer from the trailing edge is of secondary importance. This justified the use of short span, large chord wings which from a practical point of view allows easier incorporation of means for perturbing the vortex, i.e. air supplies. Two perturbation schemes are presented. The first is blowing axially into the vortex from a jet just inboard of the wing tip. The second perturbation scheme was to use pulsed span-wise jets in the wing tip to deflect the vortex formation outboard. PIV results showed that the vortex position could be oscillated with significant amplitude at the Crow instability frequency for this set-up. As such, this method shows promise for seeding instability in multiple vortex wakes and could equally be applied to flap edges.

Heyes, A. L., Hubbard, S. J., Marquis, A. J. and Smith, D. A.

"ON THE ROLL-UP OF A TRAILING VORTEX SHEET IN THE VERY NEAR FIELD"

Proc. IMechE, Vol. 217, Part G, 2003, pp. 263-269.

This paper addresses a discrepancy found between the rate of roll-up of a trailing vortex sheet calculated from point vortex simulations and that from measured data. Measurements of the wake behind a rectangular planform NACA 0012 section wing at 7.5 deg angle of attack show that some 50 per cent of the circulation in the wake is already present in the vortex core or 'rolled-up region' at the trailing edge of the wing, and that there is no increase in the circulation contained within this region

within one chord length downstream of the trailing edge. This conflicts with two-dimensional point vortex simulations of sheet roll-up which predict no initial core at the trailing edge and a constantly increasing value of circulation in the vortex in the downstream direction. A modification to include the effect of the tip vortex in the simulation is proposed and is shown to represent the behavior of the vortex sheet in the very near field accurately.

Heyes, A. L., Jones, R. F. and Smith, D. A. R.

"WANDERING OF WING-TIP VORTICES"

The Calouste Gulbenkian Foundation, 12th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, July 2004

Vortex wakes are an example of flows which exhibit unsteadiness from sources other than turbulence. The phenomenon of vortex wandering is where the vortex core moves in an apparently random fashion relative to the fixed observer. This prevents reliable conclusions from being drawn from temporally averaged measurements which, for example, reduces their value for CFD validation unless its effects are dealt with. Previous studies have demonstrated possible strategies to extract reliable data from that affected by wandering, but the methods used are not necessarily universal or convenient. In this study we demonstrate a relatively simple method for recovering the vortex structure from flow-field data taken using PIV and compare with a statistically based method for carrying out the same. Data is presented showing that wandering amplitude increases linearly with stream-wise distance, and also increases with background turbulence intensity, but decreases with vortex strength. Reliable data, corrected for the effects of wandering, shows that the vortex studied here grows at a more rapid rate than a Lamb-Oseen vortex undergoing viscous diffusion.

Heyson, H. H.

"SOME WAKE-RELATED OPERATIONAL LIMITATIONS OF ROTORCRAFT"

NASA TM-81920, December 1980, NASA Langley Research Center, Hampton, VA

Wind tunnel measurements show that the wake of a rotor, except at near hovering speeds, is not like that of a propeller. The wake is more like that of a wing except that, because of the slow speeds, the wake velocities may be much greater. The helicopter can produce a wake hazard to following light aircraft that is disproportionately great compared to an equivalent fixed wing aircraft. This hazard should be recognized by both pilots and airport controllers when operating in congested areas. Ground effect is generally counted as a blessing since it allows overloaded takeoffs; however, it also introduces additional operation problems. These problems include premature blade stall in hover, settling in forward transition, shuddering in approach to touchdown and complications with yaw control. Some of these problems were treated analytically in an approximate manner and reasonable experiment agreement was obtained. An awareness of these effects can prepare the user for their appearance and their consequences.

Hiejima, T.

"STABILITY OF COMPRESSIBLE STREAMWISE VORTICES"

Physics of Fluids, Vol. 27, 2015, pp. 074107-1 to 074107-10.

A sufficient condition for instability of full compressible inviscid streamwise vortices has been derived using asymptotic analysis with large wavenumbers. Based on the nature of instability, the obtained growth rate is described using an entropy instability term, a spiral instability term, a helicity instability term, and an acoustic instability term. The entropy instability term correlates with compressibility. The spiral instability term is reasonably expressed by the axial and azimuthal velocities and their wavenumbers. The helicity instability term depends on the helicity profiles. In particular, the unstable condition for wake-type flows is satisfied when they possess a negative helicity in the profiles. The acoustic instability term depends on the local speed of sound. Linear and nonlinear numerical simulations are used to validate the instability conditions. The effect of the helicity instability is shown to be significantly strong by the simulations.

Hiejima, T.

"STREAMWISE VORTEX BREAKDOWN IN SUPERSONIC FLOWS"

Physics of Fluids, Vol. 29, 2017, pp. 054102-1 to 054102-13.

Transition processes in supersonic streamwise vortices with wake flows are numerically simulated for Mach numbers from 1.5 to 5.0. This paper discusses the effect of an axial velocity deficit on the breakdown for a fixed small swirl number. For the evolution of the linear unstable mode at Mach 2.5, although the linear-growth range is short, the eigenfunction profiles of the mode resolved from a numerical simulation are generally consistent with those obtained from the linear stability analysis. For the discovery of the supersonic vortex breakdown, when the deficits are large within Mach number 2.5, spiral breakdowns occur with the azimuthal wavenumber.

"EFFECTS OF STREAMWISE VORTEX BREAKDOWN ON SUPERSONIC COMBUSTION"

Physical Review E, Vol. 93, 2016, pp. 043115-1 to 043115-15.

This paper presents a numerical simulation study of the combustion structure of streamwise vortex breakdown at Mach number 2.48. Hydrogen fuel is injected into a combustor at sonic speed from the rear of a hyper-mixer strut that can generate streamwise vortices. The results show that the burning behavior is enhanced at the points of the shock waves that are incident on the vortex and therefore the vortex breakdown in the subsonic region occurs due to combustion. The breakdown domain in the mainstream is found to form a flame-holding region suited to combustion and to lead to a stable combustion field with detached flames. In this way, streamwise vortex breakdown has an essential role in combustion enhancement and the formation of flames that hold under supersonic inflow conditions. Finally, the combustion property defined here is shown to coincide with the produced-water mass flow.

This property shows that the amount of combustion is saturated at equivalence ratios over 0.4, although there is a slight increase beyond 1.

Hiejima, T.

"LINEAR STABILITY ANALYSIS ON SUPERSONIC STREAMWISE VORTICES"

Physics of Fluids, Vol. 25, 2013, pp. 114103-1 to 114103-17.

In this study, the spatial growth rates of supersonic streamwise vortices were investigated by inviscid linear stability analysis. The freestream Mach numbers were 2.5, 5.0, and 7.5. In previous measurements taken to define the streamwise vortices, the stagnation temperature profile of supersonic flows is approximately uniform. This study found that the growth rate of vortices at the uniform stagnation temperature is smaller than that of isentropic vortices. The instability properties of the streamwise vortices can be explained by the ratio of the circulation to the axial velocity deficit, and by the Mach number. Moreover, it is found that the compressibility effect, by which the instability reduces as the Mach number increases, is caused by the negative energy arising from the entropy gradient of supersonic vortices that accompanies the axial velocity deficit-like wake. From an energy perspective, the effect may reasonably be correlated with the large density perturbations in supersonic flows. This study also proposes a general convective Mach number for supersonic streamwise vortices. The normalized growth rates are shown to be a function of convective Mach number within the investigated range of ratio parameters.

Hiejima, T.

"ONSET CONDITIONS FOR VORTEX BREAKDOWN IN SUPERSONIC FLOWS"

Journal of Fluid Mechanics, Vol. 840, 2018, pp. R1-1 to R1-12.

This study proposes an onset condition of shock-free supersonic vortex breakdown from the axial momentum variation, which applies in the presence or absence of a stagnation point. The condition is derived from a comprehensive approach to vortex breakdown. Supersonic breakdown appeared when the swirl parameter and Mach number were small. Moreover, bubble-type breakdowns with a stagnation point, which occur in subsonic conditions, could not occur under the supersonic condition in the present analysis. The predicted breakdowns under this condition were consistent with the results of the three-dimensional numerical simulations for Mach numbers ranging from 1.5 to 5.0. Supersonic vortex breakdowns were clearly captured by the helicity contours in the numerical results. The threshold of the downstream Mach number required for spiral breakdown with no stagnation point was also theoretically derived and verified in numerical results. These findings provide new insights into vortex breakdown in supersonic flows.

Hiejima, T.

"SPATIAL EVOLUTION OF SUPERSONIC STREAMWISE VORTICES"

Physics of Fluids, Vol. 26, 2014, pp. 074102-1 to 074102-19.

In this paper, the spatial developments of high Mach number streamwise vortices have been investigated using direct numerical simulations for Mach numbers from 2.5 to 9.0. The particular streamwise vortices studied here are those with uniform stagnation temperatures and those with constant entropy. For vortices with uniform stagnation temperature, the calculated spatial evolutions show that for small swirl parameters, a bending wave mode is excited and spiral structures of low-wavenumber modes only develop downstream. In contrast, for swirl parameters larger than a moderate amount (approximately 0.5), relaminarization occurs downstream. This study also found that the relation between the circulation and the freestream Mach number contributes to a necessary condition as to whether perturbations can grow in supersonic flows. For isentropic streamwise vortices, instability properties at high Mach numbers parallel those in low-speed flows because the evolution can give rise to high-wavenumbers within the core. The resulting entropy instability is analogous to the Rayleigh-Taylor instability and has the advantage of being insensitive to compressibility effects in supersonic flows.

"EVALUATION OF THE WAKE OF AN S-58 HELICOPTER"

Final Report, Project No. 348-011-01V, July 1963, Federal Aviation Agency, Atlantic City, NJ

A brief exploratory study of air movements near the ground within the wake generated by a 12,000-pound Sikorsky S-58 helicopter was conducted under conditions of light and moderate winds. Windspeed instrumentation was used to measure wake speeds in a plane approximately perpendicular to the test site surface wind. The smoke patterns induced by the wake were photographed in color and were used as the basis for correlation of wake speed data. The highest wake velocities occurred during hovering flight. The wake generated by the hovering helicopter contacted the ground quickly, expanded outward from the hover center upon ground contact and exhibited rapid growth - hence rapid wake speed deterioration - and the spreading portions were contained within 20 feet of the ground. Although the wake speeds produced during forward flight were not as high as those produced in hover flight, they persisted in the air mass for a much greater time. Also, the speed of travel of the wake system toward the ground decreases as the helicopter forward speed increases. These wakes with their vortices drifted downward approximately at wind speed. The maximum propagation of wake velocities upwind was approximately 85 feet.

"ROTATING FLYING DISKS AND FORMATION OF TRAILING VORTICES"

AIAA Paper No. 2000-4001, Denver, CO, August 2000

An experimental investigation on the flow past a flying disk is carried out in a low-speed wind tunnel. Using flow visualization techniques supplemented by Digital Particle Image Velocimetry (PIV), detailed flow characteristics depicting the trailing vortices, boundary layer separation and wake structure are

obtained. Effects of disk rotation on the boundary layer transition and separation are studied. Results indicate that the effect of rotation on the vortex strength becomes negligible at high angles of attack. At low lifting conditions of the present configuration, the rotation suppresses the boundary layer separation near the trailing edge and increases the downwash. In the intermediate angles, however, the leading-edge separation bubble is affected by the rotation. The flow transition over the advancing surface is also noted.

"VORTEX ROLL-UP FROM AN ELLIPTIC WING AT MODERATELY LOW REYNOLDS NUMBERS"

AIAA Journal, Vol. 25, No. 12, December 1987, pp. 1537-1542

An experimental investigation of tip-vortex roll-up was undertaken at moderately low Reynolds numbers for an elliptic wing with a NACA 66-2-415 section. Flow visualizations and laser Doppler velocimetry measurements were carried out to examine the flow in the vortex core and the tangential velocity distributions around the core. Separation was observed on both sides of the foil for Reynolds numbers up to 5×10^5 . The observed changes in the location of separation and reattachment with angle of attack and Reynolds number were adequately predicted by laminar boundary-layer calculations. Axial and tangential velocity profile measurements were made at Reynolds numbers up to 5×10^4 . The vortex core radius was found to grow with increasing angle of attack, increasing downstream distance, and decreasing Reynolds number. A comparison of the experimentally determined velocity distributions and core sizes, with results of inviscid, laminar, and turbulent vortex models, is presented.

Hill, C.

"MODERN FIBRE-OPTIC COHERENT LIDARS FOR REMOTE SENSING"

Proceedings SPIE DLC590, Paper 9649-23, Remote Sensing and Security, September 2015.

This paper surveys some growth areas that exploit near-IR coherent laser sources and fiber-optic hardware from the telecoms industry. Advances in component availability and performance are promising benefits in several military and commercial applications. Previous work has emphasized Doppler wind speed measurements and wind/turbulence profiling for air safety, with recent sharp increases in numbers of lidar units sold and installed, and with wider recognition that different lidar/radar wavebands can and should complement each other. These advances are also enabling fields such as micro-doppler measurement of sub-wavelength vibration and acoustic waves, including non-line-of-sight acoustic sensing in challenging environments. To shed light on these different applications we review some fundamentals of coherent detection, measurement probe volume, and parameter estimation -- starting with familiar similarities and differences between 'radar' and 'laser radar.' The consequences of changing the operating wavelength by three or four orders of magnitude -- from millimetric or centimetric radar to a typical fibre-optic lidar working near 1.5 microns -- need regular review, partly because of continuing advances in telecoms technology and computing.

Hill, C., Bennett, J. and Smith, D.

"AIRPORT TRIALS WITH THE AVIATION ZEPHIR WIND LIDAR"

15th Coherent Laser Radar Conf., Toulouse, France, June 2009.

QinetiQ's ZephIR is a conical-scan coherent Doppler lidar operating eye-safe near 1.5 microns, typically providing five-height wind speed profiles up to 150 m, updated once or twice per minute. More than 50 units are installed worldwide for applications including meteorology, wind farm assessment, and wind turbine studies. QinetiQ has recently fielded a modified version 'Aviation ZephIR' using results within a single one-second scan to estimate the wind speed, and also to detect the presence of turbulence and wake vortices. Over a few consecutive scans, the vortices can be tracked as they descend and are blown by the local wind. Aviation ZephIR senses a small, possibly critical, volume of air -- for example the critical airport regions where takeoff and landing -- for real-time, low-altitude, wind profiling and gust warning at airports. We have deployed at Birmingham International Airport (where most aircraft are light or medium) and at London Heathrow Airport (used by many large Airbus and Boeing aircraft, and by the Airbus A380). We present results on wind profiles, vortex detection, and vortex tracks.

Hill, D. J.

"PART I. VORTEX DYNAMICS IN WAKE MODELS. PART II. WAVE GENERATION"

PhD Thesis, May 1998, California Institute of Technology, Pasadena, CA.

In Part I, steady wakes in inviscid fluid are constructed and investigated using the techniques of vortex dynamics. As a generalization of Foppi's flow past a circular cylinder, a steady solution is given for flow past an elliptical cylinder of arbitrary aspect ratio (perpendicular or parallel to the flow at infinity) with a bound wake of two symmetric recirculating eddies in the form of a point vortex pair. Linear stability analysis predicts an asymmetric instability and the symmetric nonlinear evolution is discussed in terms of a Kirchhoff-Routh path function. The wake behind a sphere is represented by a thin cored vortex ring of arbitrary internal structure. Steady configurations are obtained and long-wavelength perturbations to the ring centerline identify a tilting instability. A generalization of the Kirchhoff Routh function to an axisymmetric flow consisting of vortex rings and a body is presented. Using conformal maps and point vortices, translating symmetric two-dimensional bubbles with a vortex pair wake are constructed. An instability in which the bubble and vortex pair tilt away from each other is found as well as a symmetric oscillatory instability. The cross-section of a trailing vortex pair immersed in a cross-stream shear is represented by two counter-rotating vortex patches. Numerical and analytical analyses are provided. The method of Schwarz functions as introduced by Meiron, Saffman, and Schatzman is used in the computation and stability analysis of steady patch shapes. Excellent agreement is obtained using an elliptical patch model. An instability essentially isolated to a single patch is identified, the nonlinear evolution of the elliptical patch model suggests that the patch whose fluid elements rotate against the shear will be destroyed. Part II examines a possible mechanism for the generation of water waves which arises from the instability of an initially planar free surface in the presence of a parallel, sheared,

inviscid flow. A two-dimensional steady flow comprised of exponential profiles representing both wind and a drift layer in the water is infinitesimally perturbed. The resulting Rayleigh equation is analytically solved by means of Hyper-geometric functions and the dispersion relation is implicitly defined as solutions of a transcendental equation; stability boundaries are determined and growth rates are calculated. Comparisons are made with the simpler model of Caponi et al. which uses piecewise linear profiles.

Hill, D. J. and Saffman, P. G.

"COUNTER-ROTATING VORTEX PATCHES IN SHEAR: A MODEL OF THE EFFECT OF WIND SHEAR ON AIRCRAFT TRAILING VORTICES"

Proceedings of the Royal Society of London, Series A, Vol. 458, May 2002, pp. 1527-1553

The shape and stability of two-dimensional, uniform patches of vorticity in incompressible inviscid fluid are calculated. The object of the study is to investigate the effect of wind shear on trailing vortices. The wind shear is modelled by simple shear with velocities in the plane perpendicular to the trailing vorticity. The first portion of this study models the trailing vortices as a pair of uniform straight counter-rotating line vortices which are essentially point vortices. They move under their self-induced velocities and the external shear. It is shown that the equations for the positions of the vortices can be solved exactly, and they move on parabolic trajectories with the horizontal and vertical separations kept constant. The trajectories are weakly unstable: infinitesimal disturbances grow algebraically in time. But, apart from the effect of wind shear on the horizontal displacement and an asymmetry of the streamlines, wind shear has no significant effect on the motion of the vortex pair under the point vortex approximation. The situation is different when the finite size of the trailing-vortex cores is taken into account. It is found that the vortex patches may be deformed significantly, or very slightly, depending upon the sense of rotation of the trailing vortex relative to the sense of rotation in the external simple shear. When co-rotating the patch remains circular to a good approximation, as would a single co-rotating patch in a uniform shear, a case which can be solved exactly. But when counter-rotating, the patch may be significantly deformed into a long, thin shape, perpendicular to the line joining the centroids of the patches.

Hill, F. M.

"A NUMERICAL STUDY OF THE DESCENT OF A VORTEX PAIR IN A STABLY STRATIFIED ATMOSPHERE"

J. Fluid Mech., Vol. 71, Part 1, September 1975, pp. 1-13

Numerical methods are used to investigate the motion of a horizontal vortex pair through a stably stratified atmosphere. The vortices carry with them a mass of fluid whose density differs from that of the air through which it descends, and the surface of this accompanying fluid becomes a vortex sheet, which is modelled by a set of discrete line vortices. It is shown that, at first, the vortex pair slows down with the shape of the envelope of the accompanying fluid remaining constant. Later, vorticity

concentrates at the rear, initiating detrainment and causing a downward acceleration of the vortex pair. Throughout the motion, the vortices approach each other.

"FLOW VISUALIZATION OF AIRCRAFT IN FLIGHT BY MEANS OF BACKGROUND ORIENTED SCHLIEREN USING CELESTIAL OBJECTS"

AIAA Paper 2017-3553, June 2017, Denver, CO.

The Background Oriented Schlieren using Celestial Objects series of flights was undertaken in the spring of 2016 at the National Aeronautics and Space Administration Armstrong Flight Research Center to further develop and improve a flow visualization technique which can be performed from the ground upon flying aircraft. Improved hardware and imaging techniques from previous schlieren tests were investigated. A United States Air Force T-38C and NASA B200 King Air aircraft were imaged eclipsing the sun at ranges varying from 2 to 6 nautical miles, at subsonic and supersonic speeds. Images were post-processed using the Background Oriented Schlieren technique with optical flow algorithms to reveal both subsonic and supersonic flow features around the aircraft. The resulting imaging hardware and techniques demonstrated its applicability as a mature instrumentation system for performing flow visualization on vehicles in flight.

"EXPERIMENTAL INVESTIGATION OF TURBULENT SWIRLING WAKES"

AIAA Paper 2014-0958, January 2014, National Harbor, MD.

The swirling wake has been studied experimentally. A specialized swirling wake generator was developed that introduced a minimal number of artifacts to the flow. Particle Image Velocimetry was used to capture the wake flow-field. The results show that, although the swirling wakes were deeper initially, they decay faster than their non-swirling counterpart. The implications of this study are important. The range studied here was the near field (x/D less than 10), but this is more than the typical spacing between wind turbines constructed in arrays. As such, it indicates that capturing the effects of the curvature on the turbulence in these wakes is critical if the wake behavior is to be adequately captured. Since small increases in energy capture by a wind turbine translates into a significant decrease to the cost of energy, further investigation of the effects of swirl on wake behavior are warranted. In addition to this practical application, the large effect of swirl on wake behavior suggests that the swirling wake is a good case for investigating the effect of swirl on turbulence. In addition to the mean flow quantities, the swirling jet could be used to understand changes in the turbulence structure and the related change in turbulence structure. Such information would add to the understanding of the general case of turbulent flows with significant curvature that are widely found in real-world applications.

Hinton, D. A.

"DEVELOPMENT OF AN INTEGRATED WAKE VORTEX SPACING SYSTEM"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

A wake vortex spacing system has been developed to prescribe safe aircraft separation criteria at major airports. The Aircraft Vortex Spacing System (AVOSS) integrates the output of several systems to produce weather-dependent, dynamic wake vortex spacing criteria. These systems provide current and predicted (nowcast) weather conditions above the surface, models of wake vortex transport and decay in these weather conditions, and real-time feedback of wake vortex behavior from sensors. A version of AVOSS, suitable for concept demonstration, has been constructed and tested at the Dallas-Fort Worth International Airport and will be demonstrated to the aviation industry in late 2000. The demonstration is of concept feasibility, and additional effort is required to deploy an operational system for actual aircraft spacing reduction. Initial tests with the AVOSS system verify the potential to increase runway arrival rates by 10 to 15% in the first intended application of the system, reduced spacing in-trail to a single runway. The system technology may also be applied to other applications, such as enabling closely-spaced approaches to parallel runways, where the capacity gains may potentially be greater. This paper describes the AVOSS system architecture, subsystem capabilities, and results from a system deployment at DFW in the fall of 1999.

Hinton, D. A.

"DESCRIPTION OF SELECTED ALGORITHMS AND IMPLEMENTATION DETAILS OF A CONCEPT-DEMONSTRATION AIRCRAFT VORTEX SPACING SYSTEM (AVOSS)"

NASA TM 2001-211027, June 2001, NASA Langley Research Center, Hampton, VA

A ground-based system has been developed to demonstrate the feasibility of automating the process of collecting relevant weather data, predicting wake vortex behavior from a data base of aircraft, prescribing safe wake vortex spacing criteria, estimating system benefit, and comparing predicted and observed wake vortex behavior. This report describes many of the system algorithms, features, limitations, and lessons learned, as well as suggested system improvements. The system has demonstrated concept feasibility and the potential for airport benefit. Significant opportunities exist however for improved system robustness and optimization. A condensed version of the development lab book is provided along with samples of key input and output file types. This report is intended to document the technical development process and system architecture, and to augment archived internal documents that provide detailed descriptions of software and file formats.

Hinton, D. A.

"AIRCRAFT VORTEX SPACING SYSTEM (AVOSS) CONCEPT AND DEVELOPMENT"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 11-22

The goal of the Aircraft Vortex Spacing System (AVOSS) effort is to support the Terminal Area Productivity program goal of improving airport capacity during instrument operations to capacity levels comparable to current visual operations. The AVOSS system concept is to combine meteorological information, wake vortex prediction, and wake sensors into an integrated system that advises the ATC system of the wake vortex spacing required for avoidance of wake turbulence. This task is accomplished by establishing a safety corridor from the glide slope intercept point to the landing runway, then using ambient and forecast atmospheric state to predict the time required for wake vortices to clear the corridor or decay. Statistical meteorological data is used to estimate the uncertainty in the wake predictions in order to provide spacing recommendations that will be safe and usable for a significant time period. The technical challenges of the program include the ability to sense and predict atmospheric state variables, the ability to predict wake motion and decay in a range of conditions, and system performance and costs that permit a return on the installation investment. The product of the AVOSS project will be a demonstration of a system architecture and data to support sensor selection and benefit/cost tradeoff studies.

Hinton, D. A.

"WAKE VORTEX SENSORS REQUIREMENTS OVERVIEW"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 228-234

The role of wake vortex sensors within an automated wake vortex spacing system is to provide a safety monitor function by validation of predictions of wake vortex residence time in the safety corridor. This requires not only that wakes be detected, but also that the wakes be tracked until they have departed the corridor or have decayed to circulation values that are no longer an operational impact to following aircraft. Specific sensor requirements are likely to evolve in three phases. Sensors required for the AVOSS development program have minimal reliability, automation, or all-weather needs, but must provide high resolution wake data to support research efforts. Sensors required for an operational test bed will require much greater reliability, self-monitoring, and automation, as well as the ability to cover multiple locations on the approach path. Sensors in an operational system will require very high reliability and automation, but potentially low resolution of wake velocity profiles. The sensors must accommodate real-world constraints such as siting limitations, no adverse environmental impacts, detection of wakes that return to the corridor after leaving, discrimination of simultaneous presence of wakes from multiple aircraft, and tracking wakes in ambient turbulence and shear. Analysis of airport climatological data suggests that even sensors limited by cloud or low visibility may provide the necessary function in a large percentage of the conditions that require instrument approaches.

Hinton, D. A.

"AVOSS DEVELOPMENT APPROACH"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 460-468

The AVOSS development activity will provide for a field demonstration of the AVOSS concept. During the demonstration all required AVOSS subsystems will be deployed and operating in real-time as part of an integrated system. Outputs of the AVOSS system will not be provided to Air Traffic Control as part of this program, and no aircraft separations will be altered because of the AVOSS tests. The objective of the full-scale demonstration is to aggressively integrate the required system technologies, determine the utility and limitations of the currently existing state of the art in meteorological and wake prediction systems, and focus the research activities for maximum payoff. A facility is being established at the Dallas-Fort Worth airport to provide dedicated meteorological sensors, wake vortex sensors, and networks for system testing. The network will integrate atmospheric data from acoustic sodars, a radar profiler with Radio Acoustic Sounding System, a 150-foot meteorological tower, and products available from the Integrated Terminal Weather System (ITWS) test bed. A pulsed wake tracking lidar deployed by NASA Langley, a continuous wave wake tracking lidar deployed by MIT Lincoln Laboratory, and a ground wind line deployed by the Volpe National Transportation Systems Center are also interfaced to the network for automatic transfer of wake track data to AVOSS. This facility will be used for system integration, testing new wake and system algorithms, and AVOSS performance assessment.

Hinton, D. A.

"AIRCRAFT VORTEX SPACING SYSTEM (AVOSS) CONCEPTUAL DESIGN"

NASA TM-110184, August 1995, NASA Langley Research Center, Hampton, VA

A concept is presented for the development of a prototype Aircraft Vortex Spacing System (AVOSS). The AVOSS development is being performed by NASA Langley as an element of the Terminal Area Productivity (TAP) Program, and in support of the FAA integrated Wake Vortex Program Plan. The purpose of the AVOSS is to provide dynamical, weather dependent wake vortex separation criteria to ATC facilities with adequate stability and lead time for use in runway scheduling. The AVOSS will accomplish this task through a combination of wake vortex transport and decay predictions, weather state knowledge, defined aircraft operational procedures and corridors, and wake vortex safety sensors. With the appropriate interface to planned ATC automation, spacing can be tailored to specific generator/follower aircraft types rather than several broad weight categories of aircraft. In a manual ATC environment, the AVOSS may be used to determine when reduced separation standards may be used. Work is currently underway to address the critical disciplines and knowledge needs to demonstrate a prototype AVOSS in the 1999 time-frame. This document describes the concept and candidate form of an operational AVOSS system, system ground rules and requirements, research needs, and the development efforts being followed.

Hinton, D. A.

"AN AIRCRAFT VORTEX SPACING SYSTEM (AVOSS) FOR DYNAMICAL WAKE VORTEX SPACING CRITERIA"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 23-1 to 23-12

A concept is presented for the development and implementation of a prototype Aircraft Vortex Spacing System (AVOSS). The purpose of the AVOSS is to use current and short-term predictions of the atmospheric state in approach and departure corridors to provide, to ATC facilities, dynamical weather dependent separation criteria with adequate stability and lead time for use in establishing arrival scheduling. The AVOSS will accomplish this task through a combination of wake vortex transport and decay predictions, weather state knowledge, defined aircraft operational procedures and corridors, and wake vortex safety sensors. Work is currently underway to address the critical disciplines and knowledge needs so as to implement and demonstrate a prototype AVOSS in the 1999/2000 time-frame.

Hinton, D. A. and Charnock, J. K.

"AIRCRAFT VORTEX SPACING SYSTEM CURRENTLY UNDER DEVELOPMENT WOULD SAFELY INCREASE RUNWAY CAPACITY"

ICAO Journal, Vol. 53, No. 7, September 1998, pp. 14-17, 28

Researchers are at work developing technology needed to support an aircraft vortex spacing system that adjusts separation from wake vortices according to weather conditions. Recent studies have examined aircraft responses to wake encounters and assessed wake strength, and an AVOSS system demonstration is planned at a major airport in 2000.

Hinton, D. A. and O'Connor, C. J.

"DEVELOPMENT OF A WAKE VORTEX SPACING SYSTEM FOR AIRPORT CAPACITY ENHANCEMENT AND DELAY REDUCTION"

Proceedings of the 19th IEEE Digital Avionics Systems Conference, Vol. 1, October 2000, pp. 3E6-1-3E6-10

The Terminal Area Productivity project has developed the technologies required (weather measurement, wake prediction, and wake measurement) to determine the aircraft spacing needed to prevent wake vortex encounters in various weather conditions. The system performs weather measurements, predicts bounds on wake vortex behavior in those conditions, derives safe wake spacing criteria, and validates the wake predictions with wake vortex measurements. System performance to date indicates that the potential runway arrival rate increases with AVOSS, considering common path effects and ATC delivery variance, is 5% to 12% depending on the ratio of large and heavy aircraft. The concept demonstration system, using early generation algorithms and minimal optimization, is performing the wake predictions with adequate robustness such that only 4 'hard exceedances' have been observed in 1235 wake validation cases. This performance demonstrates the feasibility of predicting wake behavior bounds with multiple uncertainties present, including the unknown aircraft weight and speed, weather persistence between the wake prediction and the

observations and the location of the weather sensors several kilometers from the approach location. A concept for the use of the AVOSS system for parallel runway operations has been suggested, and an initial study at the JFK International Airport suggests that a simplified AVOSS system can be successfully operated using only a single lidar as both the weather sensor and the wake validation instrument. Such a self-contained AVOSS would be suitable for wake separation close to the airport, as is required for parallel approach concepts such as SOIA.

Hinton, D. A. and Tatnall, C. R.

"A CANDIDATE WAKE VORTEX STRENGTH DEFINITION FOR APPLICATION TO THE NASA AIRCRAFT VORTEX SPACING SYSTEM (AVOSS)"

NASA TM-110343, September 1997, NASA Langley Research Center, Hampton, VA

A significant effort is underway at NASA Langley to develop a system to provide dynamical aircraft wake vortex spacing criteria to Air Traffic Control (ATC). The system under development, AVOSS, combines the inputs of multiple subsystems to provide separation matrices with sufficient stability for use by ATC and sufficient monitoring to ensure safety. The subsystems include a meteorological subsystem, a wake behavior prediction subsystem, a wake sensor subsystem, and system integration and ATC interfaces. The proposed AVOSS can use two factors, singly or in combination, for reducing in-trail spacing. These factors are wake-vortex motion out of a predefined approach corridor and wake decay below a strength that is acceptable for encounter. Although basic research into the wake phenomena has historically used wake total circulation as a strength parameter, there is a requirement for a more specific definition that may be applied across multiple disciplines and teams to produce a real-time, automated system. This paper presents some of the limitations of previous applications of circulation to aircraft wake observations and describes the results of a preliminary effort to bound a spacing system strength definition.

Hinton, D. A., Charnock, J. K. and Bagwell, D. R.

"DESIGN OF AN AIRCRAFT VORTEX SPACING SYSTEM FOR AIRPORT CAPACITY IMPROVEMENT"

AIAA Paper No. 2000-0622, Reno, NV, January 2000

The National Aeronautics and Space Administration (NASA) is addressing airport capacity enhancements through the Terminal Area Productivity (TAP) program. Within TAP, the Reduced Spacing Operations element at the NASA Langley Research Center is developing an Aircraft Vortex Spacing System (AVOSS). AVOSS will integrate the output of several systems to produce weather dependent, dynamic wake vortex spacing criteria. These systems provide current and predicted weather conditions, models of wake vortex transport and decay in these weather conditions, and real-time feedback of wake vortex behavior from sensors. The goal of the NASA program is to provide the research and development to demonstrate an engineering model AVOSS, in real-time operation, at a major airport. A wake vortex system test facility was established at the Dallas-Fort Worth International Airport (DFW) in 1997 and tested in 1998. Results from operation of the initial AVOSS system, plus

advances in wake vortex prediction and near-term weather forecast models, 'nowcast', have been integrated into a second-generation system. This AVOSS version is undergoing final checkout in preparation for a system demonstration in 2000. This paper describes the revised AVOSS system architecture, subsystem enhancements, and initial results with AVOSS version 2 from a deployment at DFW in the fall of 1999.

Hinton, D. A., Charnock, J. K., Bagwell, D. R. and Grigsby, D.

"NASA AIRCRAFT VORTEX SPACING SYSTEM DEVELOPMENT STATUS"

AIAA Paper No. 1999-0753, Reno, NV, January 1999

The National Aeronautics and Space Administration (NASA) is addressing airport capacity enhancements during instrument meteorological conditions through the Terminal Area Productivity (TAP) program. Within TAP, the Reduced Spacing Operations sub-element at the NASA Langley Research Center is developing an Aircraft Vortex Spacing System (AVOSS). AVOSS will integrate the output of several systems to produce weather dependent, dynamic wake vortex spacing criteria. These systems provide current and predicted weather conditions, models of wake vortex transport and decay in these weather conditions, and real-time feedback of wake vortex behavior from sensors. The goal of the NASA program is to provide the research and development to demonstrate an engineering model AVOSS in real-time operation at a major airport. The demonstration is only of concept feasibility, and additional effort is required to deploy an operational system for actual aircraft spacing reduction. This paper describes the AVOSS system architecture, a wake vortex facility established at the Dallas-Fort Worth International Airport (DFW), initial operational experience with the AVOSS system, and emerging considerations for subsystem requirements. Results of the initial system operation suggest a significant potential for reduced spacing.

"STUDY OF FLOW FIELD IN THE NEAR WAKE OF DELTA WINGS"

Journal of the Aero. Society of India, Vol. 36, No. 1, February 1984, pp. 17-27.

An experimental study of vortex flow field on as well as in the near wake of a plane delta wing with sharp leading edges is presented. Complete velocity measurements in this three-dimensional flow field are obtained by means of a blunt conical nosed five-hole probe. The probe is mounted on a traversing mechanism with three linear degrees of freedom and the probe is pre-calibrated for yaw and pitch. The vortex core location is also measured by total head survey using a Kiel tube. The results plotted in the form of equi-velocity contours as well as cross flow velocity contours at each of the chordwise cross flow planes and in the wake region. Using these plots the vortex core location, its growth and development along the wing and its subsequent motion in the near wake is studied. The experimental data on the vortex core location on the wing surface are found to be in good agreement with the available theoretical data.

"STUDY OF FLOW FIELD IN THE NEAR WAKE OF DELTA WINGS"

34th Annual Meeting of the Aeronautical Society of India, December 1982, Madras, India.

An experimental study of vortex flow field on as well as in the near wake of a plane delta wing with sharp leading edges is presented. Complete velocity measurements in this three-dimensional flow field are obtained by means of a blunt conical nosed five-hole probe. The probe is mounted on a traversing mechanism with three linear degrees of freedom and the probe is precalibrated for yaw and pitch. The vortex core location is also measured by total head survey using a Kiel tube. The results plotted in the form of equi-velocity contours as well as cross flow velocity contours at each of the chordwise cross flow planes, and also in the wake region. Using these plots the vortex core location, its growth and development along the wing and its subsequent motion in the near wake is studied. The experimental data on the vortex core location on the wing surface are found to be in good agreement with the available theoretical data.

Hirsa, A. H.

"AN EXPERIMENTAL INVESTIGATION OF VORTEX PAIR INTERACTION WITH A CLEAN OR CONTAMINATED FREE SURFACE"

Ph.D. Thesis, January 1990, Univ. of Michigan, Ann Arbor, MI.

The interaction between a pair of trailing vortices and a free surface was studied. The vortices were produced by a submerged delta wing and a negative angle of attack. To isolate and study the interaction, an apparatus was built to generate reproducible vortex pairs with the same Reynolds number and Froude number as the trailing vortices. The apparatus consisted of a pair of counter rotating flaps which were moved by a computer-controlled stepping motor. The vortex pairs generated with the flaps were laminar and remained laminar during the time that significant interaction with the free surface was observed. The Froude number for the vortices was low and the resulting surface deformations were small. Particle image velocimetry along with flow visualization were used to study the flow field. Striations were also observed during the interaction of the vortex pair with the free surface. The striations were found to be caused by cross-stream vortices which are stretched by the strain field between the trailing vortices and their images. Contaminants on the free surface were found to have a large influence on both the free surface deformations and the flow field of the vortices. Also, a Reynolds ridge on the free surface was observed on each side of the wake. The effect of surface contamination was studied by adding known amounts of an insoluble surfactant to the free surface. Surface depressions, termed scars, were observed above the primary vortices as well as the secondary vortices, although in the case on the secondary vortices the depression was much greater.

"EVOLUTION OF AN INITIALLY COLUMNAR VORTEX TERMINATING NORMAL TO A NO-SLIP WALL"

Experiments in Fluids, Vol. 29, 2000, pp. 309-321

The early evolution of an initially columnar vortex normal to a solid wall was examined. The vortex was generated by a pair of flaps in a water tank. Detrimental effects from the wall during the vortex generation were avoided by producing the vortex normal to a free surface and subsequently bringing a horizontal plate into contact with the surface. Digital particle image velocimetry (DPIV) measurements of the velocity and vorticity, together with laser induced fluorescence (LIF) visualizations, in a meridional plane revealed a toroidal structure with the appearance of an axisymmetric vortex breakdown bubble. Agreement was found between the measurements and numerical simulations of the axisymmetric Navier-Stokes equations. The results show that the flow in the effusive corner region is dominated by a Bodewadt-type spatially oscillatory boundary layer within the core region and a potential-like vortex boundary layer at large radius. The toroidal structure results from the interaction between these two boundary layers, leading to the roll up of a dominant shear layer within the Bodewadt structure, and does not develop from the columnar vortex itself.

Hirschel, E. H.

"VORTEX FLOWS: SOME GENERAL PROPERTIES, AND MODELING, CONFIGURATIONAL AND MANIPULATION ASPECTS"

AIAA Paper No. 1996-2514, June 1996, New Orleans, LA.

Properties of vortex flows connected with lifting wings are discussed qualitatively and quantitatively. The concept of 'local vorticity content' of a shear layer is introduced, which results from a Re approaching infinity limiting process. It permits to distinguish kinematically active and inactive vorticity. It is applied to boundary layers, shear layers, etc., and it is shown how the singularities of potential flow theory can be connected to them. The structure of wakes of lifting wings is investigated. Vorticity creation and entropy rise in Euler solutions for lifting wings are explained with the local vorticity content concept. Finally, some vortex-flow manipulation possibilities, which are derived from this concept, are discussed.

Hitzel, S.

"SUB- AND TRANSONIC VORTEX BREAKDOWN FLIGHT CONDITION SIMULATIONS OF THE F-16XL AIRCRAFT"

Journal of Aircraft, Vol. 54, No. 2, March-April 2017, pp. 428-443.

Free-flight Navier-Stokes simulations of the Cranked Arrow Wing Aerodynamics Project International F-16XL aircraft were performed to probe for the complex vortex flow-field structures at high angle of attack close to and beyond vortex breakdown conditions. The scope of the paper probes for the quality and quantity of high-resolution numerical simulations possible with the current computer capacity at free-flight Reynolds numbers. It provides an insight into the effect of turbulence modeling of these complicated flows; the free-flight measured pressure distributions are compared with solutions achieved with the one-equation Spalart-Allmaras turbulence model, the one-equation Spalart-Allmaras

turbulence model with rotation correct, the k-w model, and the turbulence model with scale-adaptive simulation. The third topic of the investigation is the complexity of the vortex flow system of the configuration at sub- and transonic speeds at vortex breakdown conditions. For this purpose, the details of the different vortex systems and their behavior are prepared and discussed.

Hoad, D. J.

"IDENTIFICATION OF METEOROLOGICAL WAKE VORTEX PREDICTORS"

Forecasting Research Technical Report No. 304, March 2000, The Met. Office Aviation Applications Group, Berkshire, UK

Wake vortex safety considerations dictate aircraft separation limits at busy airports. If weather conditions in which wake vortices decay quickly can be identified and used reliably as 'wake vortex predictors', there is potential for making the separation distances dependent on these predictors as well as aircraft weight. This could increase the capacity of airports in certain weather conditions. This study uses the ETWIRL (European Turbulent Wake Incident Reporting Log) database, which contains data for wake vortex incidents reported by the air traffic control (ATC) authority at London Heathrow airport in addition to incidents occurring around the world reported by pilots. In this study, weather data for incidents occurring at Heathrow were extracted from the ETWIRL database and compared with weather data from a 'null incident' database. This 'null incident' database holds weather data from Heathrow airport on days on which no wake vortex incidents were reported by the ATC authority at Heathrow. This comparison identified some weather-related predictors, which could indicate whether a wake vortex incident is likely to occur. A statistical analysis was then performed to analyze the performance of these predictors.

Hoad, D. J.

"IDENTIFICATION OF METEOROLOGICAL WAKE VORTEX PREDICTORS"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

Wake vortex safety considerations currently dictate aircraft separation limits at busy airports. If weather conditions in which wake vortices decay quickly can be identified and used reliably as 'wake vortex predictors', there is potential for making the separation distances dependent on these predictors as well as aircraft weight. This could increase the capacity of airports in certain weather conditions. This study uses the ETWIRL (European Turbulent Wake Incident Reporting Log) database, which contains data for wake vortex incidents reported by the air traffic control (ATC) authority at London Heathrow airport, in addition to incidents occurring around the world reported by airline pilots. Weather data for incidents occurring at Heathrow were extracted from the ETWIRL database and compared with weather data from a 'null incident' database. This null-incident database holds weather data from Heathrow on days on which no wake vortex incidents were reported by the Heathrow ATC authority. This comparison identified some weather-related predictors which could indicate whether a

wake vortex incident is likely to occur. A statistical analysis was then performed to analyze the performance of these predictors, using a wider sample of incident data from the ETWIRL database.

Hoad, D. R.

"HELICOPTER BLADE-VORTEX INTERACTION LOCATIONS -- SCALE-MODEL ACOUSTICS AND FREE-WAKE ANALYSIS RESULTS"

NASA Technical Paper 2658, 1987, Langley Research Center, Hampton, VA.

The results of a model rotor acoustic test in the Langley 4- by 7-Meter Tunnel were used to evaluate a free-wake analytical technique. The acoustic data were examined in detail for blade-vortex interaction acoustic waveform characteristics. These results were used in an acoustic triangulation technique to define the location in the rotor disk of the noise source. These locations along with the results of the free-wake analysis, were used to define the geometry of the blade-vortex interaction phenomena as well as to determine if the free-wake analysis is a capable diagnostic tool. The results of the correlation of the experimentally determined source location and the analytically generated wake geometry for the rectangular blades are encouraging. The free-wake analysis successfully predicts the occurrence of blade-vortex interaction and is able to provide information on the interaction geometry. In the case of the advanced rotor system, the correlation between analysis and experiment is poor. The reason for the poor correlation may be related to the selection of the point on the rotor blade where the vortex is defined as being generated. Additional information is needed to provide a better understanding of the wake geometries developed by nonrectangular rotor blades.

"PRELIMINARY ROTOR WAKE MEASUREMENTS WITH A LASER VELOCIMETER"

NASA-TM-83246, Langley Research Center, Hampton, VA, March 1983.

A laser velocimeter (LV) was used to determine rotor wake characteristics. The effect of various fuselage widths and rotor-fuselage spacings on time averaged and detailed time dependent rotor wake velocity characteristics was defined. Definition of time dependent velocity characteristics was attempted with the LV by associating a rotor azimuth position with each velocity measurement. Results were discouraging in that no apparent time dependent velocity characteristics could be discerned from the LV measurements. Since the LV is a relatively new instrument in the rotor wake measurement field, the cause of this lack of periodicity is as important as the basic research objectives. An attempt was made to identify the problem by simulated acquisition of LV-type data for a predicted rotor wake velocity time history. Power spectral density and autocorrelation function estimation techniques were used to substantiate the conclusion that the primary cause of the lack of time dependent velocity characteristics was the nonstationary flow condition generated by the periodic turbulence level that currently exists in the open throat configuration of the wind tunnel.

Hoeijmakers, H. W. M.

"COMPUTATIONAL AERODYNAMICS OF ORDERED VORTEX FLOWS"

PhD Thesis, May 1989, Technical University of Delft, Delft, The Netherlands.

The physical aspects, the mathematical modeling, and the development and application of computational methods for the simulation of vortical flows are described. The high-Reynolds number vortex flows considered are assumed to be steady, sub-critical and such that the structure of the flow is well-ordered and consists of thin shear layers and slender vortex cores embedded in otherwise irrotational flow. The applications considered are vortex wakes and the flow about three-dimensional (slender) configurations with the flow separating from known separation lines, mostly the sharp leading edges.

Hoeijmakers, H. W. M.

"APPROXIMATE METHOD FOR COMPUTING INVISCID VORTEX WAKE ROLL-UP, PART 2: DESCRIPTION OF COMPUTER PROGRAM VOR2DT"

NLR-TR-85149-U, November 1985, National Aerospace Lab., Amsterdam, Netherland.

In part I of the report, a method is described for approximately computing the shape of steady vortex wakes downstream of aircraft configurations in steady flight through the unsteady analogy. In the analogy the steady fully three-dimensional problem is reduced to a two-dimensional time dependent problem, corresponding to the evolution of a two-dimensional vortex sheet system in successive cross-flow planes. The geometry of the vortex wake in any cross-flow plane consists of independent segments. Each segment is built up out of a continuous vortex sheet and up to two concentrated vortices which model tightly rolled-up vortex cores. Each of the vortices is connected to one of the edges of the continuous vortex sheet. Both single- and double-branched vortices can be accommodated. The method optionally accounts for symmetry and tunnel-wall influence, as well as for cross-flow plane components of the free stream. In part II of the report, the computer program VOR2DT is described in some detail.

"NUMERICAL SIMULATION OF VORTICAL FLOW"

NLR-MP-86032-U, June 1986, National Aerospace Lab., Amsterdam, Netherlands

Methods are discussed for the numerical simulation of vortical type of flow. The various methods in use at present are discussed in some detail, primarily with a view towards three-dimensional steady flow applications such as vortex wakes and leading-edge vortex flows. Some of the computational aspects of the numerical simulation are considered. The weaknesses, strengths and prospects of the various methods are indicated, and results of different methods are compared and discussed.

Hoeijmakers, H. W. M.

"VORTEX WAKES IN AERODYNAMICS"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 1-1 to 1-12

A survey is presented of the physics of vortex wakes as occur in the flow about aircraft configurations. The emphasis is on fundamental aspects of the flows and on the assessment of the mathematical models that can be used for numerically simulating vortex wakes.

Hoeijmakers, H. W. M.

"MODELING AND NUMERICAL SIMULATION OF VORTEX FLOW IN AERODYNAMICS"

Proceedings of Fluid Dynamic Panel Symposium, Vortex Flow Aerodynamics, AGARD, CP-494, Scheveningen, The Netherlands, October 1990, pp. 1-1 to 1-46

A review is presented of mathematic models of different level of approximation for and their application to the numerical simulation of vortical type flows occurring in subsonic and transonic aircraft aerodynamics. The paper covers computational methods for predicting the downstream development of vortex wakes as well as methods for simulating the detailed characteristics of configurations with leading-edge or body vortices.

"HIGHER-ORDER PANEL METHOD APPLIED TO VORTEX SHEET ROLL-UP"

NLR-MP-81059-U, October 1982, National Aerospace Lab., Amsterdam, Netherlands

The paper describes a computational method for two-dimensional vortex sheet motion in incompressible flow. The procedure utilizes a second-order panel method, an adaptive panel scheme and a concept for treating highly rolled-up portions of the vortex sheet. Results are presented for the roll-up of the wake behind an elliptically loaded wing, a ring wing (nacelle), a fuselage/part-span-flap/wing combination and a delta wing with leading-edge vortex sheets. The examples demonstrate that the method is capable to describe complicated vortex sheet motion in a reliable and stable manner.

Hoeijmakers, H. W. M., Vaatstra, W. and Verhaagen, N. G.

"VORTEX FLOW OVER DELTA AND DOUBLE-DELTA WINGS"

J. Aircraft, Vol. 20, No. 9, September 1983, pp. 825-832

A theoretical and experimental investigation of the flow about a slender delta wing and two double-delta wings is described. The objective of the investigation is to develop accurate computational

methods for the vortex flow about slender wings and strake-wing configurations. Numerical results of computational methods developed for the flow about slender wings are compared with experimental results of the present and of earlier investigations. It is demonstrated that satisfactory numerical results are obtained for the normal force, pressure distribution, as well as vortex position and vortex sheet geometry. It is shown that for analyzing the structure of complex vortex flow the laser light-sheet flow visualization technique is very useful. Results of the flow visualization are presented for the flow about the delta wing and the double-delta wing. Based on the results for the double-delta wings, a new vortex sheet model is proposed for these wings involving a single-branched strake vortex and a double-branched wing vortex.

"CERTIFICATION OF HELICOPTERS FOR USE ON BOARD SHIP"

Europort Naval Conference, Amsterdam, November 1978

Although helicopter manufacturers usually define limits for the safe operation of a helicopter, this generally applies to a rigid platform situation only. For operation from ships, additional limitations must be observed. This paper states the requirements for the development of adapted operating procedures and the determination of new limitations to ensure optimum use and adequate safety for helicopters in this field. The relevant certification test procedure, as carried out by the National Aerospace Laboratory, is described.

Hoerner, S.

"AERODYNAMIC SHAPE OF THE WING TIPS"

Technical Report No. 5752, May 1969, USAF Wright-Patterson Air Force Base, Dayton, Ohio.

A study was made of the aerodynamic characteristics of wing tips, as well as experimental investigations concerning the mechanism of the tip vortices and the lift/drag ratio of a wing fitted with differently shaped wing tips. Results show there are two ways in which the wing tips affect flow and forces on a wing: considering the tip vortices the effective span of a wing does not coincide with the geometrical mean, i.e., the geometrical location of the tip vortices depends on the shape of the wing tips; and that some parasitic drag originates from the wing tips, its amount also depending upon the shape of the wing tip. Using these results, an optimum wing-tip shape is described. This wing tip has a sharp side edge, its plane form shows a corner at the trailing edge and its upper surface extends approximately straight to the end. Employing this kind of wing tip the climbing speed is increased in the order of 1 ft/sec and the range by 1 or 2 percent, in comparison to disadvantageous tip shapes.

Hofbauer, T.

"NUMERISCHE UNTERSUCHUNGEN ZUM EINFLUSS VON WINDSCHERUNG UND TURBULENZ AUF FLUGZEUGWIRBELSCHLEPPEN"

Dr.-Ing. Thesis, November 2002, University of Munich, Munich, Germany.

In several aspects, the behavior of aircraft wake vortices under situations of vertical wind shear is significantly different from non-shear scenarios and its operational real-time forecast is challenging. By means of numerical investigations of idealized scenarios, the influence of wind shear on the lateral and vertical transport of vortices is analyzed both, phenomenologically as well as in the scope of a sensitivity study. The results allow for the verification of controversial views and the benchmark of modeling approaches. Case studies of turbulent shear flows focus on the persistence of vortices. A detailed analysis of the flow fields evidence that unequal vortex decay rates can be attributed to the asymmetric distribution of secondary vorticity structures. The results moreover suggest that extended vortex lifespans can be expected under situations of wind shear. The unusual vortex behavior observed by means of a LIDAR measurement is reproduced by realistic simulations and permits to reveal potential causes. [In German.]

"EFFECTS OF NONLINEAR SHEAR ON THE DYNAMICS OF A COUNTER-ROTATING VORTEX PAIR"

Proceedings of 1st International Symposium on Turbulence and Shear Flow Phenomena, Santa Barbara, CA, 1999

Numerical simulations were conducted to investigate the influence of nonlinear vertical shear on the trajectories of a trailing vortex pair. Descending vortices which approach a shear layer begin to tilt and diverge. It is shown that the vortex whose vorticity is of opposite sign to the shear-layer vorticity can stall or even rebound, whereas the other vortex penetrates through the shear layer. The behavior of the vortices is highly sensitive to the vorticity distribution within the shear layer and cannot be described by circulation or maximum vorticity relations. When the vorticity distribution of the shear layer varies along the axis of the vortices, the interaction between shear and vortex is also modified in axial direction and presumably triggers a quickly growing instability of the vortex pair.

Hofbauer, T. and Gerz, T.

"SHEAR-LAYER EFFECTS ON THE DYNAMICS OF A COUNTER-ROTATING VORTEX PAIR"

AIAA Paper No. 2000-0758, Reno, NV, January 2000

The influence of three-dimensional wind-shear layers (jets) on the transport and decay of a counter-rotating vortex pair is investigated by means of direct numerical simulation. A laminar case is considered where the jet width varies periodically along the vortex axis. Further, the impact of two turbulence levels in the jet upon the vortex pair is studied. The initially laminar vortex pair penetrates from above into the jet and towards the ground. When penetrating the laminar jet, the wake vortices experience a sinusoidal perturbation but do not link. Contrarily, mutually independent dissolution of each vortex is observed when the jet is turbulent. The upstream vortex with vorticity opposing the vorticity of the upper shear layer of the jet starts to erode when it touches the upper flank of the turbulent jet, whereas the downstream vortex remains unaffected until it interacts with the lower

shear layer below the jet maximum. The vortex breakdown process and its spatial structure is discussed in detail.

Hofbauer, T. and Gerz, T.

"DECAY OF AIRCRAFT TRAILING VORTICES SUBJECTED TO TURBULENT CROSSWIND SHEAR"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

This study addresses the effect of turbulent wind shear on aircraft trailing vortex decay by means of direct numerical simulations (DNS). Prompted by the need for optimized separations, efforts are undertaken to develop an operational model, capable of forecasting the vortex behavior with respect to the variety of meteorological parameters. Thereby, the major shortcoming is the modeling of the crosswind shear effects, whose manifold impact on vortex migration and decay is most complex. Not only understanding the mechanisms of decay is an important element to predict vortex lifetimes, but to forecast the vortex trajectories as well. The objective of this study is to help clarify the underlying physical processes of vortex decay influenced by turbulent shear which in turn may contribute to the development of such a forecasting model.

Hofbauer, T. and Gerz, T.

"EFFECTS OF NONLINEAR SHEAR ON THE DYNAMICS OF A COUNTER-ROTATING VORTEX PAIR"

Proceedings of 1st International Symposium on Turbulence and Shear Flow Phenomena, Santa Barbara, CA, September 1999.

Numerical simulations were conducted to investigate the influence of nonlinear vertical shear on the trajectories of a trailing vortex pair. Descending vortices which approach a shear layer begin to tilt and diverge. It is shown that the vortex whose vorticity is of opposite sign to the shear-layer vorticity can stall or even rebound, whereas the other vortex penetrates through the shear layer. The behavior of the vortices is highly sensitive to the vorticity distribution within the shear layer and cannot be described by circulation or maximum vorticity relations. When the vorticity distribution of the shear layer varies along the axis of the vortices, the interaction between shear and vortex is also modified in axial direction and presumably triggers a quickly growing instability of the vortex pair.

"BEHAVIOR OF AIRCRAFT WAKE VORTICES SUBJECTED TO WIND SHEAR"

AIAA Paper No. 2003-3813, Orlando, FL, June 2003

Among the meteorological parameters affecting the aircraft wake vortex behavior, wind shear effects constitute one of the most challenging tasks in modeling. Despite the significance for weather dependent reduced aircraft separations, the understanding of the interaction between vortices and ambient shear is far from complete. This article investigates issues of vortex transport and decay

influenced by laminar and turbulent shear events in terms of direct numerical simulations. The results show that ambient shear leads to vortex pair tilting, the rebound of vortices, and unbalanced vortex decay rates for the upwind and downwind vortex. The imbalance is a consequence of secondary vorticity structures, which stem from the stretching of ambient turbulent eddies. The numerical results are compared with current modeling approaches. It is argued that these approaches do not meet the requirements for an accurate prediction of vortex behavior. Further, the interaction between vortex pairs and shear layers is investigated by means of a parameter study which reveals the sensitivity of vortex transport on shear layer parameters. The analysis identifies behavior patterns and describes basic parametric relations and upper limits of vortex transport that may be used for parametrization.

"ANALYSIS OF CONSTANT TIME DELAY AIRBORNE SPACING BETWEEN AIRCRAFT OF MIXED TYPES IN VARYING WIND CONDITIONS"

Fifth EUROCONTROL/FAA ATM R&D Seminar, June 2003, Budapest, Hungary

This study analyzed the performance of constant time based airborne spacing under different operational conditions using fast time simulation. The effects of time-based spacing criteria, mixed aircraft types and wind conditions on the ability of an aircraft to maintain a time spacing behind a descending lead aircraft were investigated. The spacing performance of a previously used approximate time delay spacing criterion based on current lead aircraft speed was compared with an exact time delay spacing criterion based on lead aircraft position history. The exact time delay spacing criterion resulted in smaller time delay spacing errors and smoother true airspeed behavior. The exact time delay (60 s) criterion was then used to compare the spacing performance of a heavy aircraft following a light with a heavy aircraft following a heavy for different wind conditions. The results show that a heavy aircraft followed a light with approximately 40% more maximum time spacing error than a heavy aircraft followed a heavy. Different effects for constant and turbulent winds were observed. Maximum spacing error increased slightly with constant wind speed but always remained within 10 s up to maximum constant wind speeds of 87 knots (at 30 feet altitude) and 235 knots (at 29,000 feet altitude). Turbulent winds severely degraded stability particularly in cross wind conditions.

Hoffman, F. and van der Wall, B. G.

"THE VORTEX TRAJECTORY METHOD APPLIED TO HART II PIV DATA"

IB 111-2005/34, August 2005, DLR, Braunschweig, Germany

In October 2001 the HART II test campaign took place in the Large Low-speed Facility (LLF) of the German-Dutch Wind (DNW) tunnel. During the test, data of 1 TB were acquired including extensive wake data for the advancing and retreating side of the rotor plane. In the scope of this campaign, three test cases were distinguished: Baseline (BL), Minimum Noise (MN) and Minimum Vibration (MV). 3C-Particle Image Velocimetry (PIV) measurements were conducted to understand vortex roll up in the rotor wake as well as vortex aging to develop advanced simulation tools.

Hoffman, E. R. and Joubert, P. N.

"TURBULENT LINE VORTICES"

J. Fluid Mech., Vol. 16, Part 3, July 1963, pp. 395-411

An attempt has been made to establish the laws governing the flow in a turbulent line vortex. Up to the present time theoretical solutions for laminar flow have been used for comparison with experimental results for turbulent flow to find an 'eddy viscosity' term and its variation with various parameters. An approach is developed along lines like the methods used in turbulent boundary-layer theory and is found to be reasonably successful as far as the work has proceeded. It is predicted by theory, and confirmed by experiment, that the circulation in the vortex is proportional to the logarithm of radius under certain conditions. For the present experimental conditions, the vortices are found to be completely independent of viscosity effects when the parameter WZ/K exceeds 150, and above this value the experimental results may be correlated to give a universal distribution of circulation in the inner region of the vortex. Further experiments are necessary to verify and extend the results of these tests before any definite conclusions may be made regarding the circulation distribution in the outer core region of the vortex and the growth and development of the vortex.

"DOWNWASH AND WAKE BEHIND UNTAPERED WINGS OF VARIOUS ASPECT RATIOS AND ANGLES OF SWEEP"

NACA TN-1703, October 1948, Langley Aeronautical Lab., Langley Field, VA

An investigation has been made in the Langley 7- by 10-foot tunnel to determine the downwash angles and the dynamic-pressure ratios behind wings of various sweep angles and aspect ratios, and the aerodynamic force characteristics of the wings. A brief discussion of some of the effects of the more important variables is presented. The wake center line behind swept-forward wings was found to be located higher than the wake center line behind sweptback wings. A low tail position appears to be most stabilizing for all configurations investigated, with the exception of the short tail length behind the unswept wing at an angle of attack of 16 degrees. At low tail positions and low angles of attack the rate of change of downwash angle with angle of attack increases as sweepback decreases. At high tail positions and high angles of attack the reverse tends to be true.

Hoh, R. H.

"PILOT RATING SCALE FOR VORTEX HAZARD EVALUATION"

NASA CR-143836, June 1975, Systems Tech. Inc., Hawthorne, CA.

A pilot rating scale is developed for subjective assessment of hazard resulting from wake vortex encounter upsets. The development of the rating scale is based on a survey of 48 pilots regarding the

semantic properties of various phrases and a choice of formats for the rating scale. The rating scale can be used to define a hazard/non-hazard boundary as well as to determine a measure of the hazard.

Hohne, G., Fuhrmann, M. and Luckner, R.

"CRITICAL WAKE VORTEX ENCOUNTER SCENARIOS"

Aerospace Science and Technology, Vol. 8, 2004, pp. 689-701

A simulation-based method was developed to investigate the hazard of Wake Vortex Encounters (WVEs). This paper describes an important part of this method: the determination of worst-case WVE conditions, which is referred to as Worst-Case Search (WCS). The WCS results permit to reduce time and costs of WVE hazard related piloted simulator tests and allow the comparison of the hazard that vortices of different generator aircraft exert on a follower aircraft. The WCS is based on a high fidelity, offline simulation of the follower aircraft that includes the interacting wake vortex, a hazard criterion that rates the severity of each WVE, and a pilot model. It can be formulated as an optimization problem that is solved with the optimization tool MOPS (Multi Objective Parameter Synthesis). MOPS varied the encounter geometry until the simulation yields maximum values of the WVE hazard criterion. Worst-case encounter conditions for different parameters were investigated and sensitivity studies performed. The influence of the height above ground, the core radius, and the models for the wake vortex velocity profiles on the severity of a WVE was examined. To demonstrate the capability of the method, a comparison of the hazard of a WVE behind two different heavy transport aircraft for a 20t aircraft was made. The WCS method proved its applicability and delivered the worst-case encounter geometry.

Hohne, G., Fuhrmann, M. and Luckner, R.

"CRITICAL WAKE VORTEX ENCOUNTER SCENARIOS"

DLR Congress 2003, November 2003, Munchen, Germany.

A simulation-based method was developed to investigate the hazard of Wake Vortex Encounters (WVEs). This paper describes an important part of this method: the determination of worst-case WVE conditions, which is referred to as Worst-Case Search (WCS). The WCS results permit to reduce time and costs of WVE hazard related piloted simulator tests and allow the comparison of the hazard that vortices of different generator aircraft exert on a follower aircraft. The WCS is based on a high fidelity, offline simulation of the follower aircraft that includes the interacting wake vortex, a hazard criterion that rates the severity of each WVE, and a pilot model. It can be formulated as an optimization problem that is solved with the optimization tool MOPS (Multi Objective Parameter Synthesis). MOPS varied the encounter geometry until the simulation yields maximum values of the WVE hazard criterion. Worst-case encounter conditions for different parameters were investigated and sensitivity studies performed. The influence of the height above ground, the core radius, and the models for the wake vortex velocity profiles on the severity of a WVE was examined. To demonstrate the capability of the method, a

comparison of the hazard of a WVE behind two different heavy transport aircraft for a 20t aircraft was made. The WCS method proved its applicability and delivered the worst-case encounter geometry.

"LATERAL BLOWING FROM THE TIP OF A LOW ASPECT RATIO WING"

Technical Note 25, February 1965, von Karman Institute for Fluid Dynamics, Rhode-Saint-Genese, Belgium.

The pressure distribution of an aspect ratio two rectangular wing with lateral blowing from the tip was measured. It was found that lateral blowing increases the lift at all lateral stations with an extra lift increase near the tip. The stall angle of attack was little affected by lateral blowing.

Holbrook, G. T.

"VORTEX WAKE HAZARD ANALYSIS INCLUDING THE EFFECT OF THE ENCOUNTERING WING ON THE VORTEX"

M.S. Thesis, August 1985, George Washington Univ., Washington, DC.

This thesis addresses the problem of vortex wakes and their impact on airport capacity. Dynamic vortex simulations were performed over a wide range of vortex generator and following aircraft pairs with, for the first time, an analysis of the effect of the encountering wing on the vortex and the resulting change in the roll response of the wing. The mutual interference between a wing and a vortex was accounted for by coupling the wing and vortex and applying the conservation of angular momentum flux in a control volume enclosing the wing. The following aircraft model incorporated a roll control authority based on minimum design requirements and roll responses to vortex encounters were predicted with and without roll control applied. The predictions were used to produce maps of acceptable vortex generator and following aircraft pairs. This allowed a generalized determination of the effects of the vortex generator span load, wake decay, and the mutual influence of the wing and vortex on predicted roll upsets.

"VORTEX WAKE ALLEVIATION STUDIES WITH A VARIABLE TWIST WING"

NASA-TP-2442, November 1985, NASA Langley Research Center, Hampton, VA

Vortex wake alleviation studies were conducted in a wind tunnel and a water towing tank using a multisegmented wing model which provided controlled and measured variations in span load. Fourteen model configurations are tested at a Reynolds number of one million and a lift coefficient of 0.6 in the Langley 4- by 7-Meter Tunnel and the Hydronautics Ship Model Basin water tank at Hydronautics, Inc., Laurel, MD. Detailed measurements of span load and wake velocities at one semispan downstream correlate well with each other, with inviscid predictions of span load and wake

roll up, and with peak trailing-wing rolling moments measured in the far wake. Average trailing-wing rolling moments are found to be an unreliable indicator of vortex wake intensity because vortex meander does not scale between test facilities and free-air conditions. A tapered-span-load configuration, which exhibits little or no drag penalty, is shown to offer significant downstream wake alleviation to a small trailing wing. The greater downstream wake alleviation achieved with the addition of spoilers to a flapped-wing configuration is shown to result directly from the high incremental drag and turbulence associated with the spoilers and not from the span load alteration they cause.

"FLIGHT-DECK DISPLAY OF NEIGHBORING AIRCRAFT WAKE VORTICES"

PhD Thesis, June 2003, Stanford University, Stanford, CA.

Over the coming decades, aviation operations are predicted to rise steadily, increasing the burden on already congested and constrained airspace. A major factor governing the safe minimum separation distance between aircraft is the hazard generated by the wake of neighboring aircraft. Unaware of their proximity to other traffic, aircraft have encountered the wake turbulence of neighboring aircraft tens of miles ahead of them with serious or fatal consequences. The wake display described herein is a perspective view, synthetic vision, flight deck display that enables flight crews to 'see' neighboring aircraft, as well as their wakes via a predictive algorithm. Capable of enhancing the situational awareness with respect to the wake-vortex encounter hazard by enabling the flight crew to see the relative position of their aircraft with respect to the wake hazard, the display may allow for a decrease in the standard aircraft spacing to those now used in VFR conditions and an increase in airport and airspace capacity. At present, there is no mechanism in place in the National Airspace System that warns pilots of potential wake vortex encounters. The concept of a wake vortex display addresses the need for a real-time wake vortex avoidance scheme available directly to the pilot. The wake display has been evaluated under both simulated and actual flight conditions. Thirteen pilots with flight experience ranging from a student pilot to commercial airline and military pilots served as pilot test subjects evaluating the display under simulated conditions. The pilot test subjects completed a survey concerning their knowledge and understanding of wake vortices prior to the simulation data trials and, after the trials, they completed a pilot evaluation and post-flight survey rating their experience and providing feedback for the display design. One test pilot and four guest pilots flew the display during the in-flight evaluations incorporating three wake encounter scenarios. They reported a significant increase in their awareness of the position and movement of the wake and, using the display, they were easily able to maneuver the aircraft not only to avoid the wake, but also to find the wake for experimental verification. The simulations and flight tests demonstrated that synthetic vision based on theoretical predictions can enhance a pilot's situational awareness of the wake vortex encounter hazard.

"FLIGHT DECK DISPLAY OF AIRBORNE TRAFFIC WAKE VORTICES"

20th DASC Conference, Paper No. 154, Session 2A, Daytona Beach, FL, October 2001

Over the coming decades, aviation operations are predicted to rise steadily, increasing the burden on already congested and constrained airports and terminal areas. It has long been recognized that a major factor governing the safe minimum separation distance between aircraft is the hazard associated with the wake generated by the preceding aircraft. A flight deck display that allows the pilot to 'see' the neighboring aircraft, as well as its wake, may allow for a decrease in spacing and an increase in airport and airspace capacity, while maintaining safe separation distances from wake vortices. This research evaluates a model based on aircraft parameters that are readily available in flight to predict aircraft wake vortices in real time. Using this model, several graphical representations of wake symbology were created for use in a 3-D perspective view flight deck display. This research determines the feasibility of this method of wake vortex display and ascertains the most favorable symbology for use in flight deck operations.

"DYNAMIC WAKE PREDICTION AND VISUALIZATION WITH UNCERTAINTY ANALYSIS"

US Patent 6,963,291 B2, November 2005

A dynamic wake avoidance system utilizes aircraft and atmospheric parameters readily available in flight to model and predict airborne wake vortices in real time. A novel combination of algorithms allows for a relatively simple yet robust wake model to be constructed based on information extracted from a broadcast. The system predicts the location and movement of the wake based on the nominal wake model and correspondingly performs an uncertainty analysis on the wake model to determine a wake hazard zone (no fly zone), which comprises a plurality of 'wake planes' each moving independently from another. The system selectively adjusts dimensions of each wake plane to minimize spatial and temporal uncertainty, thereby ensuring that the actual wake is within the wake hazard zone. The predicted wake hazard zone is communicated in real time directly to a user via a realistic visual representation. In an example, the wake hazard zone is visualized on a 3-D flight deck display to enable a pilot to visualize or 'see' a neighboring aircraft as well as its wake. The system substantially enhances the pilot's situational awareness and allows for a further safe decrease in spacing, which could alleviate airport and air-space congestion.

"ON THE SOUND GENERATED BY THE INTERACTION OF A VORTEX AND A SHOCK WAVE"

Aeronautical Research Council Report 18257, February 1956, University of Southampton, Southampton, UK.

Recent work by Ribner has been utilized to estimate the distribution of intensity in the sound wave resulting from the interaction between a vortex and a shock wave, to obtain the order of magnitude of

the sound pressure obtained and the dependence of their magnitude upon shock strength and vortex strength. The distribution is compared with a Schlieren photograph of the interaction. Based on the analysis, the sound pressures are found to increase steadily with both Mach number and vortex strength. Particular estimates of sound levels depend critically upon the flow condition, but curves are attached for a typical wind-tunnel case indicating very intense sound levels for small percentage velocity fluctuations.

Hollingsworth, M. A. and Richards, E. J.

"A SCHLIEREN STUDY OF THE INTERACTION BETWEEN A VORTEX AND A SHOCK WAVE IN A SHOCK TUBE"

Aeronautical Research Council Report 17985, November 1955, University of Southampton, Southampton, UK.

A method utilizing the reflected compression shock in a shock tube has been successfully developed to obtain Schlieren photographs of the sound wave pattern resulting from the interaction between a vortex and a shock wave. The interaction results in the propagation into the air behind the shock wave of a sound wave of directionally varying intensity and sign. The amplitude of this sound wave appears to depend very directly upon the vortex strength: its dependence upon the shock strength is still under investigation.

Holloway, A. G. L. and Richardson, S.

"DEVELOPMENT OF A TRAILING VORTEX FORMED WITH SPANWISE TIP JETS"

Journal of Aircraft, Vol. 44, No. 3, May-June 2007, pp. 845-857

Trailing vortices from a NACA0015 ($AR = 5$) wing were formed with spanwise tip jets to allow the study of vortex core distortions on the development of vortex size and speed. The wing-tip jets were formed from small holes arranged along the periphery of the wing cross section. Experiments covered a wide range of tip jet blowing rates for a fixed-wing incidence of 5 deg and chord Reynolds number of 100,000. Measurements of mean velocity, mean vorticity, and turbulence kinetic energy in the wake were made up to 32 chords downwind using hot-wire anemometry. The tip vortex was observed to envelop the jet and subsequently grow in diameter at a substantially higher rate than the vortex formed without tip jets. The circumferential speed of the vortex formed with tip jets was higher in the near field, but declined sharply with downstream distance. At 32 chords downwind, the vortex formed with tip jets evolved into an axisymmetric form similar to a natural vortex, but with a diameter up to three times larger and a peak circumferential velocity three times less. The turbulence intensity measured on the vortex core was 30% in the near wake and 10% at 32 chords downwind.

"EXPERIMENTAL PULSED LASER REMOTE CROSSWIND MEASUREMENT SYSTEM - FEASIBILITY STUDY AND DESIGN"

FA-TR-76065, November 1976, Oregon Graduate Center, Beaverton, Oregon.

Recent activity regarding development of a pulsed laser, remote crosswind measurement system is described. This includes a more complete theoretical formulation which includes the log-amplitude perturbation. In addition, cw experimental work used to verify the theoretical formulation and the design and construction of a new pulsed crosswind system are described. The system uses a double pulsed 1.06-micron Nd:Yag laser, a sixteen-element arrayed receiver and space-time statistical averaging.

"DYNAMIC WIND TUNNEL SIMULATION OF AIRCRAFT WAKE VORTEX TRAJECTORY IN GROUND PROXIMITY"

AIAA Paper 2016-1069, January 2016, San Diego, CA.

The trajectory of the wake vortex generated by a transport aircraft wing during take-off and landing can influence the dispersion of the engine exhaust plume and therefore impact on local air quality in the vicinity of airports. A sub-scale atmospheric boundary layer wind tunnel (ABLWT) simulation, used to predict exhaust dispersion, would therefore need to include the effect of the wing wake. A preliminary series of wind tunnel measurements are presented which examine the effectiveness of both a quasi-static and moving-model simulation of a trailing vortex pair at nominally 1/200th scale, within an ABLWT. A simple flat plate delta planform wing, at incidence, is shown to be an effective vortex wake generator at this scale and Reynolds number (nominally 300,000). The trajectory of the vortices within the wake in the range $2 < (z/b) < 26$ are shown to be consistent with that reported for aircraft flight test; ground proximity is seen to influence both the lateral and vertical displacement of the vortex cores. Using this limited dataset, differences in vortex trajectory between a quasi-static and dynamic simulation only appear significant when an aircraft climb (+6 degrees to the horizontal) or descent (-3 degrees) profile is simulated.

"AIRCRAFT WAKE VORTICES -- FROM FUNDAMENTAL RESEARCH TO OPERATIONAL APPLICATION"

Promet, Vol. 39, No. 1/2, 2014, pp. 14-22.

Aircraft trailing vortices constitute both a kaleidoscope of instructive fluid dynamics phenomena and a challenge for the sustained development of the safety and capacity of the air transportation system. An overview of the wake vortex issue is given commencing at its historical roots, proceeding with a sketch of the nature and characteristics of wake vortices resulting from field measurement and numerical simulation, and concluding with a depiction of the design and performance of wake vortex

simulation systems established for the prediction of dynamic aircraft separations in different flight phases and for sensitivity and risk analysis. [In German.]

"ADJUSTMENT OF SUBGRID-SCALE PARAMETERIZATIONS TO STRONG STREAMLINE CURVATURE"

AIAA Journal, Vol. 42, No. 7, July 2004, pp. 1369-1602

A sub-grid scale model correction for large eddy simulations that address flow fields with embedded areas of poorly resolved strong streamline curvature effects is proposed. The devised modification is termed NaCoo and provides an isotropic correction of the sub-grid scale viscosity based on local centrifugal stability. The degree of stability is identified via a rotational Richardson number that is determined based on non-Galilean-invariant streamline curvature at every grid point. NaCoo allows for a more realistic representation of inadequately resolved coherent turbulent vortices. Its main benefits are: 1) conservation of the peak vorticity in the vortex cores, 2) reduction of vortex core radius growth rates, 3) an approach to properties of tangential velocity profiles found in experiments, 4) allowance for appropriate turbulence levels in the vicinity of the vortices, and 5) non suppression of vortex core meandering. The derivation of NaCoo, its properties, and sensitivity to numerical and vortex parameters are described in detail. Applications of the correction to single vortices and aircraft wake vortices in a quiescent and turbulent environment demonstrate the capabilities of the pragmatic correction.

Holzaepfel, F.

"PROBABILISTIC TWO-PHASE AIRCRAFT WAKE-VORTEX MODEL: FURTHER DEVELOPMENT AND ASSESSMENT"

Journal of Aircraft, Vol. 43, No. 3, May-June 2006, pp. 700-708

Further developments, applications, and assessments of the probabilistic two-phase aircraft wake-vortex model P2P are described. The wake-vortex model is applied to data of two field measurement campaigns accomplished at Tarbes airport, France. Measurements corroborate unambiguously the two-phase circulation decay anticipated by theory and parameterized by P2P. Vortex age and descent speed are adjusted to match effects of axial wind and glide-slope angle. Envelopes of vortex trajectories are expanded to consider tilting, stalling, and rebounding wake vortices caused by axial- and crosswind shear. For probabilistic model output a choice between arbitrary degrees of probability is established, and a stochastic prediction mode is introduced. In a deterministic scoring procedure, model performance is compared to the skill of another model. Probabilistic model performance is evaluated by the compilation of probability density distributions that relate wake vortex measurement data to the predicted envelopes.

Holzaepfel, F.

"PROBABILISTIC TWO-PHASE WAKE VORTEX DECAY AND TRANSPORT MODEL"

J. Aircraft, Vol. 40, No. 2, March-April 2003, pp. 323-331

A new parametric wake vortex transport and decay model is proposed that predicts probabilistic wake vortex behavior as a function of aircraft and environmental parameters in real time. The probabilistic two-phase wake vortex decay model (P2P) accounts for the effects of wind, turbulence, stable stratification, and ground proximity. The model equations are derived from the analytical solution of the spatiotemporal circulation evolution of the decaying potential vortex and are adapted to wake vortex behavior as observed in large-eddy simulations. Vortex decay progresses in two phases, a diffusion phase followed by rapid decay. Vortex descent is a nonlinear function of vortex strength. Probabilistic components account for deviations from deterministic vortex behavior inherently caused by the stochastic nature of turbulence, vortex instabilities, and deformations, as well as uncertainties and fluctuations that arise from environmental and aircraft parameters. The output of P2P consists of confidence intervals for vortex position and strength. To assign a defined degree of probability to the predictions reliably, the model design allows for the continuous adjustment of decay parameters and uncertainty allowances, based on a growing amount of data. The application of a deterministic version of P2P to the Memphis wake vortex database yields favorable agreement with measurements.

Holzaepfel, F.

"ANALYSIS OF POTENTIAL WAKE VORTEX ENCOUNTERS AT A MAJOR EUROPEAN AIRPORT"

Aircraft Engineering and Aerospace Technology, Vol. 89, Issue 5, 2017, pp. 634-643.

In this study, 12 potential wake vortex encounters that were reported at a major European airport have been investigated. Because almost all encounters occurred in ground proximity, most pilots conducted a go-around. The primary purpose of this study is to discriminate between incidents caused by wake vortex or rather by effects like wind shear or turbulence. Detailed knowledge of real-world encounter scenarios and identification of worst-case conditions during the final approach constitute highly relevant background information to assess the standard scenario used for the definition of revised wake turbulence separations.

Holzaepfel, F.

"PROBABILISTIC TWO-PHASE WAKE VORTEX DECAY AND TRANSPORT MODEL"

Journal of Aircraft, Vol. 40, No. 2, March-April 2003, pp. 323-331

A new parametric wake vortex transport and decay model is proposed that predicts probabilistic wake vortex behavior as a function of aircraft and environmental parameters in real time. The probabilistic two-phase wake vortex decay model (P2P) accounts for the effects of wind, turbulence, stable stratification, and ground proximity. The model equations are derived from the analytical solution of the spatiotemporal circulation evolution of the decaying potential vortex and are adapted to wake vortex behavior as observed in large-eddy simulations. Vortex decay progresses in two phases, a

diffusion phase followed by rapid decay. Vortex descent is a nonlinear function of vortex strength. Probabilistic components account for deviations from deterministic vortex behavior inherently caused by the stochastic nature of turbulence, vortex instabilities, and deformations, as well as uncertainties and fluctuations that arise from environmental and aircraft parameters. The output of P2P consists of confidence intervals for vortex position and strength. To assign a defined degree of probability to the predictions reliably, the model design allows for the continuous adjustment of decay parameters and uncertainty allowances, based on a growing amount of data. The application of a deterministic version of P2P to the Memphis wake vortex database yields favorable agreement with measurements.

"EFFECTS OF ENVIRONMENTAL AND AIRCRAFT PARAMETERS ON WAKE VORTEX BEHAVIOR"

Journal of Aircraft, Vol. 51, No. 5, September-October 2014, pp. 1490-1500.

This study investigates the impact of meteorological parameters (crosswind, headwind, wind shear, thermal stratification, turbulent kinetic energy, dissipation rate, and density) and aircraft parameters (position, heading, speed, weight, span, and spanwise load factor) on wake-vortex behavior. Typical measurement uncertainties of these parameters, on one hand, and the range in which they typically reside, on the other hand, are mapped on variations of lateral and vertical position and lifetime of the wake vortices. For this mapping process the deterministic two-phase wake-vortex model is employed, complemented by some simple considerations, dimensional analysis, and sources from literature. Three scenarios comprising cruise conditions, flight within the atmospheric boundary layer, and ground proximity are considered. From these investigations the following ranking of the impact parameters has been deduced: wind, thermal stratification, turbulence, position, mass, and spanwise load factor. The relevance of the remaining parameters appears small.

Holzaepfel, F.

"SENSITIVITY ANALYSIS OF THE EFFECTS OF AIRCRAFT AND ENVIRONMENTAL PARAMETERS ON AIRCRAFT WAKE VORTEX TRAJECTORIES AND LIFETIMES"

AIAA Paper 2013-0363, January 2013, Grapevine, TX.

This study investigates the impact of aircraft parameters (position, heading, speed, weight, span, and spanwise load factor) and meteorological parameters (crosswind, headwind, wind shear, thermal stratification, turbulent kinetic energy, dissipation rate, and density) on wake vortex behavior. Typical measurement uncertainties of these parameters, on one hand, and the range in which they typically reside, on the other hand, are mapped on variations of lateral and vertical position and lifetime of the wake vortices. For this mapping process the D2P wake vortex model is employed complemented by some simple considerations, dimensional analysis, and sources from literature. Three scenarios comprising cruise conditions, flight within the atmospheric boundary layer, and ground proximity are considered. From these investigations the following ranking of the impact parameters has been

deduced: wind, thermal stratification, turbulence, position, mass, spanwise load factor. The relevance of the remaining parameters appears small.

Holzaepfel, F.

"PROBABILISTIC WAKE VORTEX DECAY MODEL PREDICTIONS COMPARED WITH OBSERVATIONS OF FOUR FIELD MEASUREMENT CAMPAIGNS"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

Predictions of the parametric aircraft wake vortex transport and decay model P2P are compared with field observations. The two-phase decay model predicts probabilistic wake vortex behavior as a function of aircraft and environmental parameters in real time. Observation data from field deployments accomplished at the International Airports Memphis and Dallas Fort Worth, from the WakeOP campaign performed at the airfield in Oberpfaffenhofen, Germany, and from the WakeToul campaign at Tarbes airport, France, are employed. Based on 211 Memphis cases, it is shown that the probabilistic model predicts conservative confidence intervals for vortex decay except for four cases in which constant background wind shear increases vortex lifetime. Nonetheless, the aircraft spacing reduction potential based on vortex decay appears small. In contrast, consideration of advection outside the lateral limits of a safety corridor results in a large potential spacing reduction. Vortex drift is investigated based on input from different wind measurement devices with a focus on the spatial and temporal variability of the crosswind. Safety corridor clearances based on short term weather forecasts yield promising results.

Holzaepfel, F.

"SURFACE STRUCTURE ON A GROUND SURFACE FOR ACCELERATING DECAY OF WAKE TURBULENCE IN THE SHORT FINAL OF AN APPROACH TO A RUNWAY"

US Patent Application, 2013/0313363 A1, November 2013.

The invention relates to a surface structure on a ground surface, located in the short final of an approach to a runway, with an associated start of the runway and a runway longitudinal axis. To attain accelerated decay of wake turbulence produced by an approaching aircraft, the surface structure has according to the invention a multiplicity of separate elevations with an elevation height ranging from 0.25-10 m, in particular from 1-5 m, wherein the individual elevations have a spacing between them, ranging from 1-600 m, 1-400 m, 1-200 m, 1-100 m, 1-50 m, 1-15 m, 1-10 m, or in particular 2-8 m.

"AIRCRAFT WAKE-VORTEX EVOLUTION IN GROUND PROXIMITY: ANALYSIS OF FIELD MEASUREMENT DATA AND PARAMETERIZATION"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

Field measurement data of 237 wake vortex pairs and respective environmental conditions acquired at Frankfurt Airport by means of lidar, Sodar/RASS, and ultrasonic anemometer are used to analyze wake vortex behavior in ground proximity. Statistics of descent, rebound, and lateral transport characteristics are established. Effects of crosswind, headwind, atmospheric turbulence and stable temperature stratification are evaluated. Already light crosswind turns out to be sufficient to cause pronounced asymmetric rebound characteristics. Exceptional cases with strong rebounds caused by detached shear layers and obstacles are introduced and estimates of the time needed to clear the runway from wake vortices by advection are provided. The impact of turbulence, wind and stratification on wake vortex decay turns out to be weak and difficult to verify. Nevertheless, a clear correlation of turbulence and crosswind on wake vortex decay can be established by fitting the equation for circulation evolution of the P2P wake vortex model to the measurement data. Based on the analyses of field measurement data and numerical simulation results vortex decay and rebound characteristics are parameterized and implemented into the probabilistic two-phase aircraft wake-vortex model (P2P). The devised parameterizations are also adapted to the conditions prevailing at vortex generation heights below one vortex spacing. Comparison to wake predictions out of ground effect indicates that in ground effect (i) the rapid-decay phase progresses slower, (ii) wake vortex evolution can be predicted with improved accuracy, and (iii) fair prediction skill requires only limited environmental data.

"TURBULENT DECAY MECHANISMS OF WAKE VORTICES IN THE STABLY STRATIFIED ATMOSPHERE"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

The decay of wake vortices in the stably stratified atmosphere is investigated by means of large eddy simulations. Results of in-situ measurements in the wakes of different aircraft are used to find

appropriate initializations for the simulation of wake turbulence in the quiescent atmosphere. Furthermore, cases with weak atmospheric turbulence are investigated. It is shown that the early development of the vortices is not affected by turbulence and develops almost identically as in 2D simulations. In quiescent atmosphere the subsequent decay is controlled by short-wave disturbances which strongly interfere with stable stratification effects whereas in the cases with atmospheric turbulence the long-wave instability is dominantly promoted. For very strong stratification it is observed that wake vortices may rebound but lose most of their strength before reaching the flight level. Finally, the simulation results are compared to the predictive capabilities of Greene's approximate model.

Holzaepfel, F. and Gerz, T.

"TWO-DIMENSIONAL WAKE VORTEX SIMULATIONS IN THE STABLY STRATIFIED ATMOSPHERE."

AIAA Paper No. 1998-2857, Albuquerque, NM, June 1999.

The effects of stable stratification on aircraft wake vortices are investigated by means of high-resolution two-dimensional simulations. The simulations elucidate that the vortices first decelerate and then accelerate their descent, where they largely conserve their circulation. This complex behavior is explained by the kinematic interaction of the wingtip vortices and the secondary vorticity generated by baroclinity. It is found that the impulse of the whole system, including primary and secondary vorticity, is oscillating with the Brunt-Vaisala frequency which implies that the wingtip vortices themselves do not. Nevertheless, the buoyancy force that acts on the oval enveloping the wingtip vortices develops, at least for the first quarter of the Brunt-Vaisala period, exactly as it is expected for an ideal and vertically displaced particle. This results in a relation between the descent height and the size of the oval.

Holzaepfel, F. and Gerz, T.

"PERFORMANCE OF THE WAKE VORTEX PREDICTION AND MONITORING SYSTEM WSVBS AT FRANKFURT AIRPORT"

ICAS 2008, Anchorage, AK, Sept. 2008.

The design and performance of the Wake Vortex Prediction and Monitoring System WSVBS are described. The WSVBS has been developed to tactically increase airport capacity for approach and landing on closely-spaced parallel runways. It is thought to dynamically adjust aircraft separations dependent on weather conditions and the resulting wake vortex behavior without compromising safety. Dedicated meteorological instrumentation and short-term numerical terminal weather prediction provide the input to the prediction of wake-vortex behavior and respective safety areas. As a safety net a LIDAR monitors the correctness of WSVBS predictions in the most critical gates at low altitude. The WSVBS is integrated in the arrival manager AMAN of DLR. Within 66 days of performance test at Frankfurt airport it was found that the system ran stable and the predicted minimum separation times were safe. The capacity improving concepts of operation could have been used in 75 percent of

the time. From fast-time simulations the eventual capacity gain for Frankfurt was estimated to be 3 percent taking into account the real traffic mix and operational constraints in the period of one month.

Holzaepfel, F. and Gerz, T.

"TWO-DIMENSIONAL WAKE VORTEX PHYSICS IN THE STABLY STRATIFIED ATMOSPHERE"

Aerospace Science and Tech., Vol. 3, No. 5, May 1999, pp. 261-270

The effects of stable stratification on aircraft wake vortices are investigated by means of high-resolution two-dimensional simulations. The simulations elucidate that the vortices first decelerate and then accelerate their descent, where they largely conserve their circulation. However, for very stable stratification the tip vortices may rise again to the flight path. The underlying physical mechanisms are revealed by means of a point vortex method and are examined complementarily by balancing the impulse of the wake vortices. It is shown that the prominent effects, deceleration, detrainment, and acceleration are caused by the kinematic interaction of the vorticity generated by baroclinity and the primary vorticity. Furthermore, it is found that the impulse of the 'whole' system, including the detrained secondary vorticity, is oscillating with the Brunt-Vaisala frequency which implies that the wingtip vortices themselves do not. Finally, a local shear-number is proposed which takes into account the interaction of primary and secondary vorticity and can describe the instantaneous tendency of wake vortices to accelerate or to decelerate.

Holzaepfel, F. and Gerz, T.

"AIRCRAFT WAKE VORTEX CHARACTERISTICS IN THE STABLY STRATIFIED ATMOSPHERE"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

Aircraft wake vortices (WVs) may exert a danger on a following aircraft if the separation between the leading and following aircraft is not sufficient. In view of the expected growth of air traffic, increasing demands on the capacity and safety of international airports have to be faced. A promising approach to increase the capacity of airports is to model the temporal evolution of WVs to forecast their lifespan. It is meanwhile generally accepted that meteorological conditions such as turbulence, stratification and shear dominantly determine the development of WVs. We focus on the impact of the stably stratified atmosphere, an issue which has been discussed controversially for years. Based on 2-D and large eddy simulations as well as simple vortex element methods the behavior of WVs is analyzed. Depending on the degree of stratification we observe both an accelerated and a decelerated descent of WVs. Both effects are explained by the interaction of the WV's flow field with vorticity produced due to baroclinicity.

"ASSESSMENT OF WAKE-VORTEX ENCOUNTER PROBABILITIES FOR CROSSWIND DEPARTURE SCENARIOS"

Journal of Aircraft, Vol. 48, No. 3, May-June 2011, pp. 812-822.

The WakeScene-D (Wake Vortex Scenarios Package for Departure) software package has been developed for comprehensive airspace simulations of takeoff and departure. WakeScene-D consists of modules that model traffic mix, aircraft trajectories, meteorological conditions, wake-vortex evolution, and potential hazard area. The software package estimates the probability to encounter wake vortices in different traffic and crosswind scenarios using Monte Carlo simulation in a domain ranging from the runway to an altitude of 3000 ft above ground. A comparison with measured vortex tracks of about 10,000 departures from runway 25R of Frankfurt airport indicates good agreement of global wake-vortex transport characteristics in ground proximity. The standard departure situation employing a 2 min aircraft separation is compared with scenarios with reduced departure separations and various crosswind conditions. Comprehensive sensitivity analyses have been conducted that are briefly recapitulated. Effects related to departure-route combinations and wind-direction sectors are reported in more detail. Finally, an advanced scenario with an asymmetric crosswind criterion is introduced.

Holzaepfel, F. and Kladetzke, J.

"WAKE VORTEX ENCOUNTERS DURING TAKE-OFF AND DEPARTURE: SENSITIVITY ANALYSIS AND WORST CASE SEARCH"

CREDOS Report D3-9, November 2009, DLR, Oberpfaffenhofen, Germany.

This report describes Monte Carlo simulations of the airspace during take-off and departure with respect to wake vortex encounter probabilities under different traffic and crosswind situations with the software package WakeScene-D. The investigated scenarios can be split into (i) sensitivity analyses and (ii) validation cases that shall deepen the understanding of WakeScene-D and the confidence into the software package and into (iii) scenarios serving as a reference representing the current situation and (iv) the target scenarios for crosswind reduced separations and the related safety case. The current investigations allow for suggestions how CREDOS operations could be realized without increasing the risks compared to the reference scenario.

Holzaepfel, F. and Kladetzke, J.

"ASSESSMENT OF WAKE VORTEX ENCOUNTER PROBABILITIES FOR CROSSWIND DEPARTURE SCENARIOS"

CEAS 2009 European Air and Space Conference, October 2009, Manchester, UK.

This paper briefly describes the operating sequence of WakeScene-D (Wake Vortex Scenarios Simulation Package for Departure) and the employed sub-models. Next, a reference scenario is introduced which shall represent the real current departure situation. Then the statistics achieved with reduced aircraft departure separations and different crosswind thresholds are discussed. Finally, the paper highlights a selection of the most interesting results found in the conducted comprehensive sensitivity analyses. The investigated parameters of these sensitivity analyses comprise sample size, aircraft type combination, take-off weight, departure route combination, flight path adherence, wind

direction, wake vortex model, and a comparison to the arrival situation. On one hand, these sensitivity analyses help to increase the confidence in the software package and, on the other hand, they allow identifying the parameters that control encounter probabilities during takeoff and departure. In a next step the knowledge of these key parameters may enable the optimization of criteria for reduced aircraft separation.

Holzaepfel, F. and Robins, R. E.

"PROBABILISTIC WAKE VORTEX DECAY MODEL PREDICTIONS COMPARED WITH OBSERVATIONS"

AIAA Paper No. 2003-3809, June 2003, Orlando, FL.

Predictions of the parametric aircraft wake vortex transport and decay model P2P are compared with field observations. The two-phase decay model predicts probabilistic wake vortex behavior as a function of aircraft and environmental parameters in real time. Observation data from field deployments accomplished at the International Airports Memphis and Dallas Fort Worth, and from the WakeOP campaign performed at the airfield in Oberpfaffenhofen, Germany are employed. In a scoring procedure, the predictive capabilities of a deterministic version of P2P are compared to Sarpkaya's model. Based on 211 Memphis cases, it is shown that the probabilistic model predicts conservative confidence intervals for vortex decay except for four cases in which constant background wind shear increases vortex lifetime. Nonetheless, the aircraft spacing reduction potential based on vortex decay appears small. In contrast, consideration of advection outside the lateral limits of a safety corridor results in a large potential spacing reduction. Vortex drift is investigated based on input from different wind measurement devices with a focus on the spatial and temporal variability of the crosswind. Safety corridor clearances based on short term weather forecasts yield promising results. Further, it is found that shear layers may modify vortex transport such that predicted uncertainty allowances are exceeded.

"PROBABILISTIC TWO-PHASE AIRCRAFT WAKE- VORTEX MODEL: APPLICATION AND ASSESSMENT"

Journal of Aircraft, Vol. 41, No. 5, September-October 2004, pp. 1117-1126

Predictions of the parametric probabilistic two-phase aircraft wake-vortex transport and decay model P2P are compared with field observations. The two-phase decay model predicts probabilistic wake vortex behavior as a function of aircraft and environmental parameters in real time. Observation data from field deployments accomplished at the International Airports Memphis and Dallas Fort Worth, and from the WakeOP campaign performed at the airfield in Oberpfaffenhofen, Germany are employed. In a scoring procedure, the predictive capabilities of a deterministic version of P2P are compared to Sarpkaya's model. Based on 211 Memphis cases, it is shown that the probabilistic model predicts conservative confidence intervals for vortex decay except for four cases in which constant background wind shear increases vortex lifetime. Nonetheless, the aircraft spacing reduction potential based on vortex decay appears small. In contrast, consideration of advection outside the lateral limits

of a safety corridor results in a large potential spacing reduction. Vortex drift is investigated based on input from different wind measurement devices with a focus on the spatial and temporal variability of the crosswind. Safety corridor clearances based on short term weather forecasts yield promising results. Further, it is found that shear layers may modify vortex transport such that predicted uncertainty allowances are exceeded.

"PROBABILISTIC WAKE VORTEX DECAY MODEL PREDICTIONS COMPARED WITH OBSERVATIONS"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002.

A parametric model capable of reliably predicting vortex positions and strengths in real-time in a measured or forecasted atmospheric environment along the glide slope might permit air-traffic controllers to ease some of the regulations without loss of safety. All existing parametric wake vortex models predict deterministic vortex behavior. Not specified are deviations from predicted values inherently caused by the stochastic nature of turbulence, complex vortex instabilities and deformations, and the uncertainty of environmental parameters that determine the vortices' behavior in the atmospheric boundary layer. The probabilistic two-phase wake vortex decay model (P2P) is designed to predict wake vortex behavior within defined confidence intervals. For this purpose, the model concept allows for the continuous adjustment of decay parameters and uncertainty allowances, based on a growing amount of data. The model accounts for the effects of wind, turbulence, stable thermal stratification, and ground proximity.

"AIRCRAFT WAKE-VORTEX EVOLUTION IN GROUND PROXIMITY: ANALYSIS AND PARAMETERIZATION"

AIAA Journal, Vol. 45, No. 1, January 2007, pp. 218-227

Field measurement data of 288 wake-vortex pairs and respective environmental conditions acquired at Frankfurt Airport by means of light detection and ranging, sound detection and ranging/radio acoustic sounding system, and ultrasonic anemometer are used to analyze wake vortex behavior in ground proximity. Exceptional cases with strong rebounds caused by detached shear layers and obstacles are introduced and estimates of the time needed to clear the runway from wake vortices by advection are provided. The impact of turbulence and crosswind on wake vortex decay proves to be weak, whereas already light crosswind turns out to be sufficient to cause pronounced asymmetric

rebound characteristics. Based on the analyses vortex decay and rebound characteristics are parameterized and implemented into the probabilistic two-phase aircraft wake vortex model. Deterministic and probabilistic prediction skill of the enhanced vortex model are assessed. Comparison to wake predictions out of ground effect indicates that in ground effect 1) the rapid-decay phase progresses slower, 2) wake vortex evolution can be predicted with improved accuracy, and 3) fair prediction skill requires only limited environmental data.

"FUSION OF SINGLE-POINT AND DISTRIBUTED AERODYNAMIC DATASETS FOR WAKE ENCOUNTER FLIGHT SIMULATION"

AIAA Paper 2007-6312, August 2007, Hilton Head, SC.

This paper presents an approach for the fusion of high-fidelity single point aerodynamic datasets with simplified aerodynamic datasets containing pressure distribution information to allow real-time simulation of flight under atmospheric conditions with high local wind gradients, where the aerodynamic forces and moments acting on the aircraft may no longer be computed based on the wind speed at one point of the aircraft. The approach presents a solution that saves the constraint that, for uniform atmospheric disturbances covering the whole aircraft, the distributed aerodynamic model delivers the same forces and moments as the single point data set. This approach is useful for many practical purposes, as very often extensive high fidelity single point aerodynamic data is available from a fusion of flight tests, wind tunnel measurements and computations whereas in many cases the pressure distribution leading to those forces and moments is not available from the same source or at the same level of fidelity. The algorithm is based on influence coefficients describing the contribution of strips or panels of the aircraft to the total aerodynamic force and moments. To ensure consistence with the single point data set, force and moment constraints for homogeneous, uniform disturbances are formulated and a possible solution for their enforcement is presented. Cross-flow effects due to the inhomogeneous flow conditions in disturbed air however are neglected.

"PREDICTION OF DYNAMIC PAIRWISE VORTEX SEPARATIONS FOR APPROACH AND LANDING"

AIAA Paper No. 2011-3037, June 2011, Honolulu, Hawaii.

Design and performance of the Wake Vortex Prediction and Monitoring System WSVBS are described. The WSVBS has been developed to tactically increase airport capacity for approach and landing on single runways as well as closely-spaced parallel runways. It is thought to dynamically adjust aircraft separations dependent on weather conditions and the resulting wake vortex behavior without compromising safety. Dedicated meteorological instrumentation and short-term numerical terminal weather prediction provide the input to the prediction of wake-vortex behavior and respective safety areas. LIDAR monitors the correctness of WSVBS predictions in the most critical gates at low altitude. The WSVBS is integrated in the arrival manager AMAN of DLR. Performance tests of the WSVBS have

been accomplished at Frankfurt airport in winter 1006/07 and at Munich Airport in summer 2010. Aircraft separations for landings on single runways have been compared employing the concepts of either heavy-medium weight class combinations or dynamic pairwise separations where individual aircraft type pairings are considered. For the very conservative baseline setup of the WSVBS the potential capacity gains of dynamic pairwise operations for single runways appear to be very small. On the other hand, the consideration of individual aircraft types and their respective wake characteristics may almost double the fraction of time when radar separation could be applied.

"AIRCRAFT WAKE VORTEX SCENARIOS SIMULATION PACKAGE -- WAKESCENE"

ICAS 2008, September 2008, Hamburg, Germany.

Wake-vortex advisory systems and modifications of ATC procedures that aim at increasing airport capacity without compromising safety have been developed in recent years. Prior to the introduction of such systems the associated risks must be assessed. The WakeScene (Wake Vortex Scenarios Simulation) Package allows to assess the encounter probability behind different wake-vortex generating aircraft during approach and landing. WakeScene consists of modules that model traffic mix, aircraft trajectories, meteorological conditions, wake vortex evolution, and potential hazard area. This manuscript introduces the operating sequence of WakeScene, the employed sub-models and data bases, the simulation environment and evaluation tools together with the so far accomplished validation work. Examples of WakeScene applications and an outlook on further developments of the software package conclude the report.

"THE TURBULENT DECAY OF WAKE VORTICES IN THE STABLY STRATIFIED ATMOSPHERE"

AIAA Paper No. 2000-0754, Reno, NV, January 2000

The decay of wake vortices in the stably stratified atmosphere is investigated by means of large eddy simulations. Results of in-situ measurements in the wakes of different aircraft are used to find appropriate initializations for the simulation of wake turbulence in the quiescent atmosphere. Furthermore, cases with weak atmospheric turbulence are investigated. It is shown that the early development of the vortices is not affected by turbulence and develops almost identically as in 2D simulations. In a quiescent atmosphere the subsequent vortex decay is controlled by the interaction of short-wave disturbances, owing to the aircraft induced turbulence, and baroclinic vorticity, owing to stable stratification. When in addition also atmospheric turbulence is present, the long-wave instability is dominantly promoted. For very strong stratification ($Fr < 1$) it is observed that wake vortices may rebound but lose most of their strength before reaching the flight level. Finally, the simulation results are compared to the predictive capabilities of Greene's approximate model.

Holzaepfel, F., Gerz, T. and Baumann, R.

"THE TURBULENT DECAY OF TRAILING VORTEX PAIRS IN STABLY STRATIFIED ENVIRONMENTS"

Aerospace Science and Technology, Vol. 5, No. 2, February 2001, pp. 95-108

The decay of trailing vortex pairs in thermally stably stratified environments is investigated by means of large eddy simulations. Results of in-situ measurements in the wakes of different aircraft are used to find appropriate initializations for the simulation of wake turbulence in the quiescent atmosphere. Furthermore, cases with weak atmospheric turbulence are investigated. It is shown that the early development of the vortices is not affected by turbulence and develops almost identically as in 2D simulations of wake vortices in stably stratified environments. In a quiescent atmosphere the subsequent vortex decay is controlled by the interaction of short-wave disturbances, owing to the aircraft induced turbulence, and baroclinic vorticity, owing to stable stratification. Consequently, vertical vorticity streaks between the vortices are induced which are substantially intensified by vortex stretching and finally lead to rapid turbulent wake-vortex decay. When in addition atmospheric turbulence is also present, the long-wave instability is dominantly promoted. For very strong stratification ($Fr < 1$) it is observed that wake vortices may rebound but lose most of their strength before reaching the flight level. Finally, the simulation results are compared to the predictive capabilities of Greene's approximate model.

"THE WAKE VORTEX PREDICTION AND MONITORING SYSTEM WSVBS"

Ninth USA/Europe Air Traffic Management Research and Development Seminar (ATM2011), June 2011, Berlin, Germany.

Design and performance of the Wake Vortex Prediction and Monitoring System WSVBS are described. The WSVBS has been developed to tactically increase airport capacity for approach and landing on single runways as well as closely-spaced parallel runways. It is thought to dynamically adjust aircraft separations dependent on weather conditions and the resulting wake vortex behavior without compromising safety. Dedicated meteorological instrumentation and short-term numerical terminal weather prediction provide the input to the prediction of wake-vortex behavior and respective safety areas. LIDAR monitors the correctness of WSVBS predictions in the most critical gates at low altitude. The WSVBS is integrated in the arrival manager AMAN of DLR. Within 66 days of performance test at Frankfurt airport it was found that the system ran stable and the predicted minimum separation times were correct. The capacity improving concepts of operation could have been used in 75% of the time. From fast-time simulations the eventual capacity gain for Frankfurt was estimated to be 3% considering the real traffic mix and operational constraints in the period of one month. Aircraft separations for landings on single runways have been compared employing the concepts of either heavy - medium weight class combinations or dynamic pairwise separations where individual aircraft type pairings are considered. The consideration of individual aircraft types and their respective wake characteristics may almost double the fraction of time when radar separation could be applied.

"The Decay of Wake Vortices in the Convective Boundary Layer"

AIAA Paper 99-0984, January 1999, Reno, NV.

The decay of three wake vortex pairs of a B-747 aircraft in a convectively driven atmospheric boundary layer is modelled by means of large-eddy simulations. It is shown that parts of the wake vortices may stay on flight level when updraft velocities of thermals compensate the induced descent speeds of the wake vortices. A situation which is considered as being hazardous. On the other hand, the atmospheric turbulence rapidly deforms the vortices on larger scales, and erodes them simultaneously on smaller scales such that coherent vortical structures are essentially destroyed after 70 seconds. Strip theory calculations are used to illustrate the temporal and spatial development of lift and rolling moments experienced by a following medium weight class B-737 aircraft. Characteristics of the respective distributions are analyzed. Initially, the maximum rolling moments slightly exceed the available roll control of the B-737. After 60 seconds the probability of rolling moments exceeding 50% of the roll control, a value which is considered as a threshold for acceptable rolling moments, has decreased to 1% of its initial probability. Twenty seconds later no rolling moments can be found which exceed the critical roll control level.

"WAKE VORTICES IN CONVECTIVE BOUNDARY LAYER AND THEIR INFLUENCE ON FOLLOWING AIRCRAFT"

J. Aircraft, Vol. 37, No. 6, November-December 2000, pp. 1001-1007

The decay of three wake vortex pairs of B-747 aircraft in an evolving and convectively driven atmospheric boundary layer is investigated by means of large-eddy simulations (LES). Convective boundary layers are considered hazardous because the updraft velocities of a thermal may compensate the induced descent speed of the vortex pair such that the vortices stall in the flight path. The LES results illustrate that (1) the primary rectilinear vortices are rapidly deformed on the scale of the alternating updraft and downdraft regions; (2) parts of the vortices stay on flight level but are quickly eroded by the enhanced turbulence of the updraft; (3) the longest living sections of the vortices are found in regions of relatively calm downdraft flow which augments their descent. Strip theory calculations are used to illustrate the temporal and spatial development of lift and rolling moments experienced by a following medium weight class B-737 aircraft. Characteristics of the respective distributions are analyzed. Initially, the maximum rolling moments slightly exceed the available roll control of the B-737. After 60 sec. the probability of rolling moments exceeding 50% of the roll control has decreased to 0.009% in a safety corridor around the glide path.

"THE WAKE VORTEX PREDICTION AND MONITORING SYSTEM WSVBS - PART I: DESIGN"

1st CEAS European Air and Space Conference, Berlin, Germany, September 2007, pp. 3383-3390.

The design of the Wake Vortex Prediction and Monitoring System WSVBS is described with all its components and their interaction. The WSVBS has been developed to tactically increase airport capacity for approach and landing on closely-spaced parallel runways. It is thought to dynamically adjust aircraft separations dependent on weather conditions and the resulting wake vortex behavior without compromising safety. Dedicated meteorological instrumentation and short-term numerical terminal weather prediction provide the input to the prediction of wake-vortex behavior and respective safety areas. The prediction tools employ a number of conservative aircraft parameter combinations that represent the aircraft weight categories medium and heavy. Predictions of the time when all approach corridors along the final approach do not overlap with safety areas determine aircraft separations for follower aircraft of categories medium and heavy. As a safety net a LIDAR monitors the correctness of WSVBS predictions in the most critical gates at low altitude.

"STRATEGIES FOR CIRCULATION EVALUATION OF AIRCRAFT WAKE VORTICES MEASURED BY LIDAR"

Journal of Atmospheric and Oceanic Technology, Vol. 20, No. 8, 2003, pp. 1183-1195.

An assessment of different methods for circulation evaluation from lidar measurement data of aircraft wake vortices is performed. The surface integral of vorticity serves as baseline case that is compared to a method that evaluates the lidar line-of-sight velocity midway between the vortices and to another method that calculates radii-averages of circulations derived from tangential velocities. Systematic deviations from nominal circulation are discussed based on analytical vortices. High-resolution numerical simulation data is applied to perform virtual lidar measurements that reproduce, explain, and quantify (i) the frequently observed initial overestimation of circulation and (ii) the scatter of circulation data caused by the genuine variability of wake vortices in the atmospheric boundary layer. The theoretically derived characteristics of the different evaluation methods are verified against lidar data recorded by several lidar teams during the measurement campaign WakeOP, performed in spring 2001 at special airport Oberpfaffenhofen, Germany.

"ANALYSIS OF WAKE VORTEX DECAY MECHANISMS IN THE ATMOSPHERE"

Aerospace Science and Tech., Vol. 7, Issue 4, June 2003, pp. 263-275

Results of high-resolution numerical simulations of aircraft wake vortex evolution and decay in different regimes and atmospheric conditions are presented. The different cases comprise (i) the near field interaction of a trailing vortex with an exhaust jet, (ii) the evolution of single vortices and counter-rotating vortex pairs in homogeneous isotropic turbulence, as well as (iii) the decay of wake vortices in a turbulent stably stratified atmosphere, and (iv) in a weakly turbulent sheared environment. The different cases are used to analyze common aspects of vortex dynamics and decay mechanisms. In all scenarios the formation of coherent secondary vorticity structures that enclose the primary vortices is observed. These secondary vorticity structures deform and weaken the primary vortices, and in some cases lead to rapid vortex decay. It is shown that the mean swirling flow effectively rearranges and intensifies any secondary vorticity by tilting and stretching. The secondary vorticity may either originate from the turbine jet, ambient turbulence or may be produced baroclinically. Based on the observed phenomena, eleven postulates are established that pinpoint fundamental aspects of the observed decay mechanisms.

"AIRCRAFT WAKE VORTEX EVOLUTION AND DECAY IN IDEALIZED AND REAL ENVIRONMENTS: METHODOLOGIES, BENEFITS AND LIMITATIONS"

Proceedings of the EUROMECH Colloquium, No. 412 on Advances in LES of Complex Flows, Munich, Germany, October 4-6, 2000, pp. 293-30.

After a brief introduction of the governing equations and numerical approaches that are used to simulate wake vortices in the atmosphere associated implications and restrictions are discussed. The complex interaction of turbulence and rotation in the vortex core region is not resolved appropriately and is controlled by the sub-grid scale model. A local Richardson number correction for strong streamline curvature effects is proposed that accounts for stabilizing effects of coherent rotation and reduces vortex core growth rate. Real case simulations demonstrate that LES is capable to reproduce complex wake vortex behavior as the spectacular rebound observed at London Heathrow Int'l Airport. Various idealized cases with stably stratified, turbulent, and sheared environments are used to reveal the mechanisms that control vortex decay.

"OPERATIONAL SCENARIOS FOR WAKE VORTEX ENCOUNTER SAFETY ASSESSMENT WITH WAKESCENE-D"

CREDOS Report D3-8, March 2009, DLR, Oberpfaffenhofen, Germany.

This report delineates operational scenarios that shall be investigated with WakeScene-D to contribute to the definition of safe separation distances for takeoff and departure and to the required quantitative safety assessment. For this purpose, the report first recapitulates the findings obtained from the analysis of the measurement campaigns EDDF-1 and EDDF-2 and from preliminary Monte Carlo simulations conducted with WakeScene-D. The suggested scenarios can be split into (i) sensitivity analyses and validation cases that shall deepen the understanding of WakeScene-D and the confidence into the software package and into (ii) scenarios serving as a reference representing the current

situation and the target scenarios for crosswind reduced separations and the related safety case. A ranking of the relevance of the various possible scenarios has been established with input from CREDOS partners.

"AIRCRAFT WAKE VORTEX SCENARIOS SIMULATION PACKAGE FOR TAKEOFF AND DEPARTURE"

Journal of Aircraft, Vol. 46, No. 2, March-April 2009, pp. 713-717.

The WakeScene-D software package (Wake Vortex Scenarios Simulation Package for Departure) has been developed for comprehensive airspace simulations of take-off and departure. WakeScene-D consists of modules that model traffic mix, aircraft trajectories, meteorological conditions, wake vortex evolution, and potential hazard areas. The software package estimates the probability to encounter wake vortices in different traffic and crosswind scenarios using Monte Carlo simulation in a domain ranging from the runway to an altitude of 3000 ft above ground. The operating sequence of WakeScene-D, the employed sub-models and data bases, the simulation environment and evaluation tools together with the so far accomplished validation work are introduced. The current departure situation with a two-minute aircraft separation is compared to (i) a scenario with reduced separations of one minute, (ii) the mitigation effects of crosswind and (iii) the situation prevailing during approach and landing.

"WAKE-VORTEX TOPOLOGY, CIRCULATION, AND TURBULENT EXCHANGE PROCESSES"

AIAA Paper No. 2010-7992, Toronto, Canada, August 2010.

Large eddy simulations of aircraft wake vortex evolution in various turbulent and stably stratified atmospheric environments have been conducted with two different LES codes. Passive tracers are used to investigate exchange processes between the vortex cores, the vortex oval and its environment as well as redistribution processes along the vortex tubes. A post processing method is employed to identify the vortex center lines even in progressed states of vortex decay where the coherent vortex structure is getting lost. This method allows, for example, analyzing the circulation evolution of vortex rings, establishing statistics of vortex deformation, and revealing the mechanisms of the vortex bursting phenomenon. Vortex bursting is related to the collision of secondary vorticity structures propagating along the vortex lines. In neutrally and weakly stratified environments long-living vortex rings are observed where circulation decay proceeds in three phases. During the initial diffusion phase vortex decay may depend on integral turbulence length scales. On average, the detrainment of a passive tracer from the primary vortices is correlated with circulation decay.

"ENHANCED WAKE VORTEX DECAY IN GROUND PROXIMITY TRIGGERED BY PLATE LINES"

Aircraft Engineering and Aerospace Technology Vol. 88, Issue 2, 2016, pp. 206-214.

Purpose From pilot reports, field measurements and numerical simulations, it is known that wake vortices may persist within the glide path in ground proximity, leading to an increased encounter risk. This paper aims to investigate wake vortex behavior during final approach and landing to understand why landings can be safe nevertheless. Further, it is investigated whether and to which extent the installation of plate lines beyond the runway tails may further accelerate wake vortex decay and thus improve safety by reducing the number of wake vortex encounters.

Holzaepfel, F., Stephan, A., Korner, S. and Misaka, T.

"WAKE VORTEX EVOLUTION DURING APPROACH AND LANDING WITH AND WITHOUT PLATE LINES"

AIAA Paper 2014-0925, January 2014, National Harbor, MD.

Data from numerical simulations and two field measurement campaigns are used to investigate aircraft wake vortex evolution during final approach and landing with and without a plate line. A new hybrid simulation method is employed to capture wake vortex evolution from early roll-up to final decay in ground proximity. Vortex decay is driven by the turbulence of the aircraft wake itself, the interaction of the wake vortices with the ground, the so-called end effects triggered by the sudden loss of lift during touchdown, and it is artificially augmented by a plate line installed a few hundred meters from the runway threshold. The field experiments WakeMUC at Munich airport and WakeOP at special airport Oberpfaffenhofen corroborate and complement the findings of the simulations. The end effects together with an acceleration of the decay in close ground proximity significantly accelerate vortex decay nearby the runway. Since the probability to encounter wake vortices is distinctly increased in ground effect, the described mechanisms ensure the required safety of air traffic operations. Experiments and simulations demonstrate that plate lines appreciably accelerate wake vortex decay and interfere favorably with end effects. This way safety can be further increased during the flight phase with most reported encounters.

Holzaepfel, F., Stephan, A., Tchipev, N., Heel, T., Korner, S. and Misaka, T.

"IMPACT OF WIND AND OBSTACLES ON WAKE VORTEX EVOLUTION IN GROUND PROXIMITY"

AIAA Paper 2014-2470, June 2014, Atlanta, GA.

Data from different numerical simulations and field measurement campaigns are used to investigate aircraft wake vortex evolution in ground proximity. A new hybrid simulation method is employed to capture wake vortex evolution from early roll-up to final decay in ground proximity. The method is applied to investigate effects of very low flight altitudes and the sudden loss of lift during touchdown. The investigations also comprise a parameter study of vortex behavior at different wind directions and strengths (headwind, crosswind, and combinations thereof) where the vortices are generated at a height of one initial vortex separation above ground. Furthermore, it is shown that vortex decay in ground proximity can be accelerated by the installation of plate lines at distances of a few hundred meters from the runway threshold. Field measurement data gathered during the campaigns WakeMUC at Munich airport and WakeOP at special airport Oberpfaffenhofen corroborate and complement the findings of the simulations. Experiments and simulations demonstrate that plate lines appreciably accelerate wake vortex decay and interfere favorably with end effects. This way safety case can be further increased during the flight phase with most reported encounters.

"WIND IMPACT ON SINGLE VORTICES AND COUNTERROTATING VORTEX PAIRS IN GROUND PROXIMITY"

AIAA Paper 2015-3174, June 2015, Dallas, TX.

Wall-resolved large eddy simulations are employed to investigate the behavior of wake vortices and single vortices in ground proximity at a variety of wind conditions. The six considered strengths of wind, ranging between 0.5 and 4 times the initial wake vortex descent speed include practically and theoretically significant wind speeds. A crosswind of 0.5 times the vortex descent speed may lead to windward stall posing a potential hazard to subsequently landing aircraft, whereas theoretical considerations predict that at 4 times the vortex descent speed the rebound of the luff vortex is completely suppressed. The same range of wind speeds is also used to investigate the effects of headwind and diagonal wind to discriminate between effects of environmental turbulence increasing with wind speed and the direction of the wind shear. The study has been complemented by several single vortex computations to differentiate between effects related to the mutual interaction of the vortex pair and the individual vortices with the turbulent boundary layer flow. It is shown that vortex ascent, descent, rebound, and decay characteristics are controlled by (i) the interaction of the vortices with secondary vorticity detaching from the ground and (ii) redistribution of vorticity of the boundary layer which is altering the path of the primary vortices by mutual velocity induction.

"Wind Impact on Single Vortices and Counterrotating Vortex Pairs in Ground Proximity"

Flow, Turbulence and Combustion, Vol. 97, Issue 3, October 2016, pp 829 848, DOI: 10.1007/s10494-016-9729-2

Wall-resolved large eddy simulations are employed to investigate the behavior of wake vortices and single vortices in ground proximity at a variety of wind conditions. The six considered strengths of wind, ranging between 0.5 and 4 times the initial wake vortex descent speed, w_0 , include practically and theoretically significant wind speeds. A crosswind of 0.5 w_0 may lead to windward stall posing a potential hazard to subsequently landing aircraft, whereas theoretical considerations predict that at 4 w_0 the rebound of the luff vortex is completely suppressed. The same range of wind speeds is also used to investigate the effects of headwind and diagonal wind to discriminate between effects of environmental turbulence increasing with wind speed and the direction of the wind shear. The study has been complemented by several single vortex computations to differentiate between effects related to the mutual interaction of the vortex pair and the individual vortices with the turbulent boundary layer flow. It is shown that vortex ascent, descent, rebound, and decay characteristics are controlled by (i) the interaction of the vortices with secondary vorticity detaching from the ground, (ii) the redistribution of vorticity of the boundary layer which is altering the path of the primary vortices by mutual velocity induction, and (iii) the interaction of the vortices with the environmental turbulence.

"APPLICATION OF LIDAR-DERIVED EDDY DISSIPATION RATE PROFILES IN LOW-LEVEL WIND SHEAR AND TURBULENCE ALERTS AT HONG KONG INTERNATIONAL AIRPORT"

Meteorological Applications, Vol. 21, 2014, pp. 74-85.

In aviation meteorology, eddy dissipation rate (EDR) is an internationally-adopted metric for quantifying intensity of low-level turbulence (rapid, irregular headwind fluctuations experienced by an aircraft below 1600 feet/500 m). In this paper, calculations of EDR to the 1/3 power profiles along arrival corridors (07LA, 25RA) of the Hong Kong International Airport (HKIA) were performed over a 45-month period (January to September, 2008-2012) based on radial velocity from a scanning Doppler LIDAR using the azimuthal velocity structure function approach. The quality of the LIDAR-estimated EDR was established by comparison with values calculated from in situ measurements over a 24-month period, which showed that median values of EDR profiles from both sources fell within 0.05 m to the 2/3 power per second of each other in over 90 percent (80 percent) of instances for 07LA (25RA). The performance in threshold-based alerting of low-level turbulence at HKIA was then validated against pilot reports. At alert duration of 10 percent, alerts based on the maximum value of an EDR profile could capture over 90 percent (80 percent) of reported events over 07LA (25RA), while comparable performance with the wind shear and turbulence warning system (WTWS) at HKIA was attainable using suitable alert thresholds. Positive skill, albeit inferior to WTWS, was also observed in the alerting of low-level wind shear (sustained headwind change of 15 knots or above below 1600 feet/500 m) with a hit rate of about 70 percent at alert duration of 10 percent. This study served to establish the value of EDR derived from ground-based remote-sensing instruments e.g. LIDAR in alerting of low-level turbulence for the aviation community.

"NATURAL SNOWFALL REVEALS LARGE-SCALE FLOW STRUCTURES IN THE WAKE OF A 2.5-MW WIND TURBINE"

Nature Communications, Vol. 5, June 2014, pp. 4216-1 to 4216-9.

To improve power production and structural reliability of wind turbines, there is a pressing need to understand how turbines interact with the atmospheric boundary layer. However, experimental techniques capable of quantifying or even qualitatively visualizing the large-scale turbulent flow structures around full-scale turbines do not exist today. Here we use snowflakes from a winter snowstorm as flow tracers to obtain velocity fields downwind of a 2.5-MW wind turbine in a sampling area of about 36x36 square meters. The spatial and temporal resolutions of the measurements are sufficiently high to quantify the evolution of blade-generated coherent motions, such as the tip and trailing sheet vortices, identify their instability mechanisms and correlate them with turbine operation, control, and performance. Our experiment provides an unprecedented in situ characterization of flow structures around utility-scale turbines, and yields significant insights into the Reynolds number similarity issues presented in wind energy applications.

"STREAMWISE VORTICITY IN SIMPLE MECHANICAL FLAPPING WINGS"

TheJournal of Aircraft, Vol. 44, No. 5, September-October 2007, pp. 1588-1597.

The presence of streamwise vorticity in the vicinity of the wing tip contributes to lift in thin flat plate zero pitch angle flapping wings in quiescent air. In creating flapping wing micro air-vehicles it is desirable to maintain only the mechanical and kinematic complexity that is absolutely necessary to artificially duplicate flapping wing flight. This study quantifies the lift generated from a flapping motion of absolute minimum complexity thought to be capable of generating lift. Using a flapping wing micro air vehicle with wings fabricated in-house, streamwise vortices were identified along the span of wings of various aspect ratios and at numerous different points throughout the flapping cycle under a variety of operating conditions. The lift generated by the flapping mechanism was quantified experimentally using a force transducer and a high-speed camera. Digital particle image velocimetry was used to determine the contributions of streamwise to the total measured lift. Further evidence was found of the importance of the relationship between wing span and flapping frequency in the nature of the formation and shedding of vortices.

"IMPROVED UNDERSTANDING OF EN ROUTE WAKE-VORTEX ENCOUNTERS"

Journal of Aircraft, Vol. 52, No. 3, May-June 2015, pp. 981-989.

Wake turbulence can be experienced by aircraft when encountering the wake vortex of another aircraft. The aim of this study is to improve the understanding of the risk posed by en route wake-vortex encounters in the en route flight phase. To quantify this risk, a simulation framework has been conceived that makes use of recorded historical surveillance data and computes the wake-vortex trajectory and decay for each aircraft based on a wake-vortex model. The simulation has been validated and subsequently used to determine the probability of encountering a wake vortex in upper European airspace. The simulation results bear out that a severe wake-vortex encounter can be expected approximately once every 30 days. Three factors have been identified that contribute to the risk of encountering a wake vortex during the en route phase of flight, viz., the characteristics of the exposed or generating aircraft, the encounter geometry, and the prevailing tropopause height in the atmosphere. The combined time evolution of these three factors suggests that the en-route wake-vortex encounter risk may increase in the future. Finally, both short-term and long-term mitigation measures are proposed that can potentially reduce the severity of wake-vortex encounters or even prevent their occurrence.

Hopkins, H.

"VORTEX STUDIES: CLOSING THE GAP"

Jane's Airport Review, Vol. 6, No. 2, March 1994, pp. 27-28

Most of the basic research work has been done in the US, but two studies in Europe have focused on operational questions. The UK's Civil Aviation Authority (CAA) first started vortex reporting by pilots in 1972. A study of data, mainly at London Heathrow from 1982-1990, is now a unique source of day-to-day events, albeit relating to local types and weather. The German research agency DLR has been using

a modified scanning laser doppler anemometer, ranging up to 1000m with elevation accuracy of 0.2 degrees; it was sited 850m in from the easterly thresholds at Frankfurt between parallel runways separated by 518m. The findings are said to be relevant for runways up to 750m apart. Roll rates imposed by vortices can exceed the roll control of an average aircraft - a maximum rate of 15 degrees is typical on approach, which equates to 4m/s at 15m tip distance.

"IMPLEMENTATION OF A FREE-VORTEX WAKE MODEL IN REAL-TIME SIMULATION OF ROTORCRAFT"

Journal of Aerospace Computing, Information and Communication, Vol. 3, March 2006, pp. 93-114.

Free-vortex wake models are capable of providing an accurate and physically detailed representation of the main rotor wake for flight dynamics simulation. Recent advances in computing power and efficient algorithms have made it feasible to use free wakes for real-time simulation. The CHARM free-vortex wake model was integrated with the GENHEL flight dynamics simulation of the UH-60A helicopter. A high-fidelity wake model was defined by increasing the spatial and temporal resolution of the wake until a converged response was observed, but this baseline model could not execute in real-time. A parametric study was performed to find the best combination of wake parameters to achieve real-time execution with minimal deviation from the baseline model in terms of the frequency and time responses in the pitch and roll axes. A real-time model was found and showed reasonable agreement with the baseline model as compared to a single finite-state inflow model. A parallel implementation of the free-wake model was also investigated. An increase in computational efficiency could be achieved using a distributed processing approach with asynchronous communications.

"AN EXAMINATION OF VORTEX DEFORMATION DURING BLADE-VORTEX INTERACTION UTILISING PARTICLE IMAGE VELOCIMETRY"

ICAS 1994, Paper No. 3.4.5, September 1994, Anaheim, CA.

The results of a Blade-Vortex Interaction (BVI) study incorporating Particle Image Velocimetry (PIV) are presented. Test cases encompass a variety of intersection geometries, including head-on parallel interactions. Results provide quantified flow visualization images of the flows generated during interactions. The deformation and division of the interaction vortex during head-on interactions is documented. In addition, secondary vortical structures generated during interactions are observed and their effect upon the interaction vortex is examined. All PIV results are examined in the light of understanding gained from previous pressure measurements made from the same BVI facility.

"TIP VORTEX DESTABILIZATION WITH AND WITHOUT WINGLETS"

Proceedings in Applied Mathematics and Mechanics, Vol. 6, 2006, pp. 869-870.

Wake vortices are an inevitable by-product of lift. Another airplane following too closely can be dangerously influenced by induced rolling moments. Consistent adherence to the prescribed safety margins ensures safe flight, however it also obstructs the capacity of large airports. To remedy the expected future capacity problems, research is being carried out world-wide. This paper describes some results of the research work to decrease the hazard of the vortex wake accomplished at the Institute.

Hornschemeyer, R., Neuwerth, G. and Henke, R.

"INFLUENCING AIRCRAFT WING VORTICES"

Flow Modulation and Fluid-Structure Interaction, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 109, 2010, pp. 181-204.

The goal of this project was to gain better understanding of aircraft wake vortices to investigate possibilities to mitigate the hazard posed by these to following aircraft. To this end wind tunnel testing was undertaken in which the vortex wakes of various wings were measured using hot wire anemometry. It was shown that in the near field, the rolling moment induced on a following aircraft can be significantly reduced by introducing additional turbulence into the wake. Another focus point was the investigation into excitation of short-wave instability mechanisms in the vortex wake and their effects in the far field. For these purposes experiments with various models and oscillating control surfaces were conducted in water towing tanks in which the vortex wakes were measured using particle image velocimetry. The results show that for an appropriate multi-vortex system, inherent instabilities can be excited leading to a more rapid vortex decay within the first 30 spans lengths behind the model. The effects of these mechanisms further out in the far field are, however, minimal.

"ACTIVE MANIPULATION OF A RECTANGULAR WING VORTEX WAKE WITH OSCILLATING AILERONS AND WINGLET-INTEGRATED RUDDERS"

New Results in Numerical and Experimental Fluid Mechanics VI, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 96, 2008, pp. 44-51.

This paper presents results of experimental investigations regarding the vortex wake of a rectangular wing with winglets in a water towing tank. The model comprises ailerons and additional rudders, which are integrated into the winglets. The ailerons and the rudders can oscillate around a static deflection to excite inherent short-wavelength instabilities in the vortex system. The Particle Image Velocimetry method is used to investigate the vortex wake up to about 40 spans behind the model. The results show that, depending on the preselected aileron and rudder deflections, an oscillation of correctly chosen frequency leads to a faster decay of the vortex wake in comparison to the static case.

"WAKE DEVELOPMENT BEHIND PAIRED WINGS WITH TIP AND ROOT TRAILING VORTICES: CONSEQUENCES FOR ANIMAL FLIGHT FORCE ESTIMATES"

PLoS ONE, Vol. 9, Issue 3, March 2014, pp. e91040-1 to e91040-9.

Recent experiments on flapping flight in animals have shown that a variety of unrelated species shed a wake behind left and right wings consisting of both tip and root vortices. Here we present an investigation using Particle Image Velocimetry (PIV) of the behavior and interaction of trailing vortices shed by paired, fixed wings that simplify and mimic the wake of a flying animal with a non-lifting body. We measured the flow velocities at five positions downstream of two adjacent NACA 0012 airfoils and systematically varied aspect ratio, the gap between the wings (corresponding to the width of a non-lifting body), angle of attack, and the Reynolds number. The range of aspect ratios and Reynolds number were chosen to be relevant to natural fliers and swimmers, and insect flight, in particular. We show that the wake behind the paired wings deformed as a consequence of the induced flow distribution such that the wingtip vortices move downwards while the root vortices twist around each other. Vortex interaction and wake deformation became more pronounced further downstream of the wing, so the positioning of PIV measurement planes in experiments on flying animals has an important effect on subsequent force estimates due to rotating induced flow vectors. Wake deformation was most severe behind wings with lower aspect ratios and when the distance between the wings was small, suggesting that animals that match this description constitute high-risk groups in terms of measurement error. Our results, therefore, have significant implications for experimental design where wake measurements are used to estimate forces generated in animal flight. In particular, the downstream distance of the measurement plane should be minimized, notwithstanding the animal welfare constraints when measuring the wake behind flying animals.

"STUDY OF HIGH ALTITUDE AIRCRAFT WAKE DYNAMICS: TASK 1, PROBLEM DEFINITION"

DOT-TST-90-3, December 1972, Lockheed Research Laboratory, Palo Alto, CA.

The important features of chemically reacting aircraft wakes have been identified. The aircraft wake is modeled in terms of the jet regime (wake age about 10 seconds), vortex regime (wake age about 100 seconds), and the wake dispersion regime (wake age about 100 seconds). The important thermochemical reactions were found to take place in the jet regime.

Hoshizaki, H., Redler, K. O., Meyer, J. W., Conti, R. J. and Anderson, L. B.

"STUDY OF HIGH ALTITUDE AIRCRAFT WAKE DYNAMICS, MODEL DEVELOPMENT"

DOT-TST-73-5, January 1973, Lockheed Palo Alto Research Lab., Palo Alto, CA

A chemically-reacting wake model computer program has been formulated. The wake model program computes the wake height and width from the jet engine nozzle to the point in time where

aerodynamic perturbations are small. The program also predicts the detailed chemical reactions that occur in the jet exhaust flow field.

Houbolt, J. C.

"ATMOSPHERIC TURBULENCE"

AIAA Journal, Vol. 11, No. 4, April 1973, PP. 421-437.

Atmospheric turbulence and its influence on the flight and design of aircraft is reviewed. Coverage includes accidents and costs incurred as a result of turbulence, the mechanisms of turbulence measurements that are made, aircraft response and design procedures due to turbulence encounters, and loads alleviation devices. Basic research notions associated with the interpretation of turbulence data, some of which are controversial, and areas of weakness, are also discussed.

Houbolt, J. C.

"AIRCRAFT RESPONSE TO TURBULENCE INCLUDING WAKES"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 509-522

The nature of atmospheric turbulence and the means for establishing aircraft response is reviewed, both from discrete-gust and spectral interpretations. Application is then made to the situation of wake turbulence encounter to show the nature and magnitude of the loads that result. Specific cases are treated, with encounters perpendicular to and parallel to the wake, to bring out the main parameters that are significant. General relations are also developed to show how the wake 'gust' forces on the encountering airplane are related to the lift on the airplane generating the wake. It is shown that normal loads in excess of 2 g's may be produced by a perpendicular encounter of a wake vortex, and that uncontrollable rolling moments may be caused by encounters along the axis of a vortex.

Houston, S. S. and Brown, R. E.

"ROTOR-WAKE MODELING FOR SIMULATION OF HELICOPTER FLIGHT MECHANICS IN AUTOROTATION"

Journal of Aircraft, Vol. 40, No. 5, September-October 2003, pp. 938-945.

Rotorcraft flight mechanics simulations typically use finite-state induced velocity models to mimic the effect of the rotor wake on blade loads. However, with recent developments in computational methods coupled flight mechanics and comprehensive rotor-wake analyses have become more tractable. This paper compares results from a finite-state induced velocity model with a vorticity transport wake model that computes the flow field in a domain around the aircraft. The study focuses on flight mechanics in autorotation. Simple parameter estimation using three- and five-state induced velocity model structures facilitates interpretation of the vorticity transport induced velocity field as well as providing a direct comparison with the finite-state model. Comparisons of performance, trim, and control response indicate that there is little difference between the two models where the

autorotative descent is shallow. However, as airspeed reduces the descent angle steepens, and clear discrepancies become apparent. These are directly related to a single parameter in the finite-state model. It is concluded that finite-state models are adequate for much of the autorotation regime, but for low speeds in steep descents the improved resolution of the rotor inflow provided by more comprehensive rotor-wake models might be essential.

Howard, K. B. and Guala, M.

"CHARACTERIZING THE EFFECTS OF INFLOW ON A 2.5 MW RESEARCH UTILITY TURBINE"

AIAA Paper 2016-1400, January 2016, San Diego, CA.

A series of field experiments conducted at the Eolos wind research facility studied the impact of inflow conditions on a utility scale wind turbine. This research strives to answer (i) how wind at various elevations influences the turbine's power production and (ii) what effects wind gusts have on individual blade loading. The Eolos test facility is operated by the University of Minnesota's Saint Anthony Falls Laboratory (SAFL) and is home to a 2.5-megawatt (MW) Clipper Liberty C96 wind turbine and meteorological tower. In addition to the flow information provided by the meteorological tower, on site we have a WindCube LIDAR wind profiler, allowing wind data to be gathered at any desired location on site. The wind data coupled with the time history of the power output and ten strain gauges located in each of the blades provided us with the ability to track the effect of wind gusts on the power production as well as the blade structural loading. We hope this information along with the correlation of wind at different elevations to the power output will help the wind turbine controls community mitigate fatigue loads while maintaining or increasing power production.

Howe, M. S.

"ON THE SCATTERING OF SOUND BY A RECTILINEAR VORTEX"

Journal of Sound and Vibration, Vol. 227, Issue 5, November 1999, pp. 1003-1017.

A re-examination is made of the two-dimensional interaction of a plane, time-harmonic sound wave with a rectilinear vortex of small core diameter at low Mach number. Sakov and Ford and Smith have independently resolved the 'infinite forward scatter' paradox encountered in earlier applications of the Born approximation to this problem. The first order scattered field (Born approximation) has nulls in the forward and back scattering directions, but the interaction of the wave with non-acoustically compact components of the vortex velocity field causes wavefront distortion, and the phase of the incident wave to undergo a significant variation across a parabolic domain whose axis extends along the direction of forward scatter from the vortex core. The transmitted wave crests of the incident wave become concave and convex, respectively, on opposite sides of the axis of the parabola, and focusing and defocusing of wave energy produces corresponding increases and decreases in wave amplitude. Wave front curvature decreases with increasing distance from the vortex core, with the result that the wave amplitude and phase are asymptotically equal to the respective values they would have attained in the absence of the vortex. The transverse acoustic dipole generated by translational motion of the

vortex at the incident wave acoustic particle velocity, and the interaction of the incident wave with acoustically compact components of the vortex velocity field, are responsible for a system of cylindrically spreading, scattered waves outside the parabolic domain.

Howe, M. S.

"LECTURES ON THE THEORY OF VORTEX-SOUND"

Lecture Notes in Physics, Vol. 586, 2002, pp. 31-111

The theory of vortex sound is introduced. From Lighthill's acoustic analogy, it is shown how vorticity and entropy fluctuations can be seen as sources of sound. The use of the compact Green's functions is introduced to compute the vortex sound. As an example of the method presented, this theory is applied to pressure transients generated by high-speed trains.

Hrynuk, J. T., Van Luipen, J. and Bohl, D.

"FLOW VISUALIZATION OF A VORTEX RING INTERACTION WITH POROUS SURFACES"

Physics of Fluids, Vol. 24, 2012, pp. 037103-1 - 037103-17.

The interaction of vortex rings of constant Reynolds number with porous surfaces composed of wire meshes of constant open area, i.e., surface porosity, but variable wire diameter is studied using flow visualization. The results indicate that several regimes of flow behavior exist in the parameter space investigated. The vortex ring passes through and immediately reforms downstream of the surface for porous surfaces with small wire mesh diameters. The transmitted vortex ring has the same diameter, but lower convection speed and circulation than the pre-interaction vortex ring. For these cases, secondary vortex rings are formed on the upstream side of the porous surface that move upstream away from the screen. As the wire diameter of the porous surface is increased, smaller sub-scale vortical structures are formed on the transmitted vortex ring as it passes through the surface. The spatial scale of these structures is dependent on the diameter of the mesh wire. The vortex ring is disrupted but is able to reform downstream when these structures are small compared to the scale of the vortex ring. When these structures are large enough the transmitted vortex ring is disrupted and does not reform. The results indicate that the dynamics governing the vortex ring/mesh surface interaction are dependent not only on the strength of the vortex ring and the porosity of the surface, as previously thought, but also on the length scales (i.e., the diameter and spacing of the wire mesh) of the porous surface.

Hsiao, C.-T. and Pauley, L. L.

"STUDY OF TIP VORTEX CAVITATION USING NAVIER-STOKES COMPUTATION AND BUBBLE DYNAMICS MODEL"

Journal of Fluids Engineering, Vol. 121, March 1999, pp. 198-204.

The Rayleigh-Plesset bubble dynamics equation coupled with the bubble motion equation developed by Johnson and Hsieh was applied to study the real flow effects on the prediction of cavitation inception in tip vortex flows. A three-dimensional steady-state tip vortex flow obtained from a Reynolds-Averaged Navier-Stokes computation was used as a prescribed flow field through which the bubble was passively convected. A 'window of opportunity' through which a candidate bubble must pass to be drawn into the tip-vortex core and cavitate was determined for different initial bubble sizes. It was found that bubbles with larger initial size can be entrained into the tip-vortex core from a larger window size and also had a higher cavitation inception number.

Hsiao, C.-T. and Pauley, L. L.

"NUMERICAL STUDY OF THE STEADY-STATE TIP VORTEX FLOW OVER A FINITE-SPAN HYDROFOIL"

Journal of Fluids Engineering, Vol. 120, June 1998, pp. 345-353.

The flow over a finite-span hydrofoil creating a tip vortex was numerically studied by computing the full Navier-Stokes equations. A good agreement in pressure distribution and oil flow pattern was achieved between the numerical solution and available experimental data. The steady-state roll-up process of the tip vortex was described in detail from the numerical results. The effect of the angle of attack, the Reynolds number, and the hydrofoil planform on the tip vortex was investigated. The axial and tangential velocities within the tip-vortex core in the near-field wake region were greatly influenced by the angle of attack. A jet-like profile in the axial velocity was found within the tip-vortex core at high angle of attack, while a wake-like profile in the axial velocity was found at low angle of attack. Increasing the Reynolds number was found to increase the maximum axial velocity, but only had a slight impact on the tangential velocity. Finally, a swept hydrofoil planform was found to attenuate the strength of the tip vortex due to the low-momentum boundary layer traveling into the tip vortex on the suction side.

Hsiao, F.-B., Cheng, C.-Z., Liu, W.-J. and Hsu C.-C.

"EXPERIMENTAL STUDY OF TURBULENT WAKE FLOW DEVELOPMENT BEHIND A FINITE WING WITH HIGH ANGLE OF ATTACKS"

ICAS 2002, Sept. 2002, Toronto, Canada, pp. R1-R24.

The experimental approaches are employed to investigate the wake development of finite wing with aspect ratio 3. The stream-wise and transverse velocities in the wake region are measured by the X-shaped hotwire. In the present experimental results, the wake of the finite wing in the near field could be divided into two parts in the span-wise direction. One region is with the same behaviors as those of 2-D wake and the other is affected by the wing-tip vortex. In the 2-D region, the flow field is obviously affected by the downwash. By the comparison the downwash rates of experimental results and those by theoretical analysis, a good consistence could be found. The similarity distribution of mean velocity and root-mean-square velocity could also be observed in the region. Comparing the maximum defective velocity, we found it to be proportional to one over the square root of the distance, which is

compatible with what happens in the 2-D turbulent wake. In the 3-D region, the low-pressure region will form as the result of the development of the wing tip vortices to the downstream. Hence it will suck the fluid upstream and the average velocity measured will be larger than that of free stream. According to the downstream evolution of velocity contours, the development of trailing vortices could be divided into growing, saturating, and decaying processes.

Hsu, T.-M. and Wu, J. C.

"THEORETICAL AND NUMERICAL STUDIES OF A VORTEX-AIRFOIL INTERACTION PROBLEM"

AIAA Paper No. 1986-1094, Atlanta, GA, May 1986

Three different approaches have been utilized to study the vortex-airfoil interaction problem: a theoretical approach, a simplified vortical flow numerical approach, and a fully viscous numerical approach. In the first two approaches, a viscous theorem of aerodynamics is successfully utilized to identify and to assess the individual contributions to unsteady aerodynamic forces from various vortical flow components in attached interaction flow fields. In the fully viscous study, various important features of laminar and turbulent interactions in both attached and separated flows are examined through the numerical solution of the Navier-Stokes equations. The three approaches represent different levels of approximation and are utilized together to establish a comprehensive understanding of the problem. Along with the study of the vortex-airfoil interaction problem, several new schemes are developed for unsteady flow computations. New formulas are derived for computing the unsteady flow trailing edge conditions. A new, highly efficient, iteration scheme for solving the Navier-Stokes equations in high Reynolds flows is established.

"A FULL-SPAN FREE-WAKE MODEL USING CIRCULAR-ARC VORTEX ELEMENTS AND INCORPORATING ROTOR TRIM ANALYSIS"

Proceedings of the Institution of Mechanical Engineering, Part G: Journal of Aerospace Engineering, Vol. 220, No. 2, 2006, pp. 145-163.

An analytic method incorporating a free-wake analysis with a rotor trim algorithm is developed for predicting rotor wake geometry and blade loading distribution for a helicopter in hover and forward flight. The wake model of this method is based on a multi-filament full-span free wake, using sophisticated circular-arc vortex elements. The blade model is based on the second-order lifting line theory to improve the calculation of three-dimensional tip effects. A rotor trim method is given, based on the finite-difference approximation of the blade flapping motion and the Jacobian matrix. This is subsequently coupled into the free-wake model. In order to demonstrate the capability of the coupled method, comparisons between the calculated results and the available experimental data of the rotor blade flapping motion for a model rotor are presented covering conditions from hover through forward flight. The free-wake geometry and the blade loading distribution at a low advance ratio are calculated

for the H-34 helicopter rotor, and the blade loading distribution is compared with both the measured data and calculated results based on the undistorted wake.

Hu, X. and Zhang, G.

"INVESTIGATION OF LAMB-OSEEN VORTEX EVOLUTION AND DECAY IN GROUND PROXIMITY WITH OBSTACLE"

Journal of Fluids Engineering, Vol. 141, January 2019, pp. 011203-1 to 011203-9.

The physical mechanism for the evolution and decay of Lamb-Oseen vortex pair in ground proximity with an obstacle has been investigated in detail by adopting the large eddy simulation (LES). In the present research, we mainly focus on the vortex evolution and decay mechanism in ground proximity with obstacle, so we chose one fixed height of the obstacle case ($h_{sub 0} = 0.5 (b_{sub 0})$) to investigate, and the obstacle is placed transversally to the axis of the primary wake to be analyzed. The trajectories of the primary wake-vortex cores and the circulation profiles, as well as the distribution of the tangential velocity on different axial positions, have been specifically captured and analyzed. The 'stroke' 'claw,' and 'ivory' vortices have been newly found and defined at the initial evolution stage, and they subsequently begin to harshly wind and rotate with the primary vortex. A flow structure with double helix conical shapes of the primary vortex has been found in the obstacle case. The pressure waves along the vortex axis have also been analyzed in detail. The wake-vortex on each side would be pulled in opposite axial directions and eventually pinched off at the upper surface of obstacle. Moreover, it has also been newly found that the trajectories of the wake-vortex in longitudinal directions at different axial distances away from the obstacle will experience two kinds of motion: only descending and rebounding after descending. Results obtained in this study provide a better understanding of mechanisms for the interaction of wake-vortex and the obstacle.

Huang, A.

"WAKES OF ROTORCRAFT MANEUVERING IN GROUND EFFECT"

Georgia Inst. of Technology, Atlanta, GA, 2001

The aerodynamic characteristics of rotorcraft maneuvering in ground effect are investigated to better understand and quantify the flow field structures and unsteadiness associated with various in ground effect flight conditions. The computational modeling to simulate in ground effect in hover and forward flight is being developed. These prediction models will be refined and validated with experimental results. Experimental investigations will involve flow visualization, velocity, pressure, and loads measurements aimed at examining the airflow and wake behavior associated with in ground effect. A literature study of the past research pertaining to ground effect flows has been conducted, including influences on the flow fields, rotor induced velocity, force and moment variations, tip vortex geometry, and ground vortex formation due to the ground. A simple analytical calculation has been performed to estimate the time scales for the blade tip vortex to reach the ground and recirculate back to the rotor.

For robust prediction models to exist, a good agreement between measured, computed, and analytical results is essential.

Huang, J. F., Zhou, Y. and Zhou, T.

"THREE-DIMENSIONAL WAKE STRUCTURE MEASUREMENT USING A MODIFIED PIV TECHNIQUE"

Experiments in Fluids, Volume 40, Issue 6, June 2006, pp. 884-896

Three-dimensional vortical structures have been measured in a circular-cylinder wake using particle imaging velocimetry (PIV) for the Reynolds number range of 2000 to 10,000. The PIV was modified, compared with the conventional one, in terms of its light sheet arrangement to capture reliably streamwise vortices. While in agreement with previous reports, the presently measured spanwise structures complement the data in the literature in the streamwise evolution of the near-wake spanwise vortex in size, strength, streamwise and lateral convection velocities, shedding new light upon vigorous interactions between oppositely signed spanwise structures. The longitudinal vortices display mushroom patterns in the (x, z) -plane in the immediate proximity to the cylinder. Their most likely inclination in the (x, y) -plane is inferred from the measurements in different (x, z) planes. The longitudinal vortices in the (x, z) -plane show alternate change in sign, though not discernible at $x/d > 15$. They decay in the maximum vorticity and circulation rapidly from $x/d = 5$ to 10, and are further compared with the spanwise vortices in size, strength and rate of decay.

Huang, M.-J.

"DIFFUSION VIA SPLITTING AND REMESHING VIA MERGING IN VORTEX METHODS"

International J. for Numerical Methods in Fluids, Vol. 48, June 2005, pp. 521-539

The technique of splitting a fat vortex element (with a core width larger than some threshold) into some thin ones in order to fix the convergence problem of the core-spreading vortex methods is convenient and efficient. In particular, it keeps the method purely Lagrangian. In the present investigation, the splitting process is further viewed as part of the physical diffusion process. A new splitting method in which several weaker child vortices surround a thinned but still strong parent vortex is proposed. It is found that because of the survival of the parent vortex, the error arising from the splitting events can be largely reduced. The computational amount on the other hand is kept reasonably large by merging similar and close-by vortices. The merging scheme designed herein not only involves fewer restrictions but also allows merging vortices of opposite rotations through the viewpoint of remeshing. The validity and accuracy of these techniques, proposed particularly for simulations undergoing lots of splitting and merging events, are verified by successfully simulating the interactions between two Burgers vortices under an external straining field.

Huang, R. F. and Lee, H. W.

"TURBULENCE EFFECT ON FREQUENCY CHARACTERISTICS OF UNSTEADY MOTIONS IN WAKE OF WING"

AIAA Journal, Vol. 38, No. 1, January 2000, pp. 87-94

The influences of the freestream turbulence intensity on the frequency characteristics of the instability wave and vortex shedding in the wake of a NACA 0012 wing model are studied experimentally. The functional relationships among the Strouhal, Roshko, and Reynolds numbers in the viscous-effect-dominated and the inertial-effect-dominated regimes are obtained. The freestream turbulence has apparent effect on the Strouhal and Roshko numbers in the regimes of instability wave and laminar and subcritical vortex-shedding modes that are obtained at low Reynolds numbers. However, at large Reynolds numbers in the supercritical vortex-shedding mode, particularly at large angles of attack, the effect of freestream turbulence intensity on the frequency selection is not significant. For the instability wave, the Roshko number decreases with the increase of freestream turbulence and then approaches constant values when the freestream turbulence intensity is larger than a critical value between 0.45 and 0.5%. However, the Strouhal number of the vortex shedding of laminar and subcritical modes increases significantly with an increase of turbulence intensity and then decreases when the freestream turbulence intensity is larger than a critical value between 0.45 and 0.5%. The change of the characteristic surface flow modes may contribute to the dominant mechanism of the existence of critical freestream turbulence intensity.

Huang, S.

"COMPARISON OF RAPID UPDATE CYCLE (RUC) MODEL CROSSWINDS WITH LIDAR CROSSWIND MEASUREMENTS AT ST. LOUIS LAMBERT INTERNATIONAL AIRPORT"

Proc.13th Conference on Aviation, Range and Aerospace Meteorology, New Orleans, LA, January 2008

Wake turbulence from departing and landing aircraft pose a safety hazard, including aircraft operating on Closely Spaced Parallel Runways (CSPRs). Aircraft separation standards are imposed to mitigate this potential risk. The FAA and NASA are sponsoring a development program for establishing wind-dependent procedures for improved departure operations that safely reduce spacing restrictions to allow increased airport operating capacity. These procedures are referred to collectively as Wake Turbulence Mitigation for Departures (WTMD). An important component of WTMD is a Wind Forecast Algorithm (WFA) being developed by MIT Lincoln Laboratory which predicts when runway crosswinds will persistently remain favorable for WTMD procedures. For winds up to 300 m AGL (the nominal height at which aircraft departing from parallel runways diverge and alternate forms of separation standards are applied), the algorithm relies heavily on the NOAA/NCEP Rapid Update Cycle (RUC) Model forecasts at the 2-to-4-hour time horizon. The performance suitability of RUC wind forecasts for this application is investigated. RUC crosswinds are compared with LIDAR measurement data collected at St. Louis Lambert International Airport (STL) in 2004 and 2006-2007. The results show that the RUC crosswinds generally correlate well with LIDAR measurements, with a mean difference of 0.4 m/s (s.d. 1.3-2.5 m/s) for both the RUC initialization data and the RUC forecast data. No significant degradation was observed at the longer 4-hour RUC forecast horizon, and the choice of RUC horizontal resolution from 40 to 13 km does not greatly affect the RUC crosswind estimation accuracy. On the other hand, the RUC crosswind accuracy decreases with height and frequent wind direction change. The primary

reliability concern was found to occur during rapidly changing wind conditions associated with wind field discontinuities, such as during situations of convective outflow or synoptic scale frontal passages. Overall, our comparison of the RUC and LIDAR crosswinds at STL suggests that the RUC forecast can be a reliable source for obtaining crosswinds for the WFA. Future studies will include airports (e.g., San Francisco International Airport) whose local winds are more significantly affected by regional- or local-scale effects, such as thermally induced circulations (land-sea breezes, etc.) or topographical wind channeling.

"EXPERIMENTAL INVESTIGATION OF INFLUENCE OF JETS ON AIRCRAFT WAKE VORTICES"

Acta Aeronautica et Astronautica Sinica, Vol. 31, No. 5, May 2010, pp. 899-908.

Wake vortices, especially large-scale tip vortices generated by airplanes, are hazardous for following aircraft. This article tries to explore a way to accelerate wake vortex decay through the jets spouted out of the aeroengine. In the experiment, a simplified aircraft model (with tail wing) is employed to construct a 4-vortex wake system consisting of a pair of tip vortices and a pair of counter rotating tail plane vortices. Without external disturbances, effects of vortices generated by the tail plane with different configurations acting on tip vortices differ, some tail plane vortices can lead to the acceleration of tip vortex disintegration, while others cannot. The influence of jets with different intensities on different 4-vortex systems is studied. As a contrast, a 2-vortex system (without tail wing) and without jets are also observed. The experiment is carried out in a water towing tank. A stereo particle image velocimetry (SPIV) system is employed to observe and measure a series of sections which are perpendicular to the towing direction and distributed uniformly between the tailing edge of the main wing and the position of 45 spans downstream. The result indicates that, when the jet is acting on the vortex directly, the effect depends on the original distance and relative strength between them; when the jet is acting on the overall 4-vortex system, the interruption caused by the jet can accelerate the destruction of various 4-vortex systems to a certain degree. The key is how to use jets to optimize the interaction mechanism of disturbance to the tip vortex, rather than merely the intensity of jets.

Huang, W. and Agarwal, R. K.

"CFD ANALYSIS OF TANDEM WIND TURBINES USING A ROTATING DISK MODEL"

AIAA Paper 2017-4071, June 2017, Denver, CO.

The goal of this study is to develop a numerical model to study the performance of two wind turbines operating in tandem at various tip-speed-ratios. A simplified model based on the rotating actuator disk method is developed to replace the spinning blades with two rotating actuator disks on an axisymmetric model. The computations for this model are performed using the CFD solver ANSYS-FLUENT. The results of computations are compared using the wind tunnel data. It is shown that this

simplified model can provide the power coefficient for the tandem wind turbine in good agreement with the experimental data, while maintaining the computational simplicity.

Huang, X., Igarashi, H., Durbin, P. and Hu, H.

"WIND TUNNEL EFFECTS ON WINGTIP VORTICES"

AIAA Paper No. 2010-0325, January 2010, Orlando, FL.

The influence of wind tunnel boundaries on a wing tip vortex is studied experimentally and by computation. Computations show that that vortex is like that which would exist without tunnel walls. The experimental data are corrected for meandering. Then computations are in close agreement to data. A computation with the wall moved closer to the tip shows the primary effect to be displacement of the vortex core by the image effect.

Hubbard, H. B.

"TERMINAL AIRSPACE/AIRPORT CONGESTION DELAYS"

Interfaces, Vol. 8, February 1978, pp. 1-14.

Methods of reducing airport congestion delays are discussed, with particular attention given to an FAA-sponsored program at Chicago's O'Hare Airport. Selection of low-delay runway configurations for the existing wind and weather conditions is found to reduce inbound holding delays by about two to three minutes per arrival. In addition, wake vortex detection systems have been tested to reduce in-trail separations when the wake vortices do not present a problem. More complete real-time air traffic monitoring may also aid in reducing delays.

Hubbard, S. J. and Marquis, A. J.

"INVISCID EFFECTS OF THIN SHEAR LAYERS ON FOUR-VORTEX SYSTEMS"

Journal of Aircraft, Vol. 42, No. 2, March-April 2005, pp. 391-401

The alleviation of the wake vortex hazard by, for example, promoting vortex instability during aircraft landing and takeoff offers the possibility of increased airport capacity for relatively little cost. The interaction of a vortex pair with a thin shear layer using potential flow methods is extended in this paper to shear-layer interactions with more realistic four-vortex systems. Vortex trajectories resulting from encounters with weak and strong shear layers are studied, and the behavior observed is discussed. The effect of the vortex/shear-layer interactions on the robustness of instability mechanisms of four-vortex systems is discussed in relation to the computed trajectories. The computational method enables the salient features of the vortex/shear interactions to be captured in short periods of CPU time using modest processing power. It is concluded that instability mechanisms that utilize the cooperative instability between vortex pairs on either side of the wake are most likely to survive shear-layer interactions.

Huber, H. and Polz, G.

"STUDIES ON BLADE-TO-BLADE AND ROTOR-FUSELAGE-TAIL INFERENCES"

Aircraft Engineering, Vol. 55, No. 10, October 1983, pp. 2-12

The paper focuses on some specific areas of interactional aerodynamics. The first major problem is the blade-to-blade vortex interaction phenomenon, where the unsteady pressure fluctuations, due to the vortices impact, result in highly impulsive blade loadings, excessive dynamic hub forces/moments, and impulsive noise signatures. The paper describes Messerschmitt-Bolkow-Blohm's analytical modelling techniques, including prescribed-contracted-wake analysis and free-wake models. Second, the interactional aerodynamic flow from the fuselage to the rotor blades is treated. Due to flow displacement effects around the fuselage contour, large upwash and downwash components can be produced, resulting in significant changes of the local angle of attack within the rotor disc plane. Third, interference flow effects between the rotor head and fuselage to the tail area are investigated. The wake pattern results in a reduction of the steady flow pressure and in reductions of the vehicle stability characteristics. Significant unsteady components in the wake flow may cause substantial structural loading and severe aircraft vibrations.

Huberson, S. and Daube, O.

"NUMERICAL SIMULATION OF VORTEX FLOWS"

Lecture Notes in Physics, Vol. 555, 2000, pp. 18-39

This paper presents a selection of numerical methods among the most currently used to solve the Navier Stokes equation in a vorticity formulation. The paper focuses on the connection that exists between vorticity boundary condition and the divergence free condition. The different methods have been cast in two classes: the methods which are based on divergence free approximations of the vorticity fields, and those which use a correction procedure to satisfy this constraint. For both classes, the respective advantages of Eulerian grid methods and Lagrangian methods are briefly discussed.

Huberson, S., Rivoalen, E. and Voutsinas, S.

"VORTEX PARTICLE METHODS IN AEROACOUSTIC CALCULATIONS"

Journal of Computational Physics, Vol. 227, 2008, pp. 9216-9240.

The connection between vortex particle methods and aeroacoustics is considered within the framework of Lighthill's acoustic analogy which allows to decouple the flow from noise propagation. For the flow, techniques such as tree-algorithms and the particle-mesh method are brought together with the aim to achieve the best possible performance in view of analyzing complex problems. The flow results are then input to the acoustic wave equation which is solved in integral form. It will involve monopole, dipole and quadrupole terms which can be successively integrated. The significance of such

an approach is first demonstrated in two problems, both related to vortex-solid interactions. The first is a generic one and considers the interaction of a vortex filament interacting with a sphere while the second considers helicopter noise as an example of a complex engineering set-up.

Huebsch, W. W. and Lewellen, D. C.

"SENSITIVITY STUDY ON CONTRAIL EVOLUTION"

AIAA Paper No. 2006-3749, San Francisco, CA, June 2006

It has become increasingly clear in recent years that under certain conditions, aircraft contrails will persist and grow into significant cloud cover that might otherwise be confused with natural cirrus. The projected large increases in air traffic in the coming decades and potential impact of increased cloud cover on global climate change has led to a growing realization of the importance of understanding the formation, properties, and effects of persistent contrails. A preliminary sensitivity analysis on contrail evolution out to 1000 seconds has been performed using 3-D high-resolution large-eddy simulations to solve the wake and plume development, coupled with a binned ice microphysics model. Effects of both atmospheric and aircraft parameters are investigated. It is shown that the use of binned microphysics can have a significant impact on the prediction for the contrail evolution. The atmospheric parameters include the relative humidity with respect to ice, atmospheric turbulence levels, ambient stratification, and wind shear. The aircraft parameters investigated include the ice crystal emission index and the engine placement. The results of the sensitivity analysis shed light on the relative importance of ambient and aircraft parameters on contrail growth. The aircraft wake dynamics in the first few minutes can have profound effects on the properties of the resulting persistent contrails. This occurs both through its governing of the initial plume dispersion and through the loss of a significant fraction of the ice crystals due to adiabatic heating in the falling wake plume, even for large ambient supersaturation levels.

Huenecke, K.

"EUROPEAN INVESTIGATIONS ON WAKE VORTEX PHENOMENA"

Seventh Conference on Industrial Technologies, and Proceedings of 3rd European Commission Aero Days Conference, Toulouse, France, October 1997, *Nouvelle Revue d'Aeronautique et d'Astronautique*, No. 2, March - April 1998, pp. 112-115.

A survey is presented of the range of European research activities conducted to date to deepen understanding of the wingtip vortex wake phenomenon associated with large transport aircraft. Such wakes pose a danger to smaller aircraft during landing approaches, especially when separation between aircraft must be minimized at busy airports. Attention is given to CFD prediction methods and lidar wake vortex detection techniques developed in the course of European researches.

Huenecke, K.

"THE CHARACTERISATION OF TRANSPORT AIRCRAFT VORTEX WAKES"

AIAA Paper No. 2001-2427, Anaheim, CA, June 2001

Airlines, airports and authorities are searching for advanced solutions of how to accommodate the growing air traffic, without degrading the high standards of safety. One of the most promising routes to improve the capacity situation is to reduce separation distances between aircraft. Separation is necessary, both horizontally for landing and take-off, and vertically for certain enroute legs, to avoid the risk of encountering wakes from preceding aircraft. Hence, separations are vital to assure flight safety. Because the hazard from vortices is growing with aircraft size, the wake vortex issue is becoming even more critical with the appearance of very large transport aircraft (VLTA) from 2005 onward. Standards should be defined which allow a wake to be identified according to certain characteristics. Such characterization parameters conveniently result from experimental evidence and may serve as guidance for prediction methods. The extent of possible characterization parameters reflects the complexity of vortex wakes, and the numerous influencing factors that have to be considered.

Huenecke, K.

"METHOD AND APPARATUS FOR REDUCING TRAILING VORTICES IN THE WAKE OF AN AIRCRAFT"

US Patent 6,513,761 B2, February 2003.

Harmful trailing vortices downstream of an aircraft wing are at least partly dissipated by a respective counteracting vortex for each trailing vortex at each wing. An auxiliary counteracting vortex generating flap, preferably in the form of at least part of a delta wing, is journaled to the respective wing near the outer end of a landing flap. The counteracting vortex is imposed on the respective trailing vortex, whereby the trailing vortex is caused to vibrate. The vibration dissipates the trailing vortex at least partially.

Huenecke, K.

"FROM FORMATION TO DECAY - EXTENDED-TIME WAKE VORTEX CHARACTERISTICS OF TRANSPORT-TYPE AIRCRAFT"

AIAA Paper No. 2002-3265, St. Louis, MO, June 2002

A major impediment to making full use of airspace and airport capacities is a lack of sufficiently understanding fluid dynamics of vortex wakes generated by aircraft. European research efforts have greatly contributed to filling this gap. Findings from experiments were dealt with which were obtained by using near-realistic generic half and full models in wind tunnels and a towing tank. The techniques employed allowed the complete lifetime of a wake to be accessed, from formation to decay. The different behavior of wakes from high-lift and cruise configurations is to be noted. Knowledge from this research may support in establishing methodologies which allow a more realistic description of wake behavior. The towing tank, in combination with advanced measuring and evaluation techniques, was found a useful tool to measure wakes over their complete lifetime.

Huenecke, K.

"VORTEX WAKES FROM LARGE AIRCRAFT - A CHALLENGE FOR INDUSTRIAL RESEARCH"

AIAA Paper No. 2000-2216, Denver, CO, June 2000

Great efforts have been made in recent years to increase the knowledge base on aircraft-generated wakes. Examples given demonstrate the complexity of the wake flow field in the near field where the formation of concentrated vortices takes place. In the light of a new class of high-capacity airliners that will enter service in the next decade, research must greatly intensify to better understand wake physics in particular, so that vortex-related hazards can be quantified and means to hazard reduction can be implemented.

Huenecke, K.

"RECENT DEVELOPMENTS IN INDUSTRIAL WAKE VORTEX RESEARCH"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

The capacity limitation of today's airspace and that of major airports is of increasing concern, especially if air traffic continues to grow at the present rate of 5% per year. One of the most promising routes to increase capacity is to reduce separation distances between aircraft. Separation is necessary, both horizontally for landing and take-off, and vertically for certain enroute legs to avoid the risk of encountering wakes from preceding aircraft. Hence, separations are vital to assure flight safety. Because the hazard from vortices increases with aircraft size, the wake vortex issue is becoming even more critical with the appearance of very-large transport aircraft (VLTA) from 2005 onward. Indeed, 'Wake vortex' is among the major issues that will affect the super airplane of the future, and growth of air traffic in general. Although numerous investigations were carried out worldwide in the past, it was realized that the available database was only of limited value for the industry. Therefore, dedicated research activities, both on a national and supra-national level, were launched by major European nations which focus on the characterization, and then on control, of vortex-dominated wakes.

Huenecke, K.

"WAKE VORTEX INVESTIGATIONS OF TRANSPORT AIRCRAFT"

AIAA Paper No. 1995-1773, San Diego, CA, June 1995

The problem of wake turbulence, because of its hazardous effects on flight safety, continues to be of concern to commercial aviation and aircraft manufacturers alike. Despite considerable research efforts in the past, surprisingly little is still known about wakes trailing behind aircraft. To obtain a more comprehensive understanding of the fundamentals of the formation process, several carefully selected wind tunnel tests were carried out at the DA-Airbus low-speed wind tunnel facility at Bremen, using a

half model with single and double-slotted flaps. Initial results revealed unexpected flow phenomena both in the tip and flap vortices, the knowledge of which may contribute to mitigation of the wake vortex issue.

Huenecke, K.

"STRUCTURE OF A TRANSPORT AIRCRAFT-TYPE NEAR FIELD WAKE"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 5-1 to 5-9

Investigations were carried out using the 2m x 2m low-speed wind tunnel at Bremen. Tests comprised near-field wake flow surveys using a five-hole probe. The results reveal the structure of a near field wake to be of complex nature, even though only the steady-state sector of the flow was accessible with the available testing gear. Flow field evaluation focused on: vortex relative motion, streamwise vortex development, crossflow velocity structure, streamwise velocity structure, total pressure loss, and streamwise vorticity redistribution.

Huenecke, K. and Huenecke, C.

"FLOWFIELD VISUALIZATION IN AIRCRAFT WAKE VORTEX RESEARCH"

Proceedings of 9th International Symposium on Flow Visualization, Edinburgh, Scotland, August 2000, pp. 139-1-139-12

Continuing growth of air traffic has made 'Wake Vortex' one of the most challenging technical issues in modern civil aviation. The requirement for reduced separation distances on densely flown approach routes is closely linked to the hazard caused by wake-generating aircraft and its safety impact on following aircraft. Great efforts have been made in recent years to increase the knowledge base of aircraft-generated wakes. Examples given demonstrate the complexity of the wake flow field in the near field where the formation to concentrated vortices takes place. In the light of a new class of high-capacity airliners to enter service in the next decade, research must even more intensify to better understand wake physics, so that vortex-related hazards can be quantified and means for hazard reduction implemented. A major role to achieve this goal is seen in utilizing modern visualization techniques that became available in recent years. Due to a consequent application of visualization tools, a major insight into vortical flow fields was gained.

Huffaker, R. M.

"SOLID-STATE COHERENT LASER RADAR FOR ATMOSPHERIC SENSING"

Pacific Rim Conference on Lasers and Electro-Optics (CLEO), IEEE, Vol. 2, 1999, pp. 147-148.

Coherent laser radar systems have been developed and applied to atmospheric wind field measurements, aircraft wake vortex monitoring, aerosol plume tracking, airport wind shear and gust front monitoring, as well as military air cargo drops.

Huffaker, R. M.

"LASER DOPPLER SYSTEM FOR AIRCRAFT TRAILING VORTEX TRACKING AND MEASUREMENT"

Proceedings of the Second Annual Research and Technology Review, NASA, October 1974

MSFC has developed a CO₂ Laser Doppler System for the tracking and measurement of aircraft trailing vortices under an interagency agreement between NASA and the FAA. This system has been installed at Kennedy International Airport after checkout at MSFC. This paper describes the logic for the systems design and outlines some of the hardware considerations used in the development. Results of system performance in the tracking and measurement of aircraft trailing vortices will be given.

Huffaker, R. M. and Hannon, S. M.

"AIRPORT SURVEILLANCE USING A SOLID STATE COHERENT LIDAR"

Fifth and Final Combined Manufacturers' and Technologists' Conference, Part 2, Airborne Windshear Detection and Warning Systems, NASA Langley Research Center, VA, July 1994, pp. 499-523

The utility of solid-state coherent LIDAR was assessed in the following application areas; (1) wake vortices; (2) dry and wet microburst windshear; (3) gusts; (4) vertical and general wind profiling; and (5) cloud ceiling. The system performance model described was based on a concept definition, system sizing, measurement planning, and algorithm and graphics display development. Data were collected at the Kennedy Space Center and the National Weather Service site adjacent to Denver's Stapleton Airport.

Huffaker, R. M. and Hardesty, R. M.

"REMOTE SENSING OF ATMOSPHERIC WIND VELOCITIES USING SOLID-STATE AND CO₂ COHERENT LASER SYSTEMS"

IEEE Proceedings, Vol. 84, No. 2, February 1996, pp. 181-204

Coherent lidar/laser radar systems have been used for the remote measurement of atmospheric wind velocity since 1966. Both CW and pulsed coherent lidars have been developed and applied to a variety of ground-based and airborne applications. In recent years, most efforts have concentrated on pulsed carbon dioxide and solid-state Doppler lidars for the remote measurement of atmospheric wind velocities. Issues associated with the design and application of coherent lidars to atmospheric wind measurement are discussed. Coherent lidar/laser radar systems have been applied to detection and tracking of aircraft wake vortices, measurement of atmospheric wind fields during the space shuttle

takeoff and landing, airborne windshear detection, ground-based airport microburst windshear monitoring, meteorological research, and environmental monitoring. Numerous examples of measurement results are presented. An assessment of the status of coherent lidar technology as practical devices for operational and research uses is addressed.

Huffaker, R. M. and Reveley, P. A.

"SOLID-STATE COHERENT LASER RADAR WIND FIELD MEASUREMENT SYSTEMS"

Proceedings of the Lidar Atmospheric Monitoring Meeting, Munich, Germany, June 16-18, 1997, Society of Photo-Optical Instrumentation Engineers (SPIE) Proceedings, Vol. 3104, 1997, pp. 179-189.

Diode-pumped solid-state pulsed coherent laser radar systems have recently been developed for the remote measurement of atmospheric wind fields. Flash-lamp pumped systems have been utilized since 1990 for obtaining wind field measurements. These flash-lamp pumped lidar systems have been applied to wind profiling, aircraft wake vortex measurements, airport wind shear and gust from monitoring, and military cargo air drops and many other applications. The diode-pumped coherent lidar systems currently available are capable of near-turnkey operation. The Tm:YAG laser transceivers operate at 2.02 microns with output pulse energies of 1 to 10 mJ with PRF's of 1,000 to 100 Hz respectively. Range resolution of 30-75 m is typical. A real-time lidar signal processor has also been developed for collecting and analyzing laser radar (lidar) data. The signal processor is based on a commercial PC architecture and offers a real-time data acquisition, analysis, display, recording, and playback environment. Wind measurements and overall system performance results are presented. Wind measurement performance, for a variety of applications, is presented using flashlamp- and diode-pumped coherent lidars including measured wind profiles from ground and on aircraft, wake vortex tracking results, and example flows over mountain terrain.

Huffaker, R. M. and Reveley, P. A.

"SOLID-STATE COHERENT LASER RADAR WIND FIELD MEASUREMENT SYSTEMS"

Pure Applied Optics, Vol. 7, 1998, pp. 863-873.

Diode-pumped solid-state pulsed coherent laser radar systems have recently been developed at Coherent Technologies, Inc., for the remote measurement of atmospheric wind fields. Flash-lamp pumped systems have been utilized since 1990 for obtaining wind field measurements. These flash-lamp pumped lidar systems have been applied to wind profiling, aircraft wake vortex measurements, airport wind shear and gust from monitoring, and military cargo air drops and many other applications. The diode-pumped coherent lidar systems currently available are capable of near turnkey operation. The Tm:YAG laser transceivers operate at 2.02 microns with output pulse energies of 1 to 10 mJ with PRFs of 1000 to 100 Hz, respectively. Range resolution of 30-75 m is typical. A real-time lidar signal processor has also been developed for collecting and analyzing laser radar (lidar) data. The signal processor is based on a commercial PC architecture and offers a real-time data acquisition, analysis, display, recording, and playback environment. Wind measurements and overall system performance

results will be presented. Wind measurement performance, for a variety of applications, is presented using the flashlamp- and diode-pumped coherent lidars including measured wind profiles from ground and on aircraft, wake vortex tracking results, and example flows over mountain terrain.

Huffaker, R. M., Jeffreys, H. B., Weaver, E. A., Bilbro, J. W., Craig, G. D., George, R. W., Gleason, E. H., Marrero, P. J., Reinbolt, E. J. and Shirey, J. E.

"DEVELOPMENT OF A LASER DOPPLER SYSTEM FOR THE DETECTION, TRACKING, AND MEASUREMENT OF AIRCRAFT TRAILING VORTICES"

FAA-RD-74-213, March 1975, NASA Marshall Space Flight Center, Huntsville, AL.

A Scanning Laser Doppler Vortex System (SLDVS) has been developed for use as an aircraft trailing vortex detection, tracking, and measuring system. The report describes the SLDVS design, development, and checkout at NASA. Previous efforts had demonstrated the capability of laser Doppler systems to accurately measure remote wind velocity and turbulence. To assure the proper overall system design; tradeoff studies were performed to determine the optimum design parameters that met the program objectives. Computer simulations of the SLDVS performance were used in determining the optimum design parameters. The SLDVS scans both in range and angle. A real-time vortex display system is provided which gives the vortices' center positions in the scan plane as a function of time. The SLDVS was integrated and checked out at MSFC. The SLDVS has demonstrated overall systems accuracy against known calibrated targets of + 3.3 ft at 492 ft (+ 1 m at 150 m). During cooperative flybys at MSFC, the SLDVS has located the center positions of the B-737 and B-720 aircraft vortices to within + 10 ft (+ 3 m).

Huffaker, R. M., Jelalian, A. V. and Thomson, J. A. L.

"LASER-DOPPLER SYSTEM FOR DETECTION OF AIRCRAFT TRAILING VORTICES"

IEEE Proceedings, Vol. 58, No. 3, March 1970, pp. 322-326

The paper reviews the results of a test program utilizing a CW CO₂ laser-Doppler velocimeter system that has demonstrated the capability of detecting wing tip vortices by the measurement of Doppler shifted back scatter from atmospheric aerosols naturally suspended in the atmosphere. The velocity signatures of vortices generated by a C-47 aircraft making low altitude cooperative flybys are shown. Some considerations of an operational detection system are given.

Huffaker, R. M., Jelalian, A. V., Keene, W. H. and Sonnenschein, C. M.

"APPLICATION OF LASER DOPPLER SYSTEMS TO VORTEX MEASUREMENT AND DETECTION"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 113-124

A laser Doppler system for the measurement of atmospheric wind velocity and turbulence has been developed. This system utilizes the Doppler frequency shift undergone by a beam of radiation when

scattered by particles suspended in the flows. A three-dimensional system has been developed for wind tunnel and jet type flow studies; measurements of velocity have been made for velocities in excess of Mach 2 and compared with theory and hot wire instrumentation. The laser Doppler system has also been applied to the problem of detecting the presence of an aircraft trailing vortex. The results showed that when the vortex was visually sighted and known to be in the sensitive scattering volume of the laser Doppler system, the velocity distribution of the vortex was measured.

"ASPECTS OF LOW SPEED WIND TUNNEL TESTING ON AN A400M MODEL WITH PROPELLER SIMULATION"

In New Results in Numerical and Experimental Fluid Mechanics III, Notes on Numerical Fluid Mechanics, Vol. 77, Eds. Wagner, et al., Springer-Verlag, Berlin Heidelberg, 2002, pp. 82-91.

A400M is the future European military airlifter which is currently developed to fulfil the requirements of eight European Nations. The aircraft will be driven by four turboprop engines. The disc loading of the propellers is significantly higher than realized on former tactical transport aircraft like C130H or Transall C160. Due to the tactical and logistic tasks of this airplane the high and low speed propeller interference effects contribute essentially to the A/C sizing and configuration development. The following presentation deals with aspects of wind tunnel testing with propulsion simulation in the EADS Low Speed Wind Tunnel in Bremen. The simulation of realistic propeller effects is described. Investigations on an isolated propeller are illustrated and the main results of the test campaigns, focusing on propeller effects at high lift configuration are presented.

"TECHNOLOGY-ENABLED AIRBORNE SPACING AND MERGING"

23rd Digital Avionics Systems Conference, Salt Lake City, UT, October 2004

Over the last several decades, advances in airborne and groundside technologies have allowed the Air Traffic Service Provider (ATSP) to give safer and more efficient service, reduce workload and frequency congestion, and help accommodate a critically escalating traffic volume. These new technologies have included advanced radar displays, and data and communication automation to name a few. In step with such advances, NASA Langley is developing a precision spacing concept designed to increase runway throughput by enabling the flight crews to manage their inter-arrival spacing from TRACON entry to the runway threshold. Precision spacing is enabled by Automatic Dependent Surveillance-Broadcast (ADS-B), which provides air-to-air data exchange including position and velocity reports; real-time wind information and other necessary data. On the flight deck, a research prototype system called Airborne Merging and Spacing for Terminal Arrivals (AMSTAR) processes this information and provides speed guidance to the flight crew to achieve the desired inter-arrival spacing. AMSTAR is designed to support current ATC operations, provide operationally acceptable system-wide increases in approach spacing performance and increase runway throughput through system stability, predictability

and precision spacing. In addition to providing for precision inter-arrival spacing, AMSTAR provides speed guidance for aircraft on converging routes to safely and smoothly merge onto a common approach. Much consideration has been given to working with operational conditions such as imperfect ADS-B data, wind prediction errors, changing winds, differing aircraft types and wake vortex separation requirements.

Hummel, D.

"ON THE VORTEX FORMATION OVER A SLENDER WING AT LARGE ANGLES OF INCIDENCE"

High Angle of Attack Aerodynamics, AGARD CP-247, 1978, pp. 13-1 - 13-17.

An experimental study of the flow field around an A=1 delta wing at an angle of attack of 20.5 degrees is presented. The free vortex sheets generated at the wing leading edges roll up into the well-known leading-edge vortices which are accompanied by some secondary vortices at the wing surface because of boundary-layer separations. The effect of Reynolds number on the formation of the secondary vortex is studied in detail. Boundary-layer measurements have been carried out for laminar and turbulent boundary layers and the bound vortex lines in the lifting surface have been determined for both cases. The free vortex sheet originating from the wing trailing edge rolls up into a concentrated trailing vortex the rotation of which is opposite to that of the leading-edge vortex. The flow field has been measured in four planes perpendicular to the free stream direction and located in different positions downstream of the wing trailing edge. The magnitude and the direction of the local velocity vector have been determined by means of a 5-hole probe. The results are given for each plane by lines of constant total pressure, static pressure, dynamic pressure and by a presentation of the local flow directions. The interference between leading-edge vortex, secondary vortex and trailing-edge vortex is studied in detail. The positions of the vortex sheets and of all concentrated vortices in relation to the wing are given quantitatively. They are now available for comparisons with results of numerical calculations.

"THE USE OF AIRCRAFT WAKES TO ACHIEVE POWER REDUCTIONS IN FORMATION FLIGHT"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 36-1 to 36-13

Many migrating bird species fly in regular V-shaped formations. Each wing experiences an upwash field generated by all other wings in the formation and this leads to a reduction in flight power demand for each wing as well as for the whole formation. In this paper the aerodynamic interference is studied by means of aerodynamic theory. The total energy saving for the whole formation increases with the number of wings and with decreasing lateral distance. Local power reductions are highest in the inner parts of a formation and they decrease towards the apex and the side-edges. The technical realization of this principle is analyzed for two airplanes. In calibration flights of gliders large distances must be kept or the aerodynamic interference must be considered. In formation flights of two airplanes a

power reduction of 15% is obtainable for the rear airplane flying close to the wake of the front aircraft. The corresponding aileron and rudder deflections for compensation of the corresponding moments are small. Flight tests with two airplanes DO-28 show that the power reduction can be achieved in practical flight. The results are in excellent agreement with aerodynamic theory. To enable the rear airplane to find the proper position relative to the wake of the front airplane an automatic control system has been adapted. A formation flight controller has been designed which leads the upwash in the symmetry plane and the aileron deflections to maximum values. The application of this control system led to a considerable relief of the pilot and important power reductions could be achieved automatically.

Hunecke, K.

"WAKE VORTEX CONTROL - A CHALLENGE FOR LARGE TRANSPORT AIRCRAFT"

Air and Space Europe, Vol. 3, Issues 3-4, May-August 2001, pp. 209-213.

One of the many promising routes to increase capacity at over-crowded European airports is to reduce the separation distance between aircraft on landing and take-off, or vertical separations in densely flown enroute sectors. Separations are necessary to avoid the risk of encountering a wake from a preceding aircraft - and hence are vital for flight safety. This is becoming even more critical with the advent of very-large transport aircraft. This article explains the characterization of wave vortices, and explores the European Projects looking at the problem.

Hunt, D. L., Cummings, R. M. and Giles, M. B.

"WAKE INTEGRATION FOR THREE-DIMENSIONAL FLOWFIELD COMPUTATIONS: APPLICATIONS"

Journal of Aircraft, Vol. 2, March-April 1999, pp. 366-373.

A momentum balance approach is used to extract lift and drag from flow field computations for wings and wing/bodies in subsonic/transonic flight. The drag is decomposed into vorticity, entropy, and enthalpy components that can be related to the established engineering concepts of induced drag, wave and profile drag, and engine power and efficiency. This decomposition of the drag is useful in formulating techniques for accurately evaluating drag using computational fluid dynamics calculations or experimental data. A formulation for reducing the size of the region of the crossflow plane required for calculating the forces is developed using cutoff parameters for viscosity and entropy. This improves the accuracy of the calculations and decreases the computation time required to obtain the results. The improved method is applied to a variety of configurations, including an elliptic wing, the M6 wing, the W4 wing-body, the M165 wing-body fore plane, and the Lockheed Wing A. The accuracy of the force calculations is related to various aspects, including the axial position of the downstream crossflow plane, grid type (structured or unstructured), grid density, flow region (subsonic or transonic), and boundary conditions.

"VORTICES, COMPLEX FLOWS AND INERTIAL PARTICLES"

Journal of Flow, Turbulence and Combustion, Vol. 79, 2007, pp. 207-234.

The properties of vortical structures at high Reynolds number in uniform flows and near rigid boundaries are reviewed. New properties are derived by analyzing the dynamics of the main flow features and the related integral constraints, including the relations between mean swirl and bulk speed, the relative level of internal fluctuations to bulk properties, and connections between the steadiness and topology of the structures. A crucial property that determines energy dissipation and the transport of inertial particles (with finite fall speed) is the variation across the structure of the ratio of the mean strain rate to the mean vorticity. It is shown how, once such particles are entrained into the vortical regions of a coherent structure, they can be transported over significant distances even as the vortices grow and their internal structure is distorted by internal turbulence, swirling motions and the presence of rigid boundaries. However, if the vortex is strongly distorted by a straining motion so that the mean strain rate is greater than the mean vorticity, the entrained particles are ejected quite rapidly. These mechanisms are consistent with previous studies of entrained and sedimented particles in disperse two phase flows over flat surfaces, and over bluff obstacles and dunes. They are also tested in more detail here through laboratory observations and measurements of 50-200-micron particles entrained into circular and non-circular vortices moving first into still air and then onto rigid surfaces placed parallel and perpendicular to the direction of motion of the vortices.

"WINGTIP VORTEX PRESERVATION USING A COUPLED VORTEX PARTICLE METHOD AND COMPUTATIONAL FLUID DYNAMICS SOLVER"

AIAA Paper 2017-4405, June 2017, Denver, CO.

This paper presents a coupled Vortex Particle Method-Computational Fluid Dynamics solver. The Vortex Particle Method solution is used to correct the Computational Fluid Dynamics. This is achieved by using the Split Velocity Method, which includes the influence of the particles through their induced velocities and additional source terms. The coupled solver is demonstrated on a two-dimensional and three-dimensional test case and the results are compared to the solutions of the CFD solver on its own using a coarse mesh and a fine mesh. It is shown that the hybrid solver preserves the tip vortex on a coarse mesh and is computationally more efficient than using the fine mesh.

"INVESTIGATION OF ENGINE JET/WING-TIP VORTEX INTERFERENCE"

Aerospace Science and Tech., Vol. 8, 2004, pp. 175-183

The wing-tip vortex of a rectangular wing half-model with a model engine is studied experimentally and numerically. The airfoil has a supercritical BAC 3-11/RES/30/21 geometry with a chord length of $c =$

150 mm. The investigations include three different spanwise positions of the engine and two jet velocities with a constant free stream velocity. The numerical simulation is divided into two parts. First the flow around the airfoil is calculated. In a second step the data is taken as an input to calculate the wake downstream of the trailing edge. Experiments include 2C- and 3C-PIV-measurements for the velocity distribution of the jet and the wing-tip vortices. The experimental and numerical results show the significance of the streamwise velocity component for the analysis of the jet/wing-tip vortex interaction.

Huppertz, G., Klaas, M. and Schroeder, W.

"PIV MEASUREMENTS OF UNSTEADY VORTEX BEHAVIOR IN THE NEAR WAKE OF A SWEPT WING MODEL"

13th International Symposium on Application of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, June 2006

The results indicate that a span wise change of the location of the engine jet modifies the stability properties of the wake flow. Depending on the engine position, the operation mode, and the wing configuration, the unsteady vortex behavior and the vortex topology are different and the interaction of wing tip and flap edge vortices is affected.

Huppertz, G., Schroder, W. and Klaas, M.

"ENGINE JET/VORTEX INTERACTION IN THE NEAR WAKE OF AN AIRFOIL"

AIAA Paper 2006-3747, June 2006, San Francisco, CA

Experimental results concerning the engine jet/vortex wake interaction will be presented. A method is described that improves the evaluation of unsteady vortex measurements and allows to analyze the effect of unsteady vortex movement. The results indicate that the engine jet modifies the stability properties of the wake flow. Depending on the engine position and operation mode the mean wandering amplitudes and the velocity fluctuations in the vortex wake are different and the topology of the vortex is affected. The current results suggest that for high-lift configurations the preferable engine position is closer to the wingtip if the focus is on the stability properties of the vortex wake.

Huppertz, G., Schroder, W. and Klass, M.

"ENGINE JET/VORTEX INTERACTION IN THE NEAR WAKE OF AN AIRFOIL"

AIAA Paper No. 2006-3747, San Francisco, CA, June 2006

Experimental results concerning the engine jet/vortex wake interaction will be presented. A method is described that improves the evaluation of unsteady vortex measurements and allows to analyze the effect of unsteady vortex movement. The results indicate that the engine jet modifies the stability properties of the wake flow. Depending on the engine position and operation mode the mean

wandering amplitudes and the velocity fluctuations in the vortex wake are different and the topology of the vortex is affected. The current results suggest that for high-lift configurations the preferable engine position is closer to the wing-tip if the focus is on the stability properties of the vortex wake.

"A MULTIBLOCK MULTIGRID AMR METHOD IN 3D USING A MUSCL OR A DISCONTINUOUS GALERKIN APPROACH"

3rd International Symposium on Finite Volumes for Complex Applications, June 24-28, 2002, Porquerolles, France

In this paper we present a 3D implementation of the AMR method for curvilinear or Cartesian grids. Two compressible flow solvers (MUSCL and DG) are used. The adapted solutions of the transonic flow past a twisted wing and of the wake vortex of a A300 model show the capabilities of this method.

Husain, H. S., Shtern, V. and Hussain, F.

"CONTROL OF VORTEX BREAKDOWN BY ADDITION OF NEAR-AXIS SWIRL"

Physics of Fluids, Vol. 15, No. 2, February 2003, pp. 271-279

We present a new method for controlling vortex breakdown (VB) via addition of co- or counter-rotation near the axis. Co-rotation is adequate to totally suppress VB, whereas counter-rotation increases the number and size of VB 'bubbles' and makes the flow unsteady. We study these effects in a closed cylindrical container, in which a rotating end disc drives the base flow; an independently rotating central rod (with rod radius much less than disk radius) is employed to control VB. This flow, being free of ambient disturbances, is well suited for understanding both the VB mechanism and its control; the present work appears to be the first to study VB control. We develop and explain our control strategy using flow visualization and simple analytical reasoning. Our results suggest that an additional co- or counter-rotation, applied near the vortex axis, can be effective in suppressing or enhancing VB in practical flows.

Hussain, F.

"DYNAMICS OF SLENDER VORTICES NEAR THE WALL IN A TURBULENT BOUNDARY LAYER"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

It is now well-established that the enhanced drag and heat transfer of turbulent boundary layers is dominated by slender longitudinal vortices immediately near the wall. Despite their immense practical significance, the geometry and dynamics of near-wall vortices are not well understood and often controversial. To gain new insight into the near-wall dynamics, we deduce coherent structures (CS) near the wall from a numerically simulated turbulent channel flow using a conditional sampling scheme which extracts the entire extent of locally dominant vortical structures. Such structures are detected

from the instantaneous flow field using our newly developed vortex definition -- a region of negative λ_2 , the second largest eigenvalue of the tensor $S_{ik}S_{kj} + \Omega_{ik}\Omega_{kj}$ -- which accurately captures the structure details, unlike velocity, vorticity or pressure-based reduction schemes. Extensive testing shows that λ_2 correctly captures vortical structures, even in the presence of strong shear occurring near the wall of a boundary layer. Our conceptual model of the CS array reproduces nearly all experimentally observed events reported in the literature, such as VITA, gradient and counter-gradient Reynolds stress distributions (Q1, Q2, Q3 and Q4 and their relative contributions), wall pressure variation, elongated low-speed streaks, spanwise shear, etc. Notably, the often-heralded hairpin vortices, not to be confused with hairpin-shaped vortex line bundles, are absent both in the instantaneous and ensemble-averaged fields. We have also discovered a new instability mechanism for generation of these dominant longitudinal vortices from a basic flow initially containing no streamwise vorticity. The structure evolution agrees quite well with that observed in DNS of minimal channel flow.

"NONLINEAR TRANSIENT GROWTH IN A VORTEX COLUMN"

Journal of Fluid Mechanics, Vol. 682, 2011, pp. 304-331.

Growth of optimal transient perturbations to an Oseen vortex column into the nonlinear regime is studied via direct numerical simulation (DNS) for Reynolds number, Re (circulation/viscosity), up to 10000. An optimal bending-wave transient mode is obtained from linear analysis and used as the initial condition. (DNS of a vortex column embedded in finer-scale turbulence reveals that optimal modes are preferentially excited during vortex-turbulence interaction.) Tilting of the optimal mode's radial vorticity perturbation into the azimuthal direction and its concomitant stretching by the column's strain field produces positive Reynolds stress, hence kinetic energy growth. Modes experiencing the largest growth are those with initial vorticity localized at a 'critical radius' outside the core, such that this perturbation vorticity resonantly induces core waves. Resonant forcing leads to growth of perturbation energy concentrated within the core. Moderate-amplitude (about 5 percent) perturbations cause significant distortion of the core and generate secondary filament-like spiral structures ('threads') outside the core. As the mode evolves into the nonlinear region, radially outward self-advection of thread dipoles accelerates growth arrest by removing the perturbation from the critical radius and disrupting resonant forcing. With increasing Re , the evolving vorticity patterns become more chaotic, more turbulent-like (finer scaled, contorted vorticity), and persist longer. This suggests that at typical Re (about 1,000,000), nonlinear transient growth may indeed be able to break up, hence induce rapid decay of, column vortices -- highly relevant for addressing the aircraft wake hazard crisis and the looming air traffic capacity crisis. In addition, we discover a regenerative transient growth scenario in which threads induce secondary perturbations closer to the vortex column. A parent-offspring regenerative mechanism is postulated and verified by DNS. There is a clear trend towards stronger regenerative growth with increasing Re . These results, showing an important role of transient growth in turbulent vortex decay, are highly relevant to the prediction and control of vortex-dominated flows.

Hutcheson, F. V. and Stead, D. J.

"PIV MEASUREMENTS ON A BLOWING FLAP"

AIAA Paper No. 2005-0212, Reno, NV, January 2005

PIV measurements of the flow in the region of a flap side edge are presented for several flap configurations. The test model is a NACA 63-215 Hicks Mod-B main-element airfoil with a half-span Fowler flap. Air is blown from small slots located along the flap side edge on either the top, bottom, or side surfaces. The experimental set up is described and flow measurements are presented for a baseline and three blowing flap configurations. The effects that the flap tip jets have on the structure of the flap side edge flow are discussed for each of the flap configurations tested. The results indicate that blowing air from a slot located along the top surface of the flap greatly weakened the top vortex system and pushed it further off the top surface. Blowing from the bottom flap surface kept the strong side vortex further outboard while blowing from the side surface only strengthened the vortex system or accelerated the merging of the side vortex to the flap top surface. It is concluded that blowing from the top or bottom surfaces of the flap may lead to a reduction of flap side edge noise.

"ASSESSMENT OF S-76 ROTOR HOVER PERFORMANCE IN GROUND EFFECT USING AN UNSTRUCTURED MIXED MESH METHOD"

AIAA Paper 2016-0033, January 2016, San Diego, CA.

In the present study, the aerodynamic performance of an S-76 rotor in hover was numerically investigated by using an unstructured mixed mesh flow solver. The study was made for the rotor for both OGE (out-of-ground-effect) and IGE (in-ground-effect) conditions, and the results are compared against each other. In the present mixed mesh methodology, body-fitted prismatic/tetrahedral mesh was adopted in the near-body flow domain to easily treat complex geometries and to capture the viscous layer on the solid surface accurately, while in the off-body region away from the blades Cartesian mesh was used. To better resolve the flow characteristics and to prevent numerical dissipation, high-order accurate weighted essentially non-oscillatory (WENO) scheme was employed in the off-body flow region. An overset mesh technique was adopted to treat the rotating blades and to exchange the flow variables between the two different mesh regions. The calculations were made for three different blade configurations, having swept-tapered, rectangular, and swept-tapered-anhedral tip shapes, and the results are compared with experimental rotor performance data in terms of thrust, torque and figure of merit. The predictions were obtained for a collective pitch angle sweep from 5 to 10 degrees at a tip Mach number of 0.60 for both cases with and without ground effect. The detailed flow characteristics, such as the vorticity contours and the tip-vortex trajectory, were also investigated.

Iafrati, A. and Riccardi, G.

"A NUMERICAL EVALUATION OF VISCOUS EFFECTS ON VORTEX INDUCED NOISE"

Journal of Sound and Vibration, Vol. 196, Issue 2, September 1996, pp. 129-146

The effect of viscosity on the noise generated by interactions of simple axisymmetric vorticity structures is numerically investigated. A low Mach number is assumed, and hence the feedback of the acoustic field on the flow can be neglected. With this assumption, Lighthill's acoustic analogy enables one to determine the far field pressure perturbation due to vorticity motion. For a swirl-free incompressible flow, numerical simulations are performed with a finite difference scheme in terms of the vorticity and the stream function. The acoustics of collision and pairing of vortex rings is investigated for growing Reynolds numbers. Results show that the quadrupole term converges to the inviscid one, while the acoustic term due to the energy dissipation vanishes, according to the theoretical prediction of Obermeier.

Iannotta, B.

"VORTEX DRAWS FLIGHT RESEARCH FORWARD"

Aerospace America, Vol. 40, No. 3, March 2002, pp. 26-30

Following a lead aircraft at just the right location in its vortex may prove a feasible way to fly farther and save fuel.

Iannuzzelli, R. J., Schemm, C. E., Marcotte, F. J., Manzi, L. P., Gilreath, H. E., Hanson, Jr., J. M., Frostbutter, D. A., Hughes, A. S., Bric, A. D. and Kershner, D. L.

"AIRCRAFT WAKE DETECTION USING BISTATIC RADAR - ANALYSIS OF EXPERIMENTAL RESULTS"

Johns Hopkins APL Technical Digest, Vol. 19, No. 3, July-September 1998, pp. 299-314

The Applied Physics Laboratory has built and fielded an experimental bistatic X-band CW radar system for studies in aircraft wake vortex detection. The radar, along with an acoustic pumping system, was installed at the Baltimore-Washington International Airport in the fall of 1996. Controlled experiments using a NASA C-130 aircraft were conducted on 23 September, 29 October, and 10 December. Results from two specific runs on 29 October are presented and discussed along with numerical simulations of those runs.

Ibrahim, K.

"SELECTING WING LOADING AND THRUST TO WEIGHT RATIO FOR MILITARY JET TRAINERS"

AIAA Paper 2002-3153, June 2002, St. Louis, MO.

Configuration and performance data of jet trainers and light attack airplanes has been analyzed. Correlations have been evolved for selecting wing loading and thrust to weight ratio for baseline design configuration of military jet trainers and light attack airplanes for compliance with a set of mission requirements in terms of 1) take-off distance, b) maximum rate of climb at sea level, c) maximum level speed at any altitude below tropopause, and d) landing distance.

ICAO Journal, Vol. 56, No. 7, September 2001, pp. 8-10, 28.

"Current aircraft separation requirements are effective in preventing wake vortex encounters, but are often overly conservative. Scientists are studying vortex behavior in all weather conditions to determine whether separation requirements may be relaxed under certain conditions."

Ickes, J., Wang, J., Zhao, Q. and Sheng, C.

"COUPLED CFD/CSD SIMULATIONS OF HELICOPTER ROTORS WITH A FREE WAKE MODEL"

AIAA Paper 2014-1251, January 2014, National Harbor, MD.

A Computational Fluid Dynamics/Computational Structural Dynamics (CFD/CSD) coupling technique is used to analyze the four-bladed UH-60A and Bell 427 main rotors, and the results are compared to flight test data. The unstructured Reynolds-Averaged Navier Stokes (RANS) solver U2NCLE was coupled to DYMORE 2 by means of an automated script. A single blade was rendered in the CFD model for each case, and the wake of a four-bladed system was represented by a free wake model. The UH-60A loose coupling flight conditions were the forward flight high speed and moderate speed cases corresponding to flight counters c8534 and c8513, respectively. The Bell 427 flight case simulated was a high-speed forward flight case. After convergence of the coupling procedure air load prediction was improved, and some flow features missed by the low fidelity aerodynamics of the CSD code were resolved by the high-fidelity flow solver. Aerodynamic loads associated with reverse flow and Blade-Vortex Interaction (BVI) showed the most improvement. Blade structural loads predicted by DYMORE 2 showed signs of moderate improvement because of the increased accuracy of the CFD-based air loads for one flight condition.

Igarashi, H., Durbin, P. A., Hu, H., Waltermire, S. and Wehrmeyer, J.

"THE EFFECTS OF WIND TUNNEL WALLS ON THE NEAR-FIELD BEHAVIOR OF A WINGTIP VORTEX"

AIAA Paper No. 2011-1165, January 2011, Orlando, FL.

An experimental study was conducted to investigate the behavior of the wing-tip vortex structures generated by a square-tipped, rectangular NACA0012 wing. A Stereoscopic Particle Image Velocimetry (SPIV) system was used to conduct detailed flow field measurements to elucidate the key features of the wing-tip vortex structure in the near field. One of the great advantages of the present SPIV measurements over the classical measurement technique is that the vortex wandering can be removed directly by tracking the center of the wingtip vortex in the instantaneous measurement frames. By tracking the center of the wingtip vortex, the wandering and turbulence in the vortex can be decoupled completely. This method was applied to investigate the effects of the angle of attack of the test wing and wind tunnel wall on the evolution of the wingtip vortex in the near field. To decouple the effects of vortex wandering, Devenport et al. (1996) suggested an analytical method to predict the wandering free velocity profile. The velocity profile predicted by the Devenport et al. (1996) method was compared with the SPIV re-centered velocity profile quantitatively.

Igarashi, H., Durbin, P. A., Ma, H. and Hu, H.

"A STEREOSCOPIC PIV STUDY OF A NEAR-FIELD WINGTIP VORTEX"

AIAA Paper 2010-1029, January 2010, Orlando, FL.

An experimental study was conducted to investigate the wing-tip vortex generated from a rectangular NACA0012 airfoil model. A high-resolution Stereoscopic Particle Image Velocimetry (SPIV) system was used to conduct detailed flow field measurements to quantify the transient behavior of the wing-tip vortex in the near field. The characteristics of the vortex wandering phenomena, i.e., the slow side-to-side movement of the wing-tip vortex core were revealed in detail based on the SPIV measurement results.

"COMPUTATIONAL STUDY OF AERODYNAMIC CHARACTERISTICS OF SINGLE-ROTOR HELICOPTER TAIL ROTOR UNDER THE INFLUENCE OF VORTICAL WAKE OF MAIN ROTOR AT THE HOVER WITH CROSSWIND"

Civil Aviation High Technologies, Vol. 19, No. 6, 2016, pp. 58-67.

For single-rotor helicopters there are special flight modes, when tail rotor (TR) is under significant inductive influence of vortical wake of main rotor (MR). Inductive influence of vortical wake of MR can provoke essential changes in flowing of TR and its aerodynamic characteristics compared to isolated rotor. In this case increase of tail rotor pitch, necessary for helicopter controlling, is possible. The article contains computational modelling of TR work with vortical wake of MR at the example of MIL Mi-171 helicopter. The modelling has been made on the basis of non-linear blade (free wake) vortical model of rotor, produced at Helicopter Design Department of MAI. Helicopter hovering modes with crosswind of various intensity V_z were considered. Thrust-time relationship for isolated TR and TR with vortical wake of MR for equal flight modes was obtained. Flow around the rotors was analyzed, the vortical wake was considered. The results make it possible to clarify the peculiarities of TR work on considered modes and MR influence on its work. It was found out that vortical wake of MR has a more significant impact on TR work with crosswind on the right, when TR falls into vortex ring state mode. Inductive influence of vortical wake of TR leads to vortex ring state mode for TR at lower speeds ($V_z \sim 5$ m/s) than in case of isolated work of TR ($V_z \sim 12.5$ m/s). In that case the required tail rotor pitch has increased by 13% for $V_z \sim 5$ m/s. The results of modelling and flight tests led to good agreement. [In Russian.]

Iida, O., Tsujimura, S. and Nagano, Y.

"DIRECT NUMERICAL SIMULATION OF HOMOGENEOUS STRATIFIED ROTATING TURBULENCE"

Theoretical and Computational Fluid Dynamics, Vol. 19, No. 6, 2005, pp. 441-460

The effects of the Prandtl number on stratified rotating turbulence have been studied in homogeneous turbulence by using direct numerical simulations and a rapid distortion theory. Fluctuations under strong stable-density stratification can be theoretically divided into the WAVE and the potential vorticity (PV) modes. In low-Prandtl-number fluids, the WAVE mode deteriorates, while the PV mode remains. Imposing rotation on a low-Prandtl-number fluid makes turbulence two-dimensional as well as geostrophic; it is found from the instantaneous turbulent structure that the vortices merge to form a few vertically-elongated vortex columns. During the period toward two-dimensionalization, the vertical vortices become asymmetric in the sense of rotation.

"NUMERICAL STUDY ON THE DYNAMICS OF A JET-VORTEX INTERACTION"

Applied Mathematics and Computation, Vol. 217, 2011, pp. 5103-5112.

The interaction of a vortex and a jet plays an important role for many industrial processes such as carbon black formation or combustion in diesel engines. The knowledge of physics of these phenomena is crucial for engineers, but also for scientists who wish to study this complex flow pattern. In this research, we numerically investigate cases where a cylindrical reactor is charged with gas injected through five ports. The first one is located along the main axis of the cylinder and this leads to the formation of the main jet. The other four ports are situated along the side walls such that the gas entering the cylinder tangentially through them causes a vortex to be formed. The objective of this paper is to show the fundamental physical phenomena, and also how the initial and boundary conditions influence the results. It is shown how the process is influenced not only by modifying the velocity of injected gas, but also by the orientation and position of the vortex inlet nozzles.

Ilie, M., Nitzsche, F. and Matida, E.

"INFLUENCE OF ANGLE OF ATTACK ON THE HELICOPTER BLADE-VORTEX MECHANISM OF INTERACTION USING LARGE EDDY SIMULATION"

AIAA Paper No. 2008-551, Reno, NV, January 2008

The influence of angle of attack on the helicopter blade-vortex mechanism of interaction is investigated using large eddy simulation (LES). The LES technique provides a promising tool for obtaining the unsteady wall-pressure fields, aerodynamic coefficients, and the acoustic source functions. A large eddy simulation is carried out for parametric investigations of Blade-Vortex Interaction (BVI) problem, for a chord-based Reynolds number of $1.3 \times 1,000,000$. Computations are carried out to investigate the influence of angle of attack on the aerodynamic coefficients.

"RESULTS OF FIELD EXPERIMENT COMPARISONS OF NEW SELF-CALIBRATED, UNMANNED, GROUND-BASED, MULTICHANNEL RADIOMETER FOR WATER VAPOR AND TEMPERATURE PROFILES MEASUREMENTS"

WMO Technical Conference on Meteorological and Environmental Instruments and Methods of Observation, September 2016, Madrid, Spain.

Well known problem of multichannel radiometers measurements of water vapor and temperature profiles techniques is the problem of manual calibration procedures. To solve this problem in IAA RAS it was developed self-calibrated and unmanned dual-channel microwave complex WVR-2 (20 and 35 GHz) which measures integrated water vapor and liquid water content in atmosphere. This complex has been combined with single-channel microwave radiometer, with working frequency of 56.6 GHz for continuous measurement of ABL temperature profiles. As result we have received self-clearing, self-calibrated, unmanned and no consumables multichannel radiometer for water vapor, liquid water content and temperature profiles measurements (MRWT). To test stability and accuracy of MRWT it was installed in Central Aerological Observatory, Dolgoprudny, Russia (coordinates 55 deg 55'28.70"N, 37 deg 31'25.55"E) in December 2014. The paper shows the results of comparison of MRWT with radio sounding data (WMO station index 27612) and following devices: multichannel microwave complex for temperature profiles integrated water vapor and liquid water content measurement RPG-HARPRO G4 (Germany) and the results of the GNSS signal, GNSS signal processing (troposphere delay) received by the equipment located in Mendeleevo, Moscow region, at the point with coordinates 56 deg 1'17.18"N, 37 deg 12'52.02"E, altitude 257.1 m was also used to compare the MRWT measurement results of integral water vapor content.

Ilyin, S. P.

"INVESTIGATION OF DYNAMICS AND STABILITY OF VORTEX MULTICOMPONENT FLOW IN THE WAKE OF SUPERSONIC AIRCRAFT"

Report ISTC 1477-02, January 2004, Russian Federal Nuclear Center, Nizhni Novgorod Region, Russia.

The goal of the project is to (1) develop measurement procedures for combustion products (CO₂ mainly) present at various distances of the supersonic airliner engine and determine concentration ranges detectable with these procedures; (2) perform computerized predictions and analysis of a set of fundamental physical processes occurred in the viscous core of the trailing vortex generated behind the wing of supersonic civil aircraft. The report describes a pilot facility built around a tunable CO₂ laser and multi-pass cell, provides experimental results on control of the substance typical for the aircraft wake (carbon oxides and nitrogen, ozone, water vapors, etc.). The conditions typical of the supersonic aircraft wake have been simulated. The feasibility of 80-ppb real time measurements of the substances in question has been shown experimentally. Computerized prediction models have been developed. Results of the calculations of the substances in question generation and evolution in turbulent swirl flow have been obtained. A mathematical model and program code simulating numerically two-phase turbulent flow in isolated trailing vortex and initial stage of contrail formation behind supersonic aircraft have been validated.

"TUNABLE CO₂ LASER MEASUREMENTS OF COMPOSITION AND CONCENTRATIONS IN MULTICOMPONENT WAKE BEHIND SUPERSONIC CIVIL AIRCRAFT"

Proceedings SPIE, Vol. 5777, XV International Symposium on Gas Flow, Chemical Lasers, and High-Power Lasers, April 2005, pp. 1019-1022.

The paper describes experimental and theoretical investigations on tunable CO₂-laser-assisted measurements of the composition and concentrations in multicomponent wake behind supersonic civil aircraft. An experimental facility based on a tunable CO₂ laser and multi-pass cell is presented and results of experiments on determination of substances typical for civil aircraft wake (carbon and nitrogen oxides, ozone, water vapor, etc.) are given. The conditions characteristic of the aircraft wake are simulated. A possibility to perform real-time measurements of substances in question at a level of 80 ppb is demonstrated. Calculative models were created and results of calculations of generation and evolution of substances in question in a turbulent twisted flow are reported. A mathematical model and program code were validated for numerical simulations of two-phase turbulent flow in a single trailing vortex in initial stage of contrail generation behind supersonic aircraft.

"NUMERICAL SIMULATION OF THE INTERACTION BETWEEN SMALL PARTICLES AND A VORTEX CLUSTER DURING ITS EVOLUTION IN THE FAR VORTEX WAKE"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 389-395

This paper considers the behavior of tracer particles of different size and density in a vortex cluster near the ground surface and the cases of interaction between small particles and a vortex cluster when it evolves in the far wake behind an aircraft. The method developed for computing particles' trajectories enables investigation of particle motion in the velocity field that is not only specified analytically but also obtained numerically. Initial data for computations are taken from the results of full-scale experiments with the vortex wake generated by the heavy aircraft of the Boeing-747 category. Particle entrainment into vortex motion is investigated for different parameters of the particles and vortices and a set of their mutual arrangements.

Ilyina, I. P. and Soudakov, V. G.

"INVESTIGATION OF THE INFLUENCE OF A TURBULENT ATMOSPHERE ON MOTION OF SMALL PARTICLES IN THE VORTEX WAKE BEHIND AN AIRCRAFT"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 396-400

This work deals with the behavior of tracer particles of various sizes and densities in the vortex cluster in the far vortex wake behind an aircraft in a turbulent atmosphere. An assessment has been made of the time during which various particles remain within a vortex with the purpose to work out requirements for sizes and densities of particles to be used for vortex wake visualization.

"NUMERICAL SIMULATION OF NACA0012 WINGTIP FLOW LEADING TO NOISE GENERATION"

AIAA Paper 2005-2854, May 2005, Monterey, CA.

In this study, a flow around a blunt-tipped wing is solved using Reynolds averaged Navier-Stoke (RANS) equations, detached eddy simulation (DES) and large eddy simulation (LES) in order to simulate flap edge flow structure with a simple one-element wing. A rectangular wing with NACA0012 airfoil section is chosen as a model. A preliminary analysis around this configuration using RANS indicated that the flow structures are similar to that of the flap edge, and consequently the noise generation mechanism is expected to be similar as well. The computed results are compared with that of wind tunnel experiments, which were also performed at JAXA for the purpose of CFD validation. The present unsteady computation using LES indicates the existence of two different noise sources, one around the side edge and the other over the upper surface.

"REDUCED ORDER MODELING OF CONTRAILS: JET INDUCTION AND VORTEX PHASES"

AIAA Paper 2016-3136, June 2016, Washington, DC.

Persistent contrails are formed downstream of aircrafts at ambient conditions where the Schmidt-Appleman criterion is met. Excess water vapor in the ambient condenses on activated soot particles present in the jet exhaust as it gets entrained by the aircraft wake vortices and interacts with the ambient. Contrails are a matter of considerable interest in the context of their contribution to anthropogenic global warming. This paper introduces a reduced order predictive ODE model for the evolution of integrated quantities of interest (QoIs) of contrails in stationary ambient conditions up to vortex linkage. The QoIs such as wake size, downwash, mean particle size and particle survival rate depend on a wide range of parameters such as wingspan, weight, EI sub ice, fuel burn rate, ambient supersaturation w.r.t. ice, stratification, and turbulence intensity. The impact of the competition and interplay between physical processes that depend on all the aforementioned parameters, on the QoIs, is captured by the present model using only 4 non-dimensional (ND) groupings achieving a huge reduction in the order of the problem and consequently the computational cost. The dynamics of the contrail are sufficiently described using bulk conservation of mass and momentum. The microphysics involves bulk energy conservation of the wake.

Inamdar, A. R., Lele, S. K. and Jacobson, M. Z.

"A PROBABILISTIC ICE HABIT MODEL FOR LES OF CONTRAILS"

AIAA Paper 2013-2553, June 2013, San Diego, CA.

This study aims at using a three-dimensional large-eddy simulation (LES) model for quantifying the effects of non-sphericity of ice particles on the dynamics of aircraft condensation trails. A new model to incorporate ice habits is proposed and used with LES calculations for a time horizon of 20 minutes after the aircraft has passed. It is found that ice particle density and ice area are significantly higher for non-spherical than spherical ice particles -- for an ambient RHi of 130 percent, the ice area is about 30 percent higher while almost all initialized particles remain active throughout the time horizon considered. Optical depth is observed to be about 25 percent higher for non-spherical particles than for spherical particles.

"DETAILED OBSERVATIONS OF INTERACTIONS OF WINGTIP VORTICES IN CLOSE-FORMATION FLIGHT"

Journal of Aircraft, Vol. 49, No. 1, January-February 2012, pp. 206-213.

The interaction of wingtip vortices in close-formation flight of two wings were examined experimentally. Both wings consisting of a NACA 23012 airfoil section and a rectangular planform of an aspect ratio of 5 were set in echelon formation in a wind tunnel. The lift-to-drag ratio increased the most effectively when the two wings were overlapped with each other by 5 percent of the wingspan with zero vertical offset for the present wing configuration. Flow visualizations and particle image velocimetry measurements showed that the trailing vortex of the lead wing collided at a slightly inboard point of the trail wing and was divided into two streamwise vortices in the most effective overlap condition. It was also observed that the tip vortices of the lead and trail wings interacted closely with each other to form a pair of counter-rotating vortices for smaller overlap conditions less than 5 percent with zero vertical offset. For such small overlap cases, circulation of the trailing vortex of the trail wing was reduced markedly by influences of the trailing vortex of the lead wing.

"APPLICATION OF THE SYMMETRICAL-SINGULARITY PANEL METHOD TO CALCULATING THE FLOW OVER AN AIRCRAFT WITH ACCOUNTING FOR THE EFFECT OF ENGINE EXHAUST JETS"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 41-53

The formation of the near wake behind an aircraft in the airport airspace is considered. Low flight velocities of aircraft during takeoffs and landings allow the usage of panel methods to simulate the flow of an ideal incompressible fluid around aircraft configurations with consideration for the effect of engine exhaust jets. Presented in the work are the results of the computer code's verification using a comparison with analytical solutions, computational results based on other computer codes, and experimental data. "HIGH ALTITUDE TURBULENCE DETECTION USING AN AIRBORNE DOPPLER LIDAR"

ICAS 2014, September 2014, St. Petersburg, Russia.

Air turbulence is a serious problem that affects airline operations. The Japan Aerospace Exploration Agency (JAXA) is developing an airborne Doppler LIDAR (Light Detection and Ranging) for on-board turbulence detection. Flight experiments demonstrated that a high-altitude prototype can measure wind speeds at the more than 9 km range at altitude of 12 km. This paper describes the development of the airborne Doppler LIDAR and presents sample high-altitude flight experiment results.

Inoue, O. and Hattori, Y.

"ACOUSTIC WAVES GENERATED BY COLLISIONS OF TWO VORTEX RINGS"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

Three-dimensional, unsteady, compressible flow fields produced by collisions of two vortex rings are simulated numerically, and the basic natures of the sound generated by the collisions are clarified. The Navier-Stokes equations are solved by a finite difference method. For spatial derivatives, a sixth-order accurate compact Pade scheme is used for time-integration. The non-reflecting boundary conditions (Poinsot and Lele) are imposed. Non-uniform mesh system is applied in this study to save computation time, because a large computational domain is required in order to capture the sounds in far fields. Two different types of a vortex ring are considered, depending on the initial vorticity distribution: Hill's spherical vortex and Gaussian type.

Inoue, O. and Hattori, Y.

"SOUND GENERATION BY SHOCK-VORTEX INTERACTIONS"

J. Fluid Mech., Vol. 380, 1999, pp. 81-116

Two-dimensional, unsteady, compressible flow fields produced by the interactions between a single vortex or a pair of vortices and a shock wave are simulated numerically. The Navier-Stokes equations are solved by a finite difference method. The sixth-order-accurate compact Pade scheme is used for spatial derivatives, together with the fourth-order-accurate Runge-Kutta scheme for time integration. The detailed mechanics of the flow fields at an early stage of the interactions and the basic nature of the near-field sound generated by the interactions are studied. The results for both a single vortex and a pair of vortices suggest that the generation and the nature of sounds are closely related to the generation of reflected shock waves. The flow field differs significantly when the pair of vortices moves in the same direction as the shock wave than when opposite to it.

Inoue, O., Hattori, Y. and Sasaki, T.

"SOUND GENERATION BY COAXIAL COLLISION OF TWO VORTEX RINGS"

Journal of Fluid Mechanics, Vol. 424, 2000, pp. 327-365.

Sound pressure fields generated by coaxial collisions of two vortex rings with equal/unequal strengths are simulated numerically. The axisymmetric, unsteady, compressible Navier-Stokes equations are solved by a finite difference method, not only for a near field but also for a far field. The sixth-order-accurate compact Pade scheme is used for spatial derivatives, together with the fourth-order-accurate Runge-Kutta scheme for time integration. The results show that the generation of sound is closely related to the change of direction of the vortex ring motion induced by the mutual interaction of the two vortex rings. For the case of equal strength (head-on collision), the change of direction is associated with stretching of the vortex rings. Generated sound waves consist of compression parts and rarefaction parts, and have a quadrupolar nature. For the case of unequal strengths, the two vortex rings pass through each other; the weaker vortex ring moves outside the stronger vortex ring which shows a loop motion. The number of generated waves depends on the relative strength of the two vortex rings. The sound pressure includes dipolar and octa-polar components, in addition to monopolar and quadrupolar components which are observed for the case of a head-on collision.

Isambert, E.

"THE CREDOS PROJECT: COMMUNICATION PLAN"

D5-2, June 2007.

This document describes the approach chosen by the CREDOS project to define the CREDOS communication strategy and then proposes a plan to allow effective and efficient communication towards CREDOS stakeholders and other target audiences throughout the lifecycle of the project (2006-2009). The communication is built using the ADKAR approach to address change management in organizations. The scope of the communication plan addresses initial phases of the ADKAR framework, i.e. 'awareness' and 'desire to participate' steps, that fits with the objectives and organization of the CREDOS project.

Isambert, E.

"THE CREDOS PROJECT: STAKEHOLDER SEGMENTATION MODEL"

D5-3, September 2007.

This document contains the generic Stakeholder Segmentation Model for the development and implementation of reduced separations for flight departure operations targeted by the CREDOS project (favorable crosswind conditions) for European airports. Segmentation means here categorizing the various parties having an interest (Stakeholders) in the development, implementation or execution of these operations according to a set of criteria. The analysis along different viewpoints shows that a

common 'interest' for CREDOS operations exist for the enhancement of airport operations through decrease of departure delay and the increase of airport productivity.

"NAVIER-STOKES CALCULATIONS FOR VORTEX RINGS IN AN UNBOUNDED DOMAIN"

Computers Fluids, Vol. 22, No. 4/5, 1993, pp. 589-605.

A computational code for the vorticity-potential method is developed for a three-dimensional bounded vorticity field. The evaluation of the boundary data for the vector potential in the code is improved so that the numerical solution simulates that in an unbounded domain to a high order. The time evolution of two vortex rings and that of an elliptic ring are investigated with this code. The cut-and-connect phenomena of vortex rings are successfully captured. The results are compared with those of asymptotic theory and the experiment. They also highlight the need for additional theoretical and numerical investigations.

"ACCURATE NUMERICAL SIMULATION OF THREE-DIMENSIONAL LID-DRIVEN CAVITY FLOWS WITH DIFFERENT SPAN LENGTHS"

In Vortex Dominated Flows, edited by D. Blackmore, E. Krause and C. Tung, 2005, World Scientific, New Jersey, Chapter 5, pp. 87-98.

The steady incompressible vortical flows at the Reynolds number of 850 in three-dimensional lid-driven rectangular cavities with square cross sections and different span lengths are studied using a combined compact finite difference scheme with high accuracy and spectral-like resolution. The simulations have been done at the span wise aspect ratios of 1, 3, 4, 5 and 6.55. The results of 1, 3 and 4 shows that the streamlines in the cavities are chaotic and a streamline occupies the whole flow region. On the other hand, the tori of streamlines are found near the symmetric plane in the cavities with longer spans at aspect ratios of 5 and 6.55, though the global chaotic streamlines are also observed along the central axis of the cavity and around the tori.

"NUMERICAL EXAMINATION OF THE EFFECT OF CROSS-WIND ON JET BLAST"

AIAA Paper No. 2012-0862, January 2012, Nashville, Tennessee.

The runways A and B of Tokyo international airport (Haneda airport) have a cross over point. When an aircraft takes off from the runway A, it may be possible at this cross over point that the jet blast from the aircraft constitutes a hazard for another aircraft landing on the runway B. Therefore, it is required for operational safety and for improvement of capacity and efficiency of air traffic control to predict the trajectory of long-distance jet blast with high accuracy. To examine the far-field velocity of jet blast by

computational fluid dynamics in this research, simulation using Reynolds averaged Navier-Stokes equation is carried out with very large computational domain. The velocity profiles obtained by numerical simulation agree well with those obtained by experiments. Then, we perform the parametric study of wind direction. It is found that the wind direction angle that has the most effect on the deflection of jet blast is lower than ninety degrees. Moreover, the trajectory of jet blast can be described by power law.

Ishiko, K., Hashimoto, A., Matsuo, Y. and Watanabe, S.

"NUMERICAL STUDY OF THE EFFECTS OF CROSSWIND ON THE JET BLAST DEFORMATION"

ICAS Paper 2012-10.10.3, September 2012, Brisbane, Australia.

In Tokyo international airport (Haneda airport), runways A and B have a cross over point. At this point, it may be possible that the jet blast of aircraft on takeoff from the runway A constitutes a hazard for another aircraft landing on runway B. For operational safety and for improvement of capacity and efficiency of air traffic control, it is required to predict the trajectory of long-distance jet blast with high accuracy. To examine far-field velocity of jet blast by computational fluid dynamics, simulation using Reynolds averaged Navier-Stokes equation is carried out with very large computational domain in this research. The velocity profiles obtained by numerical simulation agree well with those obtained by experiments. Then, we perform the parametric study of wind direction. It is found that the wind direction angle that has more effect on the deflection of jet blast is lower than ninety degrees. Moreover, the trajectory of jet blast can be described by power law.

"NUMERICAL ANALYSIS OF THREE-DIMENSIONAL WALL JET USING ANISOTROPIC TURBULENCE MODEL"

AIAA Paper 2013-0268, January 2013, Grapevine, TX.

In order to predict the flow field of three-dimensional wall jets, an anisotropic constitutive relation is incorporated into the Spalart-Allmaras turbulence model. A modification of the model for the improvement of the predictability of free jets is employed. FaST Aerodynamic Routines (FaSTAR) developed by JAXA is used as a compressible-flow solver. Firstly, a turbulent boundary layer flow along a flat plate is computed to confirm the validity of the anisotropic constitutive relation. The obtained logarithmic velocity profile agrees well with the analytical solution, regardless of whether the anisotropy of the Reynolds stress is considered or not. As a result, the modification is confirmed to have no adverse effects on the prediction of the typical wall-bounded flow. Secondly, computations of three-dimensional free and wall jets are performed. For free jets, the computed results appropriately give the streamwise decay and the half-width of the velocity, confirming the applicability of the modification for free jets. For wall jets, the present model properly reproduces the secondary flow observed in the experiment, and the computed ratio of two half-widths in the lateral direction is shown to be improved by taking the anisotropic constitutive relation into account. The anisotropic constitutive relation is then used to extend the Shear-Stress Transport turbulence model. The better

results of the velocity half-widths are obtained using the different model parameters of the anisotropic constitutive relation rather than the use of the original values.

"DESIGN AND ANALYSIS OF WINGLETS FOR MILITARY AIRCRAFT"

AFFDL-TR-76-6, February 1976, Boeing Commercial Airplane Company, Seattle, WA.

A study of the design and analysis of winglets for Military Aircraft has been completed. The program consisted of investigating analytically winglet concepts for application to the KC-135 and C-141, designing and building winglets for an 0.035 and 0.070 scale model KC-135, and conducting a structural feasibility investigation of the winglet installation on the KC-135. The analysis of the winglets showed a 14 percent reduction in induced drag for the KC-135 and a 11 percent reduction for the C-141. The structural design study of the KC-135A winglet installation estimated a 592lb weight increase. An 8.4 percent improvement was estimated in $M(L/D)$ sub MAX and an 8.1 percent improvement in range factor for the KC-135A. An 0.070 scale half span KC-135 wind tunnel model has been tested in the NASA 8 Ft Transonic Tunnel. Preliminary unpublished test data have substantiated the analytical procedures used by The Boeing Company to determine the aerodynamic characteristics and performance benefits from winglets on the KC-135 aircraft.

Ishimitsu, K. K. and Zanton, D. F.

"DESIGN AND ANALYSIS OF WINGLETS FOR MILITARY AIRCRAFT: PHASE II"

AFFDL-TR-77-23, May 1977, Boeing Commercial Airplane Company, Seattle, WA.

A study of the design and analysis of winglets for military aircraft has been completed. This study is a continuation of the work reported in AFFDL-TR-76-6. The program consisted of investigating analytically the AFFDL/Boeing winglet on the take-off and landing configuration of KC-135A. Also investigated analytically were the effect of a wing leading-edge device on the performance of the AFFDL/Boeing winglets and the design of a compromise high-speed/low-speed winglet. Two wind tunnel tests were conducted by the NASA-Langley Research Center 9-foot transonic tunnel. A high-speed and low-speed test were conducted to determine the effect of the AFFDL/Boeing winglets on the KC-135A's aerodynamic performance and longitudinal and lateral-directional stability. A preliminary plan for a KC-135A winglet retrofit program was developed and its cost estimated. Based on a 1979 program start, the retrofit costs would be recovered by the start of 1984.

"EXPERIMENTAL CONTROL OF VORTEX BREAKDOWN BY DENSITY EFFECTS"

Physics of Fluids, Vol. 23, 2011, pp. 034104-1 - 034104-9.

The vortex breakdown inside a cylinder with a rotating top lid is controlled experimentally by injecting at the bottom a fluid with a small density difference. The density difference is obtained by mixing a heavy dye or alcohol with water to create a jet denser or lighter than water. The injection of a heavy fluid creates a buoyancy force downward, which counteracts the meridional recirculation in the cylinder and thus enhances the formation of a vortex breakdown bubble. The stability diagram shows that even a very small density difference of 0.02% can decrease by a factor of 2 the critical Reynolds number of appearance of the breakdown. On the other hand, the injection of a lighter fluid does not destroy the vortex breakdown. However, for density differences larger than 0.03%, the lighter fluid can pierce through the bubble and leads to a new structure of the vortex breakdown. Finally, a parallel is drawn between a light jet and a vortex ring generated at the bottom of the cylinder: strong vortex rings can pierce through the bubble, whereas weak vortex rings are simply advected around the bubble.

Israel, D. R.

"AN OVERVIEW OF THE UPGRADED THIRD GENERATION AIR TRAFFIC CONTROL SYSTEM"

EASCON '74 Record, IEEE Electronics and Aerospace Systems Conference, 1974, pp. 244-249

With the continuing growth of aviation, improvements to our current air traffic control system will be required. The system planned for use in the 1980's and beyond is now known as the Upgraded Third Generation System. It is designed to meet the FAA's goals of: (a) maintaining or improving safety, (b) constraining or reducing costs, and (c) increasing or improving performance. The system will be characterized by nine major features - Intermittent Positive Control, the Discrete Address Beacon System, Area Navigation, Microwave Landing System, Increased Automation, Airport Surface Traffic Control, a Wake Vortex Avoidance System, Flight Service Stations, and Aeronautical Satellites.

Israel, D. R.

"WAKE VORTEX PROGRAM STATUS"

Inter. Air Trans. Conf., Am. Soc. Civil Engineers, San Francisco, CA, March 1975, pp. 143-160

The paper describes past results, present status, and future outlook and approaches of programs for studying wake vortex behavior and reduction of its effects. The main characteristics of several vortex sensing systems are examined, including a pulsed acoustic vortex sensing system, a Doppler acoustic sensing system, a ground wind sensing system, and a laser Doppler system. Three stages in the life of an aircraft wake have been discerned by recent study: the inviscid wake stage, the entraining wake stage, and the decaying wake stage. A prototype vortex advisory system for a large airport is described.

Ito, Y.

"DESIGN AND PERFORMANCE OF AN ACOUSTIC ANTENNA FOR A PHASED ARRAY DOPPLER SODAR"

Meteorological Applications, Vol. 5, 1997, pp. 149-156.

An acoustic array antenna which has a narrow main lobe and suppressed sidelobes is studied. The directivity function formed by the multiple point sources is used to estimate the aperture of an array and the spacing between the transducer elements to make a desired beam. Then the aperture tapering based on a Chebyshev distribution and the effect of an acoustic shield are evaluated to suppress the sidelobe radiation. The total performance of the phased array system has been examined by comparison with tower instruments. The field test shows that the measured beam pattern agrees with the calculated one and the sodar-derived winds have a correlation of 0.96 and a standard deviation of differences of about 0.47-0.52 m/s compared with in situ measurements. These statistical values are as good as or even better than those from the previous experiments.

Itoh, E. and Mitici M.

"EVALUATING THE IMPACT OF NEW AIRCRAFT SEPARATION MINIMA ON AVAILABLE AIRSPACE CAPACITY AND ARRIVAL TIME DELAY"

The Aeronautical Journal, Vol. 124, No. 1274, April 2020, pp. 447-471

Although the application of new, reduced aircraft separation minima can directly increase runway throughput, the impact thereof on the traffic flow of aircraft arriving at the destination airport has not been discussed yet. This paper proposes a data-driven and queue-based modeling approach and presents an analysis of the impact on the delay time of arriving aircraft in the airspace within a radius of 100 nautical miles around an airport. The parameters of our queuing model were estimated by analyzing the data contained in the radar tracks and flight plans for flights that arrived at Tokyo International Airport during the 2 years of 2016 and 2017. The results clarified the best arrival strategy according to the distance from the arrival airport: The combination of airspace capacity control and reduction of the flight time and separation variance is the most powerful solution to mitigate delays experienced by arriving traffic while also allowing an increase in the amount of arrival traffic. The application of new wake vortex categories would enable us to increase the arrival traffic to 120%. In addition, the arrival delay time could be minimized by implementing the proposed arrival traffic strategies together with automation support for air traffic controllers.

Iungo, G. V.

"EXPERIMENTAL CHARACTERIZATION OF WIND TURBINE WAKES: WIND TUNNEL TESTS AND WIND LIDAR MEASUREMENTS"

Journal of Wind Engineering and Industrial Aerodynamics, Vol. 149, 2016, pp. 35-39.

The characterization of wind turbine wakes produced for different loading conditions of the turbine and incoming wind is a crucial task for design of wind farm layout. Indeed, the optimization of the power harvested from a wind farm can only be achieved if detrimental wake interactions are carefully inhibited or mitigated. In this paper the importance of performing wind turbine wake measurements is emphasized through two experiments, which are complementary for the experimental measurement techniques used and scientific results achieved. First, wind tunnel tests of a down-scaled wind turbine

are presented, for which fixed-point turbulence measurements are leveraged to predict the hub vortex instability encountered in the near wake. The second experiment consists in wind LIDAR measurements of the wake produced by a utility-scale wind turbine under different regimes of the atmospheric thermal stability. It is shown that wind turbine wakes recover faster under convective conditions than for neutral ones.

Iungo, G. V. and Porte-Agel, F.

"MEASUREMENT PROCEDURES FOR CHARACTERIZATION OF WIND TURBINE WAKES WITH SCANNING DOPPLER WIND LIDARS"

Advances in Science and Research, Vol. 10, 2013, pp. 71-75.

The wake flow produced from an Enercon E-70 wind turbine is investigated through three scanning Doppler wind LiDARs. One LiDAR is deployed upwind to characterize the incoming wind, while the other two LiDARs are located downstream to carry out wake measurements. The main challenge in performing measurements of wind turbine wakes is represented by the varying wind conditions, and by the consequent adjustments of the turbine yaw angle needed to maximize power production. Consequently, considering possible variations of the relative position between the LiDAR measurement volume and wake location, different measuring techniques were carried out to perform 2-D and 3-D characterizations of the mean wake velocity field. However, larger measurement volumes and higher spatial resolution require longer sampling periods; thus, to investigate wake turbulence tests were also performed by staring the LiDAR laser beam over fixed directions with the maximum sampling frequency. The characterization of the wake recovery along the downwind direction is performed. Moreover, wake turbulence peaks are detected at turbine top-tip height, which can represent increased fatigue loads for downstream wind turbines within a wind farm.

Iungo, G. V., Skinner, P. and Buresti, G.

"CORRECTION OF WANDERING SMOOTHING EFFECTS ON STATIC MEASUREMENTS OF A WING-TIP VORTEX"

Exp. Fluids, Vol. 46, 2009, pp. 435-452

Wandering is a typical feature of wing-tip vortices and it consists in random fluctuations of the vortex core. Consequently, vortices measured by static measuring techniques appear to be more diffuse than in reality, so that a correction method is needed. In the present paper statistical simulations of the wandering of a Lamb-Oseen vortex are first performed by representing the vortex core locations through bi-variate normal probability density functions. It is found that wandering amplitudes smaller than 60 percent of the core radius are well predicted by using the ratio between the RMS value of the mean cross-velocity and its slope measured at the mean vortex center. Furthermore, the principal axes of wandering can be accurately evaluated from the opposite of the cross-correlation coefficient between the spanwise and the normal velocities measured at the mean vortex center. The correction of the wandering smoothing effects is then carried out through four different algorithms that perform

the deconvolution of the mean velocity field with the probability density function that represents the wandering. The corrections performed are very accurate for the simulations with wandering amplitudes smaller than 60 percent of the core radius, whereas errors become larger with increasing wandering amplitudes. Subsequently, the whole procedure to evaluate wandering and to correct the mean velocity field is applied to static measurements, carried out with a fast-response five-hole pressure probe, of a tip vortex generated from a NACA 0012 half-wing model. It is found that the wandering is predominantly in the upward-outboard to downward-inboard direction. Furthermore, the wandering amplitude grows with increasing streamwise distance from the wing, whereas it decreases with increasing angle of attack and free-stream velocity.

"FIELD MEASUREMENTS OF WIND TURBINE WAKES WITH LIDARS"

Journal of Atmospheric and Oceanic Technology, Vol. 30, February 2013, pp. 274-287.

Field measurements of the wake flow produced from a 2-MW Enercon E-70 wind turbine were performed using three scanning Doppler wind lidars. A GPS-based technique was used to determine the position of the wind turbine and the wind lidar locations, as well as the direction of the laser beams. The lidars used in this study are characterized by a high spatial resolution of 18 m, which allows the detailed characterization of the wind turbine wake. Two-dimensional measurements of wind speed were carried out by scanning a single lidar over the vertical symmetry plane of the wake. The mean axial velocity field was then retrieved by averaging 2D scans performed consecutively. To investigate wake turbulence, single lidar measurements were performed by staring the laser beam at fixed directions and using the maximum sampling frequency. From these tests, peaks in the velocity variance are detected within the wake in correspondence of the turbine top tip height; this enhanced turbulence could represent a source of dangerous fatigue loads for downstream turbines. The spectral density of the measured velocity fluctuations shows a clear inertial-range scaling behavior. Then, simultaneous measurements with two lidars were performed to characterize both the axial and the vertical velocity components. For this setup, the two velocity components were retrieved only for measurement points for which the two laser beams crossed nearly at a right angle. Statistics were computed over the sample set for both velocity components, and they showed strong flow fluctuations in the near-wake region at turbine top tip height, with a turbulence intensity of about 30 percent.

Ivanell, S., Mikkelsen, R., Sorensen, J. N. and Henningson, D.

"STABILITY ANALYSIS OF THE TIP VORTICES OF A WIND TURBINE"

AIAA Paper No. 2008-1322, Reno, NV, January 2008

The aim of the present project is to get a better understanding of the stability properties of wakes generated by wind turbine rotors. To determine the stability properties of wind turbine wakes a numerical study on the stability of the tip vortices behind the Tjaereborg wind turbine has been carried out. The numerical model is based on large eddy simulations of the Navier-Stokes equations using the

actuator line method to generate the wake and the tip vortices. To determine critical frequencies the flow is perturbed by inserting a harmonic perturbation. The results show that the instability is dispersive and that growth arise only for some specific frequencies and type of modes.

Ivanov, S. V.

"MICROWAVE ABSORPTION SPECTRA OF THE ATMOSPHERE AND AIRCRAFT WAKE"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 329-339

Absorption spectra of the atmospheric air and aircraft wake are analyzed within 1-1000 GHz spectral region to estimate possibilities of aircraft vortex wake visualization from emission or absorption of the microwave radiation. The standard atmosphere and Boeing 707 aircraft wake conditions are considered regarding the gaseous components (oxygen, nitrogen, water, small gas constituents) and probable presence of water aerosol and raindrops. The Liebe MPM model is used for the oxygen, nitrogen, water, aerosol, and rain attenuation calculation. Absorption of trace gases is modeled using the HITRAN-96 database. Absorption of water dimers is calculated separately and its contribution to continuum is discussed. Water vapor is found to be a suitable exhaust gas for the aircraft wake visualization in microwave region.

Ivanov, S. V.

"SPECTROSCOPIC DETECTION OF AIRCRAFT WAKE GASES"

Physics of Wave Phenomena, Vol. 15, No. 1, 2007, pp. 57-65.

Using the technique of limiting information-metric scales, the potential of laser IR absorption spectroscopy for detecting small gas components of aircraft wake was quantitatively analyzed. Formulas for minimum distinguishable and minimum detectable gas concentrations were derived. Calculation was carried out for SO₂, NO, and NO₂ under typical conditions near the Boeing 707 aircraft engine nozzle at altitude $H = 12.2$ km. Alternative IR laser spectroscopy methods for detecting various gas components in the near wake were considered. Two possibilities to improve the concentration measurement sensitivity were analyzed: (i) a decrease in the background absorption of CO₂ and H₂O and (ii) an increase in the absorption cross section of detected gas.

Iversen, J. D.

"CORRELATION OF TURBULENT TRAILING VORTEX DECAY DATA"

Journal of Aircraft, Vol. 13, No. 5, May 1976, pp. 338-342

A correlation function, derived based on self-similar variable eddy-viscosity decay, is introduced and utilized to correlate aircraft trailing vortex velocity data from ground and flight experiments. The correlation function collapses maximum tangential velocity data from scale-model and flight tests to a

single curve. The resulting curve clearly shows both the inviscid plateau and the downstream decay regions. A comparison between experimental data and numerical solution shows closer agreement with the variable eddy viscosity solution than the constant viscosity analytical solution.

Iversen, J. D.

"STUDIES OF VORTEX DECAY AND VORTEX ROLLUP"

Proceedings of the AFFDL/NASA/FAA Wake Turbulence Work Shop, Air Force Flight Dynamics Laboratory, AFFDL-TM-75-16-FGC, 1974, pp. 50-58

The effect of generating aircraft span loading on the following aircraft rolling moment is discussed for the particular cases of tailored loading, sawtooth loading and unconventional flap loading on the generating aircraft. A correlation function is introduced with correlates maximum tangential velocity in the vortex with downstream distance for a wide range of Reynolds numbers.

Iversen, J. D.

"INVISCID TO TURBULENT TRANSITION OF TRAILING VORTICES"

ISU-ERI-AMES-74241, November 1974, Iowa State University, Ames, IA

It has been discovered experimentally that a so-called 'plateau' region exists in the vortex system which trails from a lifting wing. The decay of the vortex due to viscous or turbulent shear is very slow in the plateau so that the maximum tangential speed in the vortices remains very nearly constant for some distance downstream of roll-up and then begins to decrease, becoming inversely proportional to the square root of the distance far downstream.

Iversen, J. D.

"INVISCID TO TURBULENT TRANSITION OF TRAILING VORTICES"

AIAA Paper No. 1975-0883, Hartford, CT, June 1975.

The plateau region in which trailing vortices initially exhibit slow decay of maximum tangential speed is demonstrated with the aid of constant and variable eddy viscosity models. The existence of the plateau is explained by the presence of the viscous core and by the necessity for transition of the initial, nearly inviscid profile to similarity far downstream. Span loading is shown to affect the initial maximum tangential speed as well as the duration of the plateau region. Triangular span loading is shown to present less hazard to trailing aircraft, at least in the near field, than elliptic loading because the inviscid profile for triangular loading exhibits a finite tangential speed at the vortex centerline and a large inviscid core.

Iversen, J. D.

"TRAILING VORTEX EFFECTS ON FOLLOWING AIRCRAFT"

ISU USAF Operations Analysis Report, ERI-66200, 1971, Iowa State University, Ames, IA

Wind tunnel tests of two C-130 aircraft models were performed to determine the effect of the wake of a leading aircraft upon the aerodynamic forces experienced by the trailing aircraft. The results of the tests along with theoretical considerations are used to calculate lift forces and rolling moments experienced by the trailing aircraft.

Iversen, J. D. and Bernstein, S.

"DYNAMIC SIMULATION OF AN AIRCRAFT UNDER THE EFFECT OF VORTEX WAKE TURBULENCE"

Annales de l'Association Pour le Calcul Analogique, Vol. 14, 1972, pp. 136-144

The introduction of modern heavy jets poses an increasing hazard to light and moderate weight aircraft due to high-intensity vortex wake turbulence. A technique is developed to simulate the responses of a trailing aircraft due to the induced rolling moments and loss of lift imposed by the vortices. Despite the nonlinear and complex nature of the problem, the method was applied successfully using an EAI 8812 analog computer with no hybrid facilities. The simulated aircraft was free to roll and move vertically and laterally with respect to the generating aircraft. Results of such a simulation for the case of a C-130 behind another C-130 and behind a C-5A are presented.

Iversen, J. D. and Bernstein, S.

"TRAILING VORTEX EFFECTS ON FOLLOWING AIRCRAFT"

Journal of Aircraft, Vol. 11, No. 1, January 1974, pp. 60-61

Wind-tunnel tests and a strip-theory analysis are utilized to estimate the change in lift force and rolling moment on an aircraft due to its penetration into the vortex trail of a leading aircraft. Values of lift and rolling moment coefficients on the trailing aircraft are presented as functions of vertical and lateral displacement with respect to the vortex.

"MERGING DISTANCE CRITERIA FOR CO-ROTATING TRAILING VORTICES"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 161-172

The merging of co-rotational vortices of equal strength is studied by flow-visualization and hot-wire anemometer wind-tunnel experiments and by preliminary numerical calculation of vortex merging. Wind-tunnel experiments and numerical calculations indicate that the effects of turbulence and

viscosity are to decrease merging distance from that predicted by inviscid calculations. Hot-wire anemometer measurements of velocity profiles and rolling-moment measurements on a follower model show reduction of the trailing vortex hazard due to merging.

Iversen, J. D., Corsiglia, V. R., Park, S., Backhus, D. R. and Brickman, R. A.

"HOT-WIRE, LASER-ANEMOMETER, AND FORCE MEASUREMENTS OF INTERACTING TRAILING VORTICES"

Journal of Aircraft, Vol. 16, No. 7, July 1979, pp. 448-45.

Single and multiple trailing vortices shed from semispan wings and a transport model in a wind tunnel were studied by means of a laser velocimeter, hot-wire anemometer, and trailing model incorporating a six-component force balance. Velocity profile and turbulence data from the laser velocimeter and hot-wire anemometer are presented and shown to compare well with the Betz inviscid circulation model. Lift and rolling moment measurements on the following model are compared with those predicted from the flow field measurements.

Iversen, J. D., Park, S., Backhus, D. R., Brickman, R. A. and Corsiglia, V. R.

"HOT-WIRE, LASER ANEMOMETER AND FORCE BALANCE MEASUREMENTS OF CROSS-SECTIONAL PLANES OF SINGLE AND INTERACTING TRAILING VORTICES"

AIAA Paper No. 1978-1194, Seattle, WA, July 197.

Single and multiple trailing vortices shed from semi-span wings and a transport model in a wind tunnel were studied by means of a laser-velocimeter, hot-wire anemometer, and a trailing model incorporating a 6-component force balance. Velocity profile and turbulence data from the laser-velocimeter and hot-wire anemometer are presented and shown to compare well with the Betz inviscid circulation model. Lift and rolling moment measurements on the following model are compared with those predicted from the flow field measurements.

Iwai, H., Ishii, S., Tsunematsu, N., Mizutani, K. Murayama, Y., Itabe, T., Yamada, I., Matayoshi, N., Matsushima, D., Sha, W., Yamazaki, T. and Iwasaki, T.

"COMPARISON OF DUAL-DOPPLER LIDAR MEASUREMENTS OF WIND WITH HELICOPTER MEASUREMENTS"

Proceedings 15th Coherent Laser Radar Conference, June 2009, Toulouse, France, pp. 103-106.

Dual-Doppler lidar and heliborne sensor were used to investigate the three-dimensional structure of the wind field over Sendai Airport in June 2007. We applied a variational method developed for multiple Doppler radar measurements to dual-Doppler lidar analysis. The comparison of wind fields retrieved from dual-Doppler analysis to wind fields measured by the JAXA heliborne sensor reveals

differences of horizontal wind speed and wind direction of 0.11 m/s and 10.1 degrees, on average, with standard deviations not exceeding 0.75 m/s and 16 degrees, respectively.

"NUMERICAL AND EXPERIMENTAL CHARACTERISATION OF AN AERONAUTIC PITOT PROBE"

The Aeronautical Journal, Vol. 123, No. 1264, June 2019, pp. 890-911.

Aeronautic Pitot probes (PPs) are extremely important for airspeed and altitude measurements in aviation. Failure of the instrument due to clogging caused by ice formation can lead to dangerous situations. In this work, a commercial aeronautic PP was characterized experimentally regarding its inner composition, material properties and its thermal performance in a climatic wind tunnel. Performance runs were taken out to analyze the thermal response of the PP under various operating conditions with a particular emphasis on the cooling process in the case of a heating element failure. Data for the thermal conductivity, diffusivity and specific heat for each material forming the PP were obtained. A numerical model to simulate the thermal behavior of the PP was created using Comsol Multiphysics (CM). Experimental data were compared with their numerical counterparts for model validation purposes. After the model was validated, the operation of the PP in flight conditions was simulated. The failure of the conventional heating system was analyzed to obtain the time until the PP reaches a tip temperature where ice formation can be expected. The tip temperature undercut the zero degrees Celsius mark 165 seconds after the heating element was switched off. The data collected in this work can be used to implement and validate mathematical models to predict the thermal performance of Pitot probes in flight conditions.

"AERONAUTICS - THE BIG 'A' IN NASA"

FAA Symposium on Turbulence, Federal Aviation Administration, 1971, pp. 13-18

The paper presents highlights of the operating systems part of the NASA aeronautics program and where wake turbulence fits into NASA's scale of priorities. The roles of aircraft noise and related research are discussed.

Jackson, W., editor, Yaras, M., Harvey, J., Winckelmans, G., Fournier, G. and Belotserkovsky, A.

"WAKE VORTEX PREDICTION: AN OVERVIEW"

TP 13629E, March 2001, Transportation Development Centre, Montreal, Canada

Aviation authorities have long recognized that reducing wake vortex separations during instrument meteorological conditions could permit the capacity at major airports to be increased by up to 15 percent, and delays on arrival and departure to be significantly reduced. This improved efficiency would be worth billions of dollars in savings worldwide. The objectives of this research project were to

increase the capacity of major airports, while maintaining or improving existing levels of safety, and to continue the evaluation and development of a Vortex Forecast System (VFS), which had been under development for several years in Russia. Transport Canada formed a team of experts from Canada, Belgium, and Russia. This team has completed seven years of developing VFS, conducting related studies, and co-operating with other researchers in Europe and North America. VFS is now one of the most capable real-time wake vortex prediction systems in the world. It is recommended that development of VFS be continued. A specific airport should be selected in Canada to provide a focus for Canadian wake vortex research. Canadian stakeholders such as Transport Canada, NAV CANADA, and major airport authorities should continue wake vortex research and continue to co-operate internationally.

Jacob, D., Lai, D. Y. and Delisi, D. P.

"DEVELOPMENT OF AN IMPROVED PULSED LIDAR CIRCULATION ESTIMATION ALGORITHM AND PERFORMANCE RESULTS FOR DENVER OGE DATA"

AIAA Paper 2013-0509, January 2013, Grapevine, TX.

A new algorithm for estimating circulation strength of aircraft wake vortices from pulsed coherent lidar measurements is described and results from processing Out of Ground Effect (OGE) field data from NASA measurements made at the Denver International Airport in 2003 are compared to results obtained using the Lockheed Martin Spectral Space Processing (Legacy) algorithm. The key improvements of the new algorithm over the Legacy algorithm concern the (a) vortex system matched filters, (b) maximum likelihood ratio algorithm, and (c) ambient wind correction. An overview of the algorithm is presented highlighting the differences between this new algorithm and the Legacy algorithm. The performance of both algorithms will be shown for FAA Large weight-category aircraft and compared to historical circulation decay estimates for similar conditions from other field campaigns.

"ASSESSMENT OF LOCKHEED MARTIN'S AIRCRAFT WAKE VORTEX CIRCULATION ESTIMATION ALGORITHMS USING SIMULATED LIDAR DATA"

AIAA Paper 2011-3196, June 2011, Honolulu, Hawaii.

A new algorithm for estimating circulation strength of aircraft wake vortices is under development by Lockheed Martin and is being evaluated by NorthWest Research Associates under the NASA Research Announcement (NASA-NRA) NextGen Airportal Program. The algorithm is being developed with the aid of Lockheed Martin's Coherent Wind Lidar Simulator, developed under the same NASA-NRA program. A brief description of the simulator tool is presented. An overview of both the legacy estimation algorithm and the new algorithm under development is presented which highlights the differences between the two algorithms. The performance of both algorithms is assessed using simulated lidar data generated from analytic wake models and Large Eddy Simulation vortex wind fields with ambient

turbulence eddy dissipation rates of 0.00004, 0.0005 and 0.0145 meters squared per second cubed. Algorithm performance is quantified in terms of standard deviation and bias of estimates as a function of SNR.

Jacob, D., Pruis, M. J., Lai, D. Y. and Delisi, D. P.

"WAKEMOD 4.1: A NEW STANDALONE WAKE VORTEX ALGORITHM FOR ESTIMATING CIRCULATION STRENGTH AND POSITION"

AIAA Paper 2015-3176, June 2015, Dallas, TX.

WakeMod 4.1 (WM41) is a new standalone algorithm for estimating circulation strength and position of aircraft wake vortices from the Lockheed Martin WindTracer spectral data product. Preliminary results of a comparison of WM41 and the Lockheed Martin Offline Wake Processing (Legacy) wake algorithm are presented. Evaluation of the WM41 algorithm was accomplished using both simulated data and field observations obtained at four different airports. There are three principal findings of this study. The first finding is that WM41 provides similar performance to Legacy for Heavy aircraft in the ability to estimate circulation strength. An additional benefit of WM41 circulation estimates is that they do not show high sensitivity to SNR, which is a known limitation of the Legacy wake algorithm. The second key finding is that WM41 and Legacy provide similar estimates regarding vortex position for Heavy and Large aircraft. Previous studies have indicated that the Legacy algorithm estimates vortex position to within 10 meters, and indications of this preliminary study is that the WM41 algorithm estimates are as good or better in that WM41 provides more consistent estimates of vortex pair orientation and spacing throughout a wake track. Furthermore, WM41 position estimates are not affected by the choice of a region of interest. The third principal finding of this study is that WM41 can detect and estimate circulation strength of weak vortices below the sensitivity limit of the Legacy algorithm (approximately 125 meters squared per second), and thereby allows for improved estimation of aircraft wake behavior for aircraft smaller than Heavy, and in the estimation of vortex strength at late wake ages when vortices are weak.

Jacob, J. D.

"EXPERIMENTAL INVESTIGATION OF THE TRAILING VORTEX WAKE OF RECTANGULAR AIRFOILS"

Ph.D. Thesis, 1995, University of California at Berkeley, Berkeley, CA

The trailing vortex wake generated by high aspect-ratio airfoils is investigated in a tow tank. DPIV is used to measure the velocities in the cross-stream plane in the laboratory reference frame as the wing is towed through the tank. The Reynolds number ranges from 20,000 to 80,000. Four sets of vortex wakes are measured: a NACA 0012, a NACA 0012 with tip-jets, a NACA 0012 with flaps and a circular arc airfoil with flaps. The natural wake is found to be very stable and long lived. Tip-jets placed on the wing affect the distribution of vorticity within the vortex core but do not affect the circulation of the vortex, though forcing does change the separation distance between the tip vortex filaments. Axial momentum injection produces instabilities on the vortex which may lead to breakup of the vortices.

The same-signed tip and flap vortices from the airfoils with deployed flaps are found to merge in all cases. In a circular arc airfoil with 30% span flaps, the geometry of the strut is found to affect the time to vortex merger. The time is doubled by using a faired flat-plate strut as opposed to a thick streamlined strut.

Jacob, J. D.

"EXPERIMENTAL INVESTIGATION OF CO-ROTATING TRAILING VORTICES"

AIAA Paper No. 1998-0590, Reno, NV, January 1998

The paper discusses preliminary results of experiments to generate a single pair of co-rotating trailing vortices and observe their behavior in a towing tank. Several configurations of lifting surfaces are used to achieve this. A laser sheet illuminates tracer particles in the flow and a digital camera is used to capture a sequence of PIV images. Planar velocity vector fields and their gradients are derived from these images using an adaptive Lagrangian parcel tracking algorithm. Iso-vorticity surfaces are extracted from time series of planar vorticity data. Reynolds numbers based on total circulation of the vortices in the present experiments range from 2500 to 10000. Merger of the co-rotating vortex pair is observed at all circulation Reynolds numbers. The relation between merger time and Reynolds number is neither constant nor monotonic however, differing from previous experiments at higher Reynolds numbers. Merger occurs from $1/4$ to $1/3$ of an orbit period for typical cases. The merger process appears to be inviscid and three-dimensional. No evidence of breakdown or strong instabilities are present.

Jacob, J. D. and Savas, O.

"VORTEX DYNAMICS IN TRAILING WAKES OF FLAPPED RECTANGULAR WINGS"

AIAA Paper No. 1997-0048, Reno, NV, January 1997

The dynamics of trailing vortex wakes from flapped airfoils are investigated in a towing tank and a wind tunnel. The wakes from a lifting rectangular circular arc airfoil with an aspect ratio of 6 and flap-spans of 30% and 67% and a NACA 0012 with an aspect ratio of 8 and flap-spans of 40% and 50% are studied as the wake evolves downstream. Chord-based Reynolds number Re_c ranged from 1.5×10^4 to 8×10^4 . A traversing five-hole pitot probe and Lagrangian Parcel Tracking (LPT) are used to measure the velocity field in a cross-stream plane behind the wing in the wind tunnel and the towing tank, respectively. The interaction of the tip and flap vortices are studied. Merger of the flap and tip vortices usually occurs within one orbit, leading to a shorter descent distance to merger for the longer flap-spans.

Jacob, J. D., Liepmann, D. and Savas, O.

"NATURAL AND FORCED GROWTH CHARACTERISTICS OF THE VORTEX WAKE OF A RECTANGULAR AIRFOIL"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 27-1 to 27-12

The forced trailing vortex wake of a rectangular NACA 0012 airfoil with an aspect ratio of 8 is investigated experimentally. The experiments include limited five-hole probe measurements in the near wake in a wind tunnel and extensive DPIV measurements in the far wake in a tow tank. Measurements are conducted on the natural wake and the forced wake at chord Reynolds numbers from 2×10^4 to 6×10^4 . The wake is forced by axial jets located on each wing-tip injecting fluid into the vortex cores. The forcing is steady or pulsatile. Pulsatile forcing is varied from 1 Hz to 40 Hz and with the wing-tip jets in phase, out of phase, or one on/one off. Relevant parameters, including vortex separation, vorticity, circulation, and core size, are measured up to 1000 chord lengths behind the wing. Forcing increases both the separation of the vortex pair and the growth rate of the vortex core size. At low frequencies, these effects are monotonic with increasing forcing frequency. At high frequencies, the measurements suggest a complex response to forcing. Based on measurements and observations, some parameters of importance are suggested in exploring possible means of controlling the behavior of the vortex wake. The complexity of the problem dictates that any search for identifying practical solutions must be a concerted effort among experiments, analyses and numerics.

Jacob, J. D., Liepmann, D. and Savas, O.

"EXPERIMENTAL INVESTIGATION OF THE TRAILING VORTEX WAKE OF A RECTANGULAR WING"

AIAA Paper No. 1995-1841, San Diego, CA, June 1995.

The trailing vortex wake behind an NACA 0012 rectangular airfoil is investigated to establish the general nature of both the near and far field wake for further experimental exploration of the stability characteristics. Measurements of the wake are made up to 250 spans downstream of the airfoil with $20,000 < Re < 60,000$. Velocity, vorticity, and circulation are determined by digital particle image velocimetry. It is found that the wake is extremely stable and long-lived. The motion of the vortex pair is steady. The growth of the vortex core and corresponding circulation shows no appreciable decay over the measurement period. No short- or long-wave instabilities are observed in the naturally evolving vortex wake.

Jacob, J. D., Savas, O. and Liepmann, D.

"EXPERIMENTAL INVESTIGATION OF FORCED WAKE VORTICES OF A RECTANGULAR WING"

AIAA Paper No. 1996-2497, New Orleans, LA, June 1996

The forced trailing vortex wake of a rectangular NACA 0012 airfoil with an aspect ratio of 8 is investigated. Measurements are conducted on the natural wake and the forced wake at chord Reynolds numbers from 20,000 to 60,000. The wake is forced by axial jets located on each wing-tip

injecting fluid into the vortex cores. The forcing is steady or pulsatile. Pulsatile forcing is varied from 1 to 40 Hz and with the wing-tip jets in phase, out of phase, or one on/one off. Relevant parameters, including vortex separation, vorticity, circulation, and core size, are measured up to 1000 chord lengths behind the wing. Forcing increases both the separation of the vortex pair and the growth rate of the vortex core size. At low frequencies, these effects are monotonic with increasing forcing frequency. At high frequencies, the measurements suggest a complex response to forcing.

"AIRCRAFT WAKE TURBULENCE AND AIRPORT CAPACITY"

Institute of Transportation Studies Review, Vol. 19, No. 4, August 1996, pp. 2-3, 5

Currently, the distance that must be maintained between aircraft when instrument flight regulations are in effect ranges from 2.5 nautical miles to 6 nautical miles, depending on the size of the aircraft and prevailing weather conditions. With a better understanding of wake vortices, we may be able to predict how far behind an aircraft the wake remains a threat, and to develop techniques that will cause the wake to dissipate more quickly. It might then be possible to reduce the FAA's current separation standards, thereby increasing the capacity of airports around the world.

Jacob, J. D., Savas, O. and Liepmann, D.

"TRAILING VORTEX WAKE GROWTH CHARACTERISTICS OF A HIGH ASPECT RATIO RECTANGULAR AIRFOIL"

AIAA Journal, Vol. 35, No. 2, February 1997, pp. 275-280

The growth characteristics of trailing vortex wakes are investigated in a towing tank. The wakes from a lifting rectangular NACA 0012 airfoil with an aspect ratio of 8 are studied up to 1400 chords downstream. The circulation Reynolds number ranged from 4,000 to 40,000. Digital particle image velocimetry is used to measure the velocity field in the cross-stream plane from which vorticity is calculated. The vortex pair is observed to be very stable and long-lived, showing little decay in the circulation of the individual vortices. The vorticity, however, diffuses over time within the cores of the vortices. The growth is found to be reminiscent of laminar diffusion. No Crow instabilities are observed within the range of these measurements.

Jacob, J., Savas, O. and Liepmann, D.

"TRAILING VORTEX WAKE GROWTH CHARACTERISTICS OF A HIGH ASPECT RATIO RECTANGULAR AIRFOIL"

AIAA Journal, Vol. 35, No. 2, February 1997, pp. 275-280

The growth characteristics of trailing vortex wakes are investigated in a towing tank. The wakes from a lifting rectangular NACA 0012 airfoil with an aspect ratio of 8 are studied up to 1400 chords

downstream. The circulation Reynolds number ranged from $4 \times 1,000$ to $4 \times 10,000$. Digital particle image velocimetry is used to measure the velocity field in the cross-stream plane from which vorticity is calculated. The vortex pair is observed to be very stable and long-lived, showing little decay in the circulation of the individual vortices. The vorticity, however, diffuses over time within the cores of the vortices. This growth is found to be reminiscent of laminar diffusion. No Crow instabilities are observed within the range of these measurements.

"HOT-WIRE ANEMOMETRY FOR IN-FLIGHT MEASUREMENT OF AIRCRAFT WAKE VORTICES"

Proceedings Fifth Annual Symposium, Society of Flight Test Engineers, 1974, pp. 4/13-4/24

An airborne hot-wire anemometry system capable of providing data with few limitations has been used in several flight studies. The design features of the technique and the operational experience with it are described. The development program has resulted in a flight-test technique that can make accurate velocity measurements in flow regimes where large velocity gradients occur.

Jacobsen, R. A.

"HOT-WIRE ANEMOMETRY FOR IN-FLIGHT MEASUREMENT OF AIRCRAFT WAKE VORTICES"

DISA Information, April 1977, pp. 21-27

A development program has demonstrated that hot-wire anemometry can be used successfully on an aircraft in flight to make measurements of wake vortices produced by another aircraft. The probe, whose wires were made of platinum/rhodium, 10 microns in diameter, provides unambiguous results for inflow angles less than about 35 deg. off the probe axis. The high frequency response capability of the hot-wire system allows detailed measurement of the flow structure, and the study of aircraft hazards associated with wake turbulence.

Jacobsen, R. A. and Barber, M. R.

"FLIGHT TEST TECHNIQUES FOR WAKE-VORTEX MINIMIZATION STUDIES"

Proceedings Wake Vortex Minimization Symposium, NASA, SP-409, 1977, pp. 193-220

Flight test techniques developed for use in a study of wake turbulence and used recently in-flight studies of wake minimization methods are discussed. Flow visualization was developed as a technique for qualitatively assessing minimization methods and is required in flight test procedures for making quantitative measurements. The quantitative techniques are the measurement of the upset dynamics of an aircraft encountering the wake and the measurement of the wake velocity profiles. Descriptions of the instrumentation and the data reduction and correlation methods are given.

Jacobsen, R. A. and Drinkwater, F. J.

"EXPLORATORY FLIGHT INVESTIGATION OF AIRCRAFT RESPONSE TO THE WING VORTEX WAKE GENERATED BY THE AUGMENTOR WING JET STOL RESEARCH AIRCRAFT"

NASA TM-X-62387, May 1975, NASA Ames Research Center, Moffett Field, CA

A brief exploratory flight program was conducted at Ames Research Center to investigate the vortex wake hazard of a powered-lift STOL aircraft. The study was made by flying an instrumented Cessna 210 aircraft into the wake of the Augmentor Wing Jet STOL research aircraft at separation distances from 1 to 4 n.mi. Characteristics of the wake were evaluated in terms of the magnitude of the upset of the probing aircraft. Results indicated that within 1 n.mi. separation the wake could cause rolling moments in excess of roll control power and yawing moments equivalent to rudder control power of the probe aircraft. Subjective evaluations by the pilot of the Cessna 210 aircraft, supported by response measurements, indicated that the upset caused by the wake of the STOL aircraft was comparable to that of a DC-9 in the landing configuration.

Jacobsen, R. A. and Short, B. J.

"A FLIGHT INVESTIGATION OF THE WAKE TURBULENCE ALLEVIATION RESULTING FROM A FLAP CONFIGURATION CHANGE ON A B-747 AIRCRAFT"

NASA TM 73263, July 1977, NASA Ames Research Center, Moffett Field, CA

A flight test investigation was conducted to evaluate the effects of a flap configuration change on the vortex wake characteristics of a Boeing 747 (B-747) aircraft as measured by differences in upset response resulting from deliberate vortex encounters by a following Learjet aircraft and by direct measurement of the velocities in the wake. The flaps of the B-747 have a predominant effect on the wake. The normal landing flap configuration produces a strong vortex that is attenuated when the outboard flap segments are raised; however, extension of the landing gear at that point increases the vortex induced upsets. These effects are in general agreement with existing wind tunnel and flight data for the modified flap configuration.

Jacquin, L.

"AIRCRAFT TRAILING VORTICES: AN INTRODUCTION"

C. R. Physique, Vol. 6, 2005, pp. 395-398

Flow momentum that is deflected in a persistent way by a wing, or by another flow, becomes organized in coherent and energetic vortex structures. This phenomenon is briefly introduced here by comparison with other phenomena such as the production of vortices by impulsive forces (e.g. during animal flight), or the production of turbulence by jets. These considerations aim at underlining the fundamental nature of this strange mechanism, which is usually hidden behind engineering models produced by aerodynamic science. The control of these mechanisms, for applications to the safety of the airplanes for example, opens a vast multidisciplinary field of research.

Jacquín, L.

"ON TRAILING VORTICES: A SHORT REVIEW"

International Journal of Heat and Fluid Flow, Vol. 26, Issue 6, December 2005, pp. 843-854.

This paper reviews some mechanisms involved in the dynamics of vortices in fluid flows. The topic is first introduced by pointing out its importance in aerodynamics. Several basic notions useful to appraise experimental observations are then surveyed, namely: centrifugal instabilities, inertial waves, cooperative instabilities, vortex merger, vortex breakdown and turbulence in vortices. Each topic is illustrated with experimental or numerical results.

Jacquín, L. and Garnier, F.

"ON THE DYNAMICS OF ENGINE JETS BEHIND A TRANSPORT AIRCRAFT"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 37-1 to 37-8

The various mechanisms that contribute to the mixing and dispersion of the engine exhausts through their interaction with the vortex wake of an aircraft are discussed. The case of a typical large transport aircraft is considered. First, the interaction between the jets and the vortices is characterized by means of non-dimensional parameters. When considering aircraft under cruise conditions, it is shown the jets have almost no effect on the vortex wake dynamics. We then consider the way the jet is changed by the vortices. This is evaluated by means of an integral model. Examples are given which show that the jet is captured by the vortices at very different distances behind the aircraft depending on the engine-wingtip separation. The model does not consider the distortion of the jet plume by the vortex shearing which becomes significant when the jet reaches the vortex center region. Results of a numerical simulation of the convection-diffusion of a passive scalar field, as well as a visualization realized during an experiment are presented in order to illustrate this point.

Jacquín, L. and Pantano, C.

"ON THE PERSISTENCE OF TRAILING VORTICES"

J. Fluid Mech., Vol. 471, 2002, pp. 159-168

The short-wave stability properties of a Batchelor vortex are used to explain the intrinsic resistance of vortices to turbulent diffusion. We show that turbulence produced within the vortex core has to overcome a stabilizing 'dispersion buffer', where energy of the perturbations is dispersed by inertial waves without interfering with the mean flow, before they can reach the periphery of the vortex. While angular momentum is maintained by this mechanism, the difference in energy extraction by turbulence from the axial and tangential velocity fields due to a lack of alignment between the mean and turbulent strain tensors, a typical effect of flow rotation or curvature, leads to stabilization through

a progressive damping of the axial shear in the vortex core. We show that the efficiency of these stabilizing mechanisms depends on the swirl number, the ratio between the maximum tangential velocity and the axial velocity difference. If the swirl parameter is low enough, turbulence is able to reach the vortex periphery and a small circulation overshoot develops, leading to weak diffusion of angular momentum outward.

"STABILITY PROPERTIES AND UNSTEADINESS OF WAKE VORTICES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Propagation of inertial waves and amplification of co-operative instabilities are basic linear mechanisms which lead to unsteadiness in trailing wake vortices. In a wind tunnel, where only a small downstream distance is usually surveyed, these unsteady phenomena lead to displacements of the vortices, which are of small amplitude but which can be measured thanks to the presence of very sharp velocity gradients within the vortices. The most promising way to produce less harmful wakes behind an aircraft is to promote the long-wave co-operative instabilities which may develop in a system of several, at least two, vortices and which lead to destructive interactions between the two halves of the wake. Such instabilities may be quantified through considering the stability of vortex filaments and by neglecting the detailed structure of the vortex cores. The respective properties of different configurations will be discussed with the objective to define optimal vortex arrangements which lead to significant amplification of initial perturbations. Short-wave instabilities are also relevant in applications because these instabilities are known to play a dominant role in the merger of the vortices. A detailed description of the vortex core structure becomes now necessary for characterizing instabilities which develop on scales of the order of the vortex core width. This will be discussed considering experimental observations and theoretical analysis. In particular, it will be shown that the basic flows involving only one length scale, e.g. the Rankine vortex or the Lamb-Oseen vortex and which are often used to characterize short-wave instabilities, are poorly representative of real wake vortices.

"THE PROPERTIES OF A TRANSPORT AIRCRAFT WAKE IN THE EXTENDED NEAR FIELD: AN EXPERIMENTAL STUDY"

AIAA Paper No. 2001-1038, Reno, NV, January 2001

An experimental study on the formation and development of the vortex wake behind a small-scale transport aircraft model is presented. The data comprises LDV and hot wire measurements including two-point correlations. Steady and unsteady properties of the wake have been characterized for two cases, a high lift, and a clean configuration of the model. The analysis particularly focuses on the

unsteady properties of the vortices which are subjected to meandering. The discussion addresses elements that contribute to a better understanding of this phenomenon.

"UNSTEADINESS, INSTABILITY AND TURBULENCE IN TRAILING VORTICES"

C. R. Physique, Vol. 6, 2005, pp. 399-41.

This paper is a review on the dynamics of vortices in fluids which get involved in aircraft wakes. Basic notions useful to appraise their dynamics are: inertial waves, 3D instabilities due to vortex interaction, vortex merging, vortex breakdown and turbulence. Each one of these topics is illustrated by means of experimental or numerical results.

Jacquín, L., Fabre, D., Sipp, D., Theofilis, V. and Vollmers, H.

"INSTABILITY AND UNSTEADINESS OF AIRCRAFT WAKE VORTICES"

Aerospace Science and Technology, Vol. 7, 2003, pp. 577-593.

This paper presents a review of theoretical and experimental results on stability and other unsteady properties of aircraft wakes. The basic mechanisms responsible for the propagation and the amplification of perturbation along vortices, namely the Kelvin waves and the cooperative instabilities, are first detailed. These two generic unsteady mechanisms are described by considering asymptotic linear stability analysis of model flows such as vortex filaments or Lamb-Oseen vortices. Extension of the linear analysis to more representative flows, using a bi-global stability approach, is also described. Experimental results obtained using LDV, hot wire and PIV in wind tunnels are presented and they are commented in the light of theory.

Jacquín, L., Fabre, D., Sipp, D., Theofilis, V. and Vollmers, H.

"INSTABILITY AND UNSTEADINESS OF AIRCRAFT WAKE VORTICES"

Proceedings 3rd ONERA-DLR Aerospace Symposium, Paris, France, June 2001, pp. S2-2/1-17

This paper presents a review of theoretical and experimental results on stability and other unsteady properties of aircraft wakes. Theory mainly concerns the dynamics of two-dimensional vortices. The basic mechanisms responsible for the propagation and the amplification of perturbation along vortices, namely the Kelvin waves and co-operative instabilities, are first detailed. These two generic unsteady mechanisms are described by considering asymptotic linear stability analysis of model flows such as vortex filaments or Lamb-Oseen vortices. Extension of the linear analysis to more representative flows, using a global stability approach, is also described. Experimental results obtained using LDV, hot wire and PIV in wind tunnels are presented and they are commented in the light of theory.

"AN EXPERIMENT ON JET-WAKE VORTEX INTERACTION"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

This experiment aims at providing original data on the interaction of propulsion jets with the wake vortices produced by a loaded wing. Considering that the jets of an aircraft interfere with the formation of its wake and the latter partly determine the dispersion of the jet exhausts, the present experiment is useful for two different types of aeronautical applications, namely the minimization of aircraft wake hazard and aircraft pollution (dispersion of pollutant, formation of contrails). The present experiment was launched to provide CFD teams with a representative data base for these two problems. The experimental device consists of a vortex generator and a hot jet generator. The vortex generator is a NACA 012 wing profile with a chord 125 mm and span 500 mm, suspended on a mast having a NACA 015 profile of chord 45 mm. The wing is positioned in the center of the test section, 750 mm downstream of the inlet section. The setup is stabilized by shrouds. The jet generator consists of two ejectors, 10 mm in diameter, on the pressure side of the airfoil, the jet being supplied with heated air. By changing the wing incidence, the thrust and temperature of the jets, different cases representative of different flight conditions could be simulated. The present paper focuses on the cruise regime and on the impact of the jet-vortex spacing. The effects of the jet temperature are also considered. Three positions of the jet-vortex spacing and two density ratios have been tested. The data base comprises surface flow visualizations, laser tomoscopies, thermocouple measurements, 3D laser velocimetry and hot wire probe measurements. The flow field measurements were conducted downstream of the wing between the wing trailing edge and 8 wingspans. The main conclusions of the study are (i) almost no effect of the jets on the vortex formation and dynamics when considering parameters representative of different flight regimes, and (ii) strong impact of the vortices on the jet dispersion, the interaction leading to different patterns when changing the jet-vortex spacing.

"AN EXPERIMENT ON JET-WAKE VORTEX INTERACTION"

AIAA Paper No. 2007-4363, Miami, FL, June 2007

The flow field produced by the interaction of two heated jets with the wake vortices of a rectangular wing is investigated in a research-type wind tunnel using an experimental set up producing conditions representative of an aircraft in cruise flight. The flow is characterized using a 3D-LDV system and thermocouples. Different spacing distances between the jets and the wing tips are considered. The temperature of the jets is also varying. In general, velocity and temperature contours reveal that the impact of the jets on the vortex properties remains small. Slight variations in the final vortex positions are observed when the jet/vortex spacing is changed due to slight modifications of the spanwise distribution of the vorticity due to the jets. Also, the statistics of the velocity fluctuations reveal that the jet turbulence promotes vortex meandering, probably through transient growth mechanisms. In most of the cases, the jet plume is wrapped around the vortices without penetrating significantly into

the cores. However, when the case jet/vortex spacing becomes small, one observes that the jets are quickly trapped into the vortices where they remain confined afterwards. As for the temperature effect, they are found to be almost negligible.

Jadic, I.

"ON AN EXTENSION OF THE KUTTA-JOUKOWSKI THEOREM TO THE SUPERSONIC REGIME"

Review Romanian Science and Technology, Vol. 24, No. 6, 1989, pp. 603-609.

In the present paper a formula is presented that enables the direct calculation of the force generated upon an infinite vortex line by a uniform supersonic flow (i.e., the equivalent of the Kutta-Joukowski theorem for subsonic flows). The methods dealing with vortex modelling of steady supersonic flows around wings make use of the small perturbation assumptions. It is shown that in the case of finite strength vortex line the induced velocity tends to infinity in the wave front and is zero elsewhere, infringing the perfect fluid hypothesis.

Jadic, I.

"AERODYNAMIC CALCULATION OF TANDEM WINGS IN SUPERSONIC FLOW BY MEANS OF SLLT"

Review Romanian Science and Technology, Vol. 35, July-August 1990, pp. 309-324.

This paper is part of a series dealing with the use of a lifting line type theory for the aerodynamic analysis of wings in supersonic flow, based upon small perturbation assumptions. The supersonic lifting line theory (LSST) makes use of a constant distribution of circulation along the chord, ensuring proper agreement with supersonic linearized flow theory for wings of large aspect ratio. The control point location resulted at 100 percent of the chord, from the condition of small aspect ratio wings to agree with Jones theoretical results. The analysis of errors involved with the SLLT approximation leads to the improved lifting line theory. In the present paper this improved theory is used for the calculation of wing-tail interference. As opposed to the the lifting line theories developed by Mirels and Haefeli, Martin and others, the loading on the wing is calculated by the lifting line procedure itself. The results presented herein show that the accuracy of the method is consistent with the linearized theory, enabling the estimation of downwash with a moderate computational effort.

Jadic, I.

"ON THE IMPROVEMENT OF THE SUPERSONIC LIFTING LINE THEORY"

Review Romanian Science and Technology, Vol. 35, March-April 1990, pp. 75-88.

In a previous paper a lifting line type theory for supersonic linearized flows (SSLT) has been defined. A prescribed (constant) distribution of bound vortices was assumed along the chord, ensuring proper agreement with 2-D supersonic flow theory for wings of large aspect ratio. The control point location has been determined by assuming that for wings with small aspect ratios, SLLT must agree with Jones'

theoretical results. It resulted that the control point must be placed at 100 percent of the chord, i.e. at the trailing edge. In the present paper two kinds of errors that affect the above-mentioned theory are discussed. The first error, due to the assumption of constant chord distribution of vortices, may be overcome by correlating the control point position with the aspect ratio. The second error is due to the possibility of information transfer beyond the inverse Mach cone limit. In order to cope with this, simple control flow solutions are used whenever possible. The resulting improved lifting line theory (SLLT + C) is ascertained by means of several comparisons with existing theoretical and experimental data. The correlation with these data is good, proving the accuracy gain of the method.

Jadic, I.

"WING CALCULATION IN SUPERSONIC FLOW BY MEANS OF THE SUPERSONIC LIFTING LINE THEORY"

Review Romanian Science and Technology, Vol. 35, May-June 1990, pp. 197-208.

A lifting line theory for supersonic linearized flows (SLLT) has been previously discussed in several papers. In the present paper the comparison of the improved supersonic lifting line theory (SLLT + C) with existing theoretical and experimental data is continued. The analysis covers the cases of straight, triangular, and swept isolated wings. The correlation with the test data is good, proving the accuracy of the method for usual planforms.

Jadic, I. and Constantinescu, V. N.

"LIFTING LINE THEORY FOR SUPERSONIC FLOW APPLICATIONS"

AIAA Journal, Vol. 31, No. 6, June 1993, pp. 987-994.

This paper is devoted to the study of a supersonic lifting line theory intended to provide both a means of aerodynamic calculation and a benchmark for the validation of the control point position for the related constant pressure panel methods. The model is based on the small perturbation assumption. A constant distribution of bound vortices is assumed along the chord whereas the spanwise load distribution is calculated by means of trigonometrical series, formally like the subsonic methods. The calculated aerodynamic coefficients are in good agreement with the reference data, the precision being compatible with the small perturbation assumption. The control panel position obtained is shown to vary as a function of aspect ratio from 100 to 88 percent of the local chord.

Jain, A. C.

"NUMERICAL SOLUTIONS OF NAVIER-STOKES EQUATIONS FOR THE STRUCTURE OF A TRAILING VORTEX"

NASA TM X-73361, January 1977, NASA Marshall Space Flight Center, Huntsville, AL

An attempt is made to understand the structure and decay of a trailing vortex through the numerical solutions of the full Navier-Stokes equations. Unsteady forms of the governing equations are recast in

terms of circulation, vorticity, and stream function as dependent variables, and a second upwind finite-difference scheme is used to integrate them with prescribed initial and boundary conditions. A discussion of the boundary conditions at the outer edge and at the outflow section of the trailing vortex is included. Different models of the flow are postulated, and solutions are obtained describing the development of the flow as integration proceeds in time. A parametric study is undertaken with a view to understand the various phenomena that may possibly occur in the trailing vortex. Using the Hoffman and Joubert law of circulation at the inflow section, the results of the present investigation are compared with the experimental data of Chigier and Corsiglia on a Convair-990 wing model and a rectangular wing. With an exponentially decaying law of circulation at the inflow section and an adverse pressure gradient at the outer edge of the trailing vortex, solutions depict vortex bursting through the sudden expansion of the core and/or through the stagnation and consequent reversal of the flow on the axis. It is found that this bursting takes place at lower values of the swirl ratio as the Reynolds number increases.

Jain, R.

"HOVER PREDICTIONS ON THE S-76 ROTOR WITH TIP SHAPE VARIATION USING HELIOS"

Journal of Aircraft, Vol. 55, No. 1, January-February 2018, pp. 66-77.

High-resolution, time-accurate computational fluid dynamics validation of a 9.34 ft, four-blade, Mach-scaled S-76 rotor in hover is performed using the U.S. Department of Defense Computational Research and Engineering Acquisition Tools and Environments -- Air Vehicles Helios software. The effect of blade tip shape variation is studied for three tip shapes: rectangular, swept tapered, and swept tapered anhedral. The effect of tip Mach number is studied for the swept-tapered tip. Computed results include rotor performance, blade air loads, and tip-vortex strength and position. The performance predictions are compared against the test measurements and good agreement is obtained. Compared with the swept-tapered tip, the rectangular blade incurs compressibility losses near the tip. The addition of anhedral to the swept-tapered tip improves performance as a result of redistribution of thrust.

Jain, R.

"SENSITIVITY STUDY OF HIGH-FIDELITY HOVER PREDICTIONS ON THE SIKORSKY S-76 ROTOR"

Journal of Aircraft, Vol. 55, No. 1, January-February 2018, pp. 78-88.

Hover performance calculations are performed for a 9.34 ft, four-blade, Mach-scaled, S-76 rotor with an anhedral tip using different computational-fluid-dynamics approaches to assess the variability in prediction. Time-accurate Navier-Stokes calculations are performed using the High Performance Computing Modernization Program Computational Research and Engineering Acquisition Tool and Environment Air Vehicles Helios software suite with OVERFLOW and FUN3D as near-body solvers, and the standalone OVERFLOW solver. Different modeling options exercised include structured and unstructured meshes for the blades, adaptive mesh refinement in the blade mesh, adaptive mesh

refinement in the wake mesh, and inviscid and detached-eddy simulation modeling in the wake. Rotor performance, blade air loads, and wake geometry from the different calculations show consistent predictions. The agreement between computed figure of merit and test data is good at high-thrust conditions but only fair at lower thrust.

Jain, R. and Conlisk, A. T.

"INTERACTIONS BETWEEN TIP-VORTICES IN ROTOR WAKES"

American Physical Society, 50th Annual Meeting Division of Fluid Mechanics, Nov. 1998, Philadelphia, PA,

In recent experiments, it was observed that the tip vortices shed from a two-bladed rotor can interact significantly. The interaction consists of a turn of the tip-vortex from one blade rolling around a turn of the tip-vortex from the other blade. Visualized in a planar light sheet, the two vortices spiral around each other prior to merging into a single vortex. Moreover, the wake does not contract monotonically as often depicted but expands as one of the vortices moves radially outward due to the interaction. This behavior is illustrated by the numerical calculation of the motion of a pair of ring vortices. It is observed that the pair of rings, placed initially parallel and of the same strength roll around each other, by alternate contraction and expansion of the ring radius. Numerical calculations show that the ring interaction is complicated when the rings are initially inclined. Numerical solutions for a two-bladed rotor in hover and descent are presented. A lifting-line theory is used to model each rotor blade and a fully unsteady computation of the motion of the tip-vortices is carried out using a highly accurate Adams-Moulton method to advance the vortices. The modified Biot-Savart law is used to describe the vortex structure. This type of interaction in the wake contradicts many of the current computational results which consider the wake to be spatially periodic.

Jain, R., Conlisk, A. T., Mahalingam, R. and Komerath, N. M.

"INTERACTION OF TIP-VORTICES IN THE WAKE OF A TWO-BLADED ROTOR"

Proceedings 54th Annual Forum of the American Helicopter Society, May 1998, Washington DC.

In recent experiments, it was observed that the tip vortices shed from a two-bladed rotor can interact significantly. The interaction consists of a turn of the tip-vortex from one blade rolling around a turn of the tip-vortex from the other blade. Visualized in a planar light sheet, the two vortices spiral around each other prior to merging into a single vortex. One complete cycle of the roll-up process takes about one and a half rotor cycles. The wake does not contract monotonically but expands as one of the vortices moves radially outward due to the roll-up. This behavior is illustrated by the numerical calculation of the motion of a pair of ring vortices. It is observed that the pair of rings, placed initially parallel and of the same strength roll around each other, by alternate contraction and expansion of the ring radius. Numerical calculations show that the ring interaction is complicated when the rings are initially inclined. Next the case of a two-bladed rotor is considered. A lifting-line theory is used to model each rotor blade and a fully unsteady computation of the motion of the tip-vortices is carried out using

a highly accurate Adams-Moulton method to advance the vortices. The modified Biot-Savart law is used to describe the vortex structure. It is shown that the tip-vortex interaction is periodic and deterministic.

James, M. and Brown, J.

"NATIONAL AIR TRAFFIC RULE CHANGE 7110.308, WAKE TURBULENCE WITH CLOSELY SPACED PARALLEL RUNWAYS"

AIAA Paper No. 2010-9166, September 2010, Fort Worth, TX.

The goal of this paper is to present the findings from two studies that modeled the Wake Turbulence Program's National Air Traffic Rule Change 7110.308 at approved airports. Rule Change 7110.308 allows approved airports to operate with parallel approach runways in Instrument Meteorological Conditions, which previously would operate as a single arrival stream runway. The purpose of this study was to show the benefits of Rule Change 7110.308 to gain strong facility support of the procedure. Multiple scenarios were modeled for the newly developed National Rule Change 7110.308 at two airports, Seattle-Tacoma and Newark Liberty International Airports. These are two very different airports yet the rule change has the potential to provide benefits regardless of the differences. The paper thoroughly explains National Rule Change 7110.308, the methodology used to quantify the potential benefits, how the rule would be used at Seattle-Tacoma and Newark Liberty International Airports and concludes with the modeling results for each airport.

Jameson, A. R. and Kostinski, A. B.

"PARTIALLY COHERENT BACKSCATTER IN RADAR OBSERVATIONS OF PRECIPITATION"

Journal of the Atmospheric Sciences, Vol. 67, 2010, pp. 1928-1946.

Classical radar theory only considers incoherent backscatter from precipitation. Can precipitation generate coherent scatter as well? Until now, the accepted answer has been no, because hydrometeors are distributed sparsely in space (relative to radar wavelengths) so that the continuum assumption used to explain coherent scatter in clear air and clouds does not hold. In this work, a theory for a different mechanism is presented. The apparent existence of the proposed mechanism is then illustrated in both rain and snow. A new power spectrum $Z(f)$, the Fourier transform of the time series of the radar backscattered reflectivity, reveals statistically significant frequencies f of periodic components that cannot be ascribed to incoherent scatter. It is shown that removing those significant f s from $Z(f)$ at lower frequencies greatly reduces the temporal coherency. These lower frequencies, then, are associated with the increased temporal coherency. It is also shown that these f s are also directly linked to the Doppler spectral peaks through integer multiples of one-half the radar wavelength, characteristic of Bragg scatter. Thus, the enhanced temporal coherency is directly related to the presence of coherent scatter in agreement with theory. Moreover, the normalized backscattered power spectrum $Z(f)$ permits the estimation of the fractional coherent power contribution to the total power, even for an incoherent radar. Analyses of approximately 26,000 one-second $Z(f)$ in both rain and snow reveal that the coherent scatter is pervasive in these data. These findings present a challenge to the

usual assumption that the scatter of radar waves from precipitation is always incoherent and to interpretations of backscattered power based on this assumption.

Janic, M.

"TOWARD TIME-BASED SEPARATION RULES FOR LANDING AIRCRAFT"

Transportation Research Record, Issue No. 2052, 2008, pp. 79-89.

Aircraft landing on the same runway are potentially exposed to a similar wake vortex hazard, under either instrument meteorological conditions (IMC) or visual meteorological conditions (VMC) when the air traffic control (ATC) distance-based instrument flight rules (IFR) and visual flight rules (VFR) are applied, respectively. Since IFR are stricter than VFR, the runway landing capacity is lower under IMC than under VMC. Possibilities are investigated for introducing time-based ATC separation rules instead of the current distance-based ATC separation rules between landing aircraft as an option for increasing the runway landing capacity under IMC and consequently decreasing the existing gap between IFR and VFR capacity. A model for calculating the landing capacity of a single runway on the basis of ATC time-based separation rules was developed. In addition to these rules, which would be set up by using the current ATC distance-based separation rules and the advanced knowledge on the current and predicted behavior of the wake vortex influenced by the weather conditions, the model uses other inputs, such as the structure of fleet mix in terms of the proportion of particular aircraft categories, which are represented by their wake vortex parameters (the approach speed, wingspan, and weight), and the geometry of the approach corridor, which enables landing on a given runway. The model output is the matrix of the standardized time-based separation rules for different combinations of landing aircraft sequences, which would be applicable to both VMC and IMC, and the runway landing capacity calculated for combinations of the time-based separation rules depending on the current and predicted wake vortex characteristics and behavior. The model is applied to calculating the landing capacity of a single airport runway.

Janic, M.

"STEEPER APPROACH PROCEDURE FOR INCREASING ULTIMATE CAPACITY OF CLOSELY SPACED PARALLEL RUNWAYS"

Transportation Research Record, 2007, pp. 81-89

The steeper approach procedure (SAP) is investigated as an innovative option for increasing the ultimate arrival capacity of closely spaced parallel runways under instrument meteorological conditions and instrument flight rules. SAP is based on the two pairs of instrumented landing systems, each enabling the certified aircraft to approach a given parallel runway at either the standard (3 deg) or steeper (5 to 7 deg) glide slope (GS) angle. The difference in the GS angles allows application of the ATC vertical separation rules between the arriving aircraft; this can mitigate the impact of wake vortices on the aircraft in trail separation while on the same or different approach trajectories. A combination of

these with the ATC longitudinal and horizontal-diagonal separation rules has the potential to increase the ultimate arrival capacity of closely spaced parallel runways. An analytical model was developed for calculating the arrival ultimate capacity of closely spaced parallel runways.

Janic, M.

"MODEL OF ULTIMATE CAPACITY OF DUAL-DEPENDENT PARALLEL RUNWAYS"

Transportation Research Record, Issue 1951, 2006, pp. 76-85

This paper develops an analytical model of the ultimate capacity of dual-dependent parallel runways (with close or intermediate spacing), where ultimate capacity is defined as the maximum number of aircraft accommodated during a given period (usually 1 h or 15 min) under constant demand for service and other given conditions. The model uses six inputs: geometry (configuration) of parallel runways; air traffic control (ATC) separation rules; technologies for aircraft primary navigation, communication, and air traffic surveillance, which influence separation rules and the degree of dependency of two runways; aircraft fleet mix in terms of wake vortex categories and approach and departure speeds; proportion of arrival and departure demand; and ATC tactics of sequencing particular aircraft types and operations. The output represents the so-called capacity coverage curve, which reflects different scenarios of using given runways. The model is used to calculate the capacity of a large European airport.

"VORTEX VISUALIZATION FOR PRACTICAL ENGINEERING APPLICATIONS"

IEEE Transactions on Visualization and Computer Graphics, Vol. 12, No. 5, September-October 2006, pp. 957-964.

In order to understand complex vortical flows in large data sets, we must be able to detect and visualize vortices in an automated fashion. In this paper, we present a feature-based vortex detection and visualization technique that is appropriate for large computational fluid dynamics data sets computed on unstructured meshes. In particular, we focus on the application of this technique to visualization of the flow over a serrated wing and the flow field around a spinning missile with dithering canards. We have developed a core line extraction technique based on the observation that vortex cores coincide with local extrema in certain scalar fields. We also have developed a novel technique to handle complex vortex topology that is based on k-means clustering. These techniques facilitate visualization of vortices in simulation data that may not be optimally resolved or sampled. Results are included that highlight the strengths and weaknesses of our approach. We conclude by describing how our approach can be improved to enhance robustness and expand its range of applicability.

"RELATIONSHIPS BETWEEN WAKE VORTEX DECAY AND ATMOSPHERIC VARIABLES"

Proceedings Sixth Conf. on Aviation Weather Systems, American Meteorological Society, Dallas, TX, January 1995, pp. 161-165

An attempt is made to relate the lifetimes and descent distances of aircraft wake vortices to measured and derived aircraft and atmospheric variables. The primary analytical method used is linear regression. The main objective is to look for physical relationships; a secondary objective is to determine the validity of predicting vortex behavior from independent data using the regression formula. Preliminary results support the observation that vortex lifetimes are shortened due to turbulence as daytime heating increases. The prediction that strong stability would also reduce lifetimes was not observed.

Janus, J. M. and Chatterjee, A.

"USE OF A WAKE-INTEGRAL METHOD FOR COMPUTATIONAL DRAG ANALYSIS"

AIAA Journal, Vol. 34, No. 1, January 1996, pp. 188-190.

The capacity to predict drag due to lift using numerical simulations of the flow field and a wake-integral approach has been studied. An important finding during this research was the presence of low-level spurious vorticity in the flow. Future work must address the problem of requiring arbitrary filters to determine the extent of the vortical wake that ultimately governs the integral limits. Since the postprocessor uses a wake-based approach to compute the lift and drag about a lifting body, it was found that to correctly predict these force components it is necessary to very accurately resolve the flow field in this region. An accurate resolution of the vortical field is critical when using the present approach for induced drag calculations. To maintain the performance of this approach, a sufficiently dense mesh is required in the wake region. This yields somewhat of a tradeoff situation since the errors associated with surface pressure integration can also be reduced with a sufficient increase in mesh density local to the body. Perhaps the use of a computational method specifically designed for the unmolested transport of vorticity would be the ultimate complement to the wake-integral method.

"OPTIMIZED MEASUREMENTS OF UAV MASS MOMENT OF INERTIA WITH A BIFILAR PENDULUM"

AIAA Paper 2007-6822, August 2007, Hilton Head, SC.

A bifilar (two-wire) pendulum is a torsional pendulum consisting of a test object suspended by two thin parallel wires. The pendulum oscillates about the vertical axis. The restoring torque of the bifilar pendulum is provided by the gravitational force as rotations from the rest state cause the test object to raise slightly. The mass moment of inertia is computed using dynamic modeling, measurements of the oscillation period, and the physical dimensions of the bifilar pendulum such as the length and separation displacement of the pendulum wires. A simulation technique is described that improves estimates of the mass moment of inertia by considering the nonlinear effects of damping and large angular displacements. An analysis of the error variance of mass moment of inertia measurements is also described. The resulting expression for the error variance is used to optimize the physical

parameters of the bifilar pendulum to obtain the moment of inertia measurement with the minimum error variance. Monte Carlo simulations were used to validate the parameter optimization technique. Experimental results are presented for a uniform-density test object for which the moment of inertia is straightforward to compute from geometric considerations. Results are also presented for a small unmanned air vehicle, which was the intended application for this moment of inertia measurement technique.

"AIRCRAFT WING-TIP VORTEX MODIFICATION"

Journal of Aircraft, Vol. 10, No. 1, January 1973, pp. 63-64

The results of a low-speed experimental wind tunnel study of the modification of a wing tip vortex using a tip mounted, upstream facing jet are discussed. The tests were performed in the MIT Wright Brothers 7 ft by 10 ft closed return subsonic wind tunnel. The vorticity of the vortex was measured by a vorticity meter located seven chord lengths downstream of the wing trailing edge and in line with the wing tip. A moveable smoke generator unit was used to obtain flow visualization photographs. It was found that the upstream facing jet is more effective in reducing the vorticity at the same value of the jet momentum coefficient (essentially a thrust coefficient) than the downstream facing jet.

"PREDICTION OF BROWNOUT INCEPTION BENEATH A FULL-SCALE HELICOPTER DOWNWASH"

Journal of the American Helicopter Society, Vol. 57, 2012, pp. 042006-1 to 042006-13.

Dust entrained by low flying helicopters leads to the degraded visual environment, brownout. Particle inception is a critical stage in the development of the dust cloud. Here, near-wall Lagrangian particle forces are considered through analyzing an approximate time-averaged full-scale rotor flow. This simplified flow does not attempt to predict brownout, instead it provides scales and velocity data in the near-wall region, compares the role of particle-fluid forces, and provides a foundation for Lagrangian entrainment models. The analysis shows that three characteristic particle sizes are exposed to different physics in different boundary layer zones, a function of the distance from the helicopter. Drag is the dominant aerodynamic force, cohesion is large for small particles, but wall-bounded lift is sufficient to entrain medium-sized particles. A complementary analytical prediction of tip vortices found that both large-scale inviscid features and small-scale viscous features of the boundary layer are significant.

"AERODYNAMIC MODELING AND SYSTEM IDENTIFICATION FROM FLIGHT DATA -- RECENT APPLICATIONS AT DLR"

Journal of Aircraft, Vol. 41, No. 4, July-August 2004, pp. 681-691

This paper provides an overview of a few selected system-identification activities carried out during the last decade at DLR, the German Aerospace Center. After a brief account of parameter-estimation methods and of consistency checking of recorded flight data, an emphasis is placed on 1) development of global, high-fidelity aerodynamic databases for training simulators; 2) models for in-flight simulator; 3) modeling of stall hysteresis; 4) estimation of aerodynamic flowfield characteristics and validation of aircraft reaction models from wake vortex encounter flights; and 5) a parametric wake distortion model to improve helicopter coupling off-axis response. These examples cover a variety of flight vehicles with widely different characteristics, namely, the military transport aircraft Transall C-160, commuter aircraft Dornier 328, in-flight simulator VFW-614 ATTAS, high-altitude research aircraft G850 Strato 2C, Airbus-type aircraft, fly-by-wire helicopter BO-105, and fly-by-light helicopter EC-135. Besides parameter estimation aspects, those related to model validation are discussed. Through succinct examples it is brought out that system identification has become an indispensable tool to support not only research but also industry activities in various key areas such as model validation, handling qualities evaluation, control law design, and flight-vehicle design and certification. Thus, it contributes significantly to risk and cost reduction.

"EFFECT OF FUSELAGE AND WIND TUNNEL WALL ON FULL-SCALE UH-60A ROTOR TIP VORTEX PREDICTION"

AIAA Paper 2016-3131, June 2016, Washington, DC.

An investigation of the effect of the fuselage and the wind tunnel wall on the prediction of rotor tip vortices is carried out for the full scale UH-60A rotor in the 40- by 80-foot National Full-Scale Aerodynamic Complex (NFAC) wind tunnel. A coupled Computational Fluid Dynamics (CFD) and Computational Structured Dynamics (CSD) simulation is carried out using the US Army and HPCMP CREATE-AV [TM] Helios flow solver. The rotor blades are modeled using structured grids and the NFAC Large Rotor Test Apparatus (LRTA) fuselage is modeled using an unstructured grid. OVERFLOW is used for the structured grids and FUN3D is used for the unstructured grids. A higher order adaptive Cartesian solver is used in the off-body to model the rotor tip vortices. Helios predictions for the isolated rotor and rotor-fuselage configurations in free air and wind tunnel are compared to the reprocessed PIV data for the low-speed descending flight condition (rotor advance ratio = 0.15). Overall, the vortex properties (core radius, circulation, and location) predicted by Helios are in good agreement with the data. Inclusion of wind tunnel walls significantly improved the vortex trajectory predictions, particularly in the later delayed azimuth locations, resulting in a close agreement with measured data. Inclusion of the LRTA fuselage changed the blade loading characteristics that lead to weaker circulation prediction compared to the isolated rotor case. No significant differences were noticed in the prediction of core radius. Rotor wake and vortex properties, but not vortex location, can be predicted with reasonable accuracy using the isolated rotor model in free air with corrected shaft angle.

"INTERACTION OF A SKEWED RANKINE VORTEX PAIR"

Physics of Fluids, Vol. 20, 2008, pp. 083601-1 - 083601-9

An analytical investigation is carried out to study the kinematics of a fluid particle in an interacting field of a skewed pair of fixed Rankine vortices. A general formulation governing the kinematics of a fluid particle has been presented based on the superposition of the velocity field due to each vortex in the pair. The kinematics of a Lagrangian fluid particle is found to be governed by a nonlinear dynamical system. The fixed or stationary points of the dynamical system have been identified analytically and their existence is confirmed by the nature of particle paths in the neighborhood of fixed points. The nature of the particle path and velocity signal is reported for general as well as special configurations of the vortex pair in the presence and absence of an external uniform flow. As a specific application of the proposed problem, superposition of the translational velocity on a semi-infinite field of longitudinal vortices generated by vortex generators mounted on fin plates of heat exchangers has also been studied.

"MTC FINAL PROGRESS REPORT: LIDAR"

Final Report, July 2007, Renewal Energy Research Laboratory, University of Massachusetts, Amherst, MA.

This report gives a detailed description of the fundamental principles that govern the operation of laser remote sensing devices. This report also outlines a process by which a specific laser anemometer is validated with respect to cup anemometry. The data validation experiment summarizes approximately 1.5 months of concurrent laser anemometer and cup anemometer wind speed data. The validation experiment concludes that the laser anemometer can achieve correlation of 0.978, 0.984 and 0.984 at 118m, 87m and 61m respectively when compared to in-situ cup anemometry. The operation of the laser anemometer is subject to certain difficulties such as power failure but its advantages over cup anemometer-based wind speed measurement are significant. The advantages in laser remote sensing over traditional cup anemometers are explored in a comprehensive uncertainty analysis of the two sensor types. The laser anemometer is found to exhibit approximately 5.2% overall wind speed measurement error while the NRG cup anemometers exhibit approximately 8.3% overall wind speed measurement error. The wind resource characteristics in Hull, Massachusetts are also characterized and the six-month average wind speed was found to be 7.27 m/s at a height of 118m while the average shear exponent, α , is found to be 0.19. Based on these results, it can be concluded that the laser anemometer used in the data validation experiment is acceptable for use in wind resource assessment applications.

"VLES OF AIRCRAFT WAKE VORTICES IN A TURBULENT ATMOSPHERE: A STUDY OF DECAY"

Advances in LES of Complex Flows, Fluid Mechanics and Its Applications, Vol. 65, 2004, pp. 311-326.

Very Large-Eddy Simulations (VLES) of aircraft wake vortices in various atmospheric turbulence conditions are carried out. The turbulence level is characterized by the eddy dissipation rate and ranges from very strong to weak. The turbulence is assumed isotropic. Two LES models are considered. Most simulations were done using explicit gaussian filtering and a mixed model: the tensor-diffusivity model supplemented by a dynamic Smagorinsky term. As a point of comparison, some simulations were done using the classical dynamic Smagorinsky model alone (thus without explicit filtering). Initially, the wake vortices are assumed to follow the fairly 'universal' circulation profile shortly after rollup. The vortex global circulation is investigated: its decay exhibits a similar behavior in all cases, leading to the exponential decay model based on the eddy dissipation rate. The present model differs from others by the presence of a time delay before the exponential decay. The constant defining the decay rate is also found to be quite different from that found in the literature. This lack of agreement is partially explained by the differences in the definitions of circulations.

"STATISTICS OF THE APPROACH PROCESS AT DETROIT METROPOLITAN WAYNE COUNTY AIRPORT"

Proceedings of the 2nd International Conference on Research in Air Transportation, 2006, Belgrade, Serbia and Montenegro.

Dealing with uncertainty is a necessary and difficult aspect in operations analysis of complex systems such as the air transportation system. We represent these uncertainties in the approach process by probability distributions. This paper provides statistical observations of the approach and landing process at Detroit Metropolitan airport (DTW) for one week of February 2003. These probability distributions are based on aircraft track record data at DTW which are collected by a multilateration surveillance system. After explaining characteristics of the database and its short comings, we present a methodology to extract necessary statistical samples. From this, we obtain appropriate probability distributions for landing time interval (LTI), inter arrival distance (IAD), and runway occupancy time (ROT) presented under instrument flight rules (IFR) and peak traffic periods.

Jeddi, B. G., Shortle, J. F. and Sherry, L.

"STATISTICAL SEPARATION STANDARDS FOR THE AIRCRAFT-APPROACH PROCESS"

IEEE/AIAA Proceedings, 25th Digital Avionic Systems Conf., October 2006, pp. 1-13

Demand for air transportation has been increasing. A response to this is enhancing the runway utilization and throughput before investing on new runways or instruments. Runway throughput can be increased by reducing in-trail landing separation between aircraft, but the consequence may be an increase in the change of a severe wake vortex encounter or a simultaneous runway occupancy (or go-around). Current instrument flight rule (IFR) standards provide fixed separation minima for given pairs of wake vortex weight classes of aircraft. In practice, the observed separation is a random variable and

fluctuates near or above the specified minimum. In this paper, we propose a framework for statistical separation standards that specifies not only a lower bound for the separation but also a standard for the target value and the variance of the process. We address the question of what a more efficient separation standard is to control the risk in the approach process. We address the question of what a more efficient separation standard is to control the risk in the approach process. We also consider whether separation variability may be reduced by employing such standards, i.e. more detailed standards that take the 'realized variability' into account. Analytical results of this study suggest that (under specific assumptions) throughput can be increased to some extent without degrading safety for the given facilities, infrastructure, and weather condition. The arguments and concepts are illustrated with statistical observations from Detroit airport (DTW).

"WIND-TUNNEL INVESTIGATION OF VORTEX REFRACTION EFFECTS ON AIRCRAFT NOISE PROPAGATION"

Journal of Aircraft, Vol. 14, No. 8, August 1977, pp. 737-745

One possible method for reducing aircraft flyover noise is to site the engines so that the wing vortex can refract sound away from the ground. A series of experiments was carried out in the RAE 24-foot wind tunnel using a model of the HP 115 slender delta research aircraft, which produced a strong leading-edge vortex when set at incidence. The engine noise was simulated by a Hartmann whistle mounted above the engine intake. The results are compared with a theoretical prediction based on ray theory and a simplified representation of the wing vortex structure.

Jeffreys, H. B.

"SYSTEMS SIMULATION FOR AN AIRPORT TRAILING VORTEX WARNING SYSTEM"

NASA TM X-64704, October 1972, NASA Marshall Space Flight Center, Huntsville, AL

This report documents the approach, development, and limited system studies associated with a system simulation for an Airport Trailing Vortex Warning System (ATVWS). It attempts to show the usefulness of a systems engineering approach to the problem of developing a system, as dictated by aircraft vortices, which will increase air traffic flow in the takeoff/landing corridors of busy airports while maintaining the required safety factor, for each operation.

Jeffreys, H. B. and Bilbro, J. W.

"DEVELOPMENT OF A LASER DOPPLER SYSTEM FOR THE DETECTION AND MONITORING OF ATMOSPHERIC DISTURBANCES"

Electro-Optics '75 International Laser Conf., Anaheim, CA, November 1975

The Marshall Space Flight Center has developed a Scanning Laser Doppler System capable of detecting and monitoring atmospheric disturbances. This system has been used successfully to detect

and track wake vortices of landing aircraft and to obtain vertical wind profiles in the atmosphere. The laser system, which is installed in a mobile van, is a focused continuous wave, CO₂ system which determines the line-of-sight velocities of particles in the focal volume of the system by measuring the Doppler shift created by these particles. At present, the system has been designed to have a range coverage of approximately 2,000 feet with a vertical angle coverage of approximately 60 deg. The system can detect Doppler velocities of up to 200 feet/second with a velocity resolution of approximately 1.8 feet/second. A complete velocity profile is provided by the system at each point in space at which it is focused. This information is further processed to provide specific velocity information in regions of interest.

"PERFORMANCE OF A CO₂ LASER VORTEX DETECTION SYSTEM"

IEEE/OSA Conf. on Laser Engineering and Applications, Washington, DC, May 1975.

A scanning CO₂ laser Doppler velocimeter has been used to obtain transport and velocity characteristics of aircraft trailing vortices. System performance and vortex data are presented.

Jelalian, A. V., Keene, W. H., McDonagh, T., Seeber, K. N. and Sonnenschein, C. M.

"WAKE VORTEX LASER RADAR"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 41-1 - 41-18

Coherent laser radar systems have been utilized to remotely detect the motion of the atmosphere, by obtaining Doppler backscattering of the laser energy from aerosols naturally suspended in air. These activities were pioneered by Raytheon under contract to the NASA Marshall Space Flight Facility, when the first remote measurements of a CO₂ laser radar system were utilized to determine the atmospheric wind velocity, with a focused CO₂ laser system in 1967. In 1969, LIDAR was first used to remotely measure aircraft wake vortex motion. These coherent detection systems use the temporal and spatial coherence of a laser radar (LIDAR) to obtain Doppler backscattering from aerosols and particulate matter. These systems operate both in the near field and far field of the system.

Jelalian, A. V., Keene, W. H., Sonnenschein, C. M. and Huffaker, R. M.

"LASER DOPPLER SYSTEMS OF REMOTE ATMOSPHERIC MEASUREMENTS"

IEEE Northeast Electronics Research and Engineering Meeting, Boston, MA, November 1971

This paper discusses several field measurements that have been performed with a CO₂ laser Doppler homodyne system sampling the clear atmosphere for the remote measurement of atmospheric winds and aircraft wake vortices. This system makes use of the particulate matter normally present in the lower atmosphere to provide backscattering and to act as tracers of air motion.

"ROTOR DOWNWASH VELOCITIES ABOUT THE UH-1M HELICOPTER - FLIGHT TEST MEASUREMENTS AND THEORETICAL CALCULATIONS"

RD-75-27, January 1975, U.S. Army Missile Command, Redstone Arsenal, Alabama

Downwash velocity data from a flight test of the UH-1M helicopter are presented in comparison with calculated values. Hot film anemometers were used to measure flow velocities at five points in the downwash for a variety of aircraft forward velocities and hover. The theoretical predictions were made using a mathematical model of sources and sinks to simulate the fuselage and vortex filaments to simulate the rotor wake.

Jenkins, M. W. M. and Hackett, J. E.

"A PILOT-IN-THE-LOOP, VISUAL SIMULATION OF TRAILING VORTEX ENCOUNTERS AT LOW SPEED"

AIAA Paper 1975-0104, Pasadena, CA, 197.

A fixed base, visual flight simulator, using a transport cab, was used to explore pilot-in-the-loop encounters of a C-130 type transport flying in the wake of a C-5A. Some 80 flight conditions were flown through a range of vortex strengths, core radii, spatial orientations, direction of rotation, and encounter altitudes. Vortex-lattice modeling techniques were used to update the forces and moments of the penetrating aircraft. It established the feasibility of digitally updating the encounter aerodynamics in real time to permit pilot-in-the-loop visual tasks to be performed. Suggested approaches to regulatory boundaries have been made.

Jenkins, M. W. M. and Meyer, R. T.

"VORTICAL WAKE HAZARD ADVISORY"

AFFDL-TR-76-146, February 1977, Lockheed-Georgia Co., Marietta, GA

The study reported herein was an analytical effort to define separation criteria for USAF aircraft during landing and taking-off. The approach used was a blend of theoretical and experimental work. Existing theoretical methods, analyses and data were used and the results were conditioned by published flight test and pilot-in-the-loop simulation data. Results from the study are presented as a suggested Interim Advisory for USAF operational aircraft when flying in the terminal area. In this advisory, the current operational fleet has been divided into four classes of vortex-generating and vortex-encountering aircraft. Specific separation recommendations are presented in the form of 'avoid volumes' of airspace for each combination of the generating and encountering aircraft. These 'avoid volumes' include the effects of aircraft relative speeds, flight paths, local winds and atmospheric conditions.

Jensen, R. J.

"EXPERIMENTAL STUDY OF FAR-FIELD WING WAKES"

M.S. Thesis, January 1973, Mass. Institute of Technology, Cambridge, MA

The results of a flow visualization experiment in the M.I.T. Ship Model Towing Tank show that sinusoidal instability and vortex breakdown in a lifting surface wake can be forced by differential flap oscillation. A theoretical investigation reveals the driving factors are displacement of the vortex from its mean position, sinusoidal variation of circulation along the trailers, and shed vorticity. Optimum wavelengths at which the sinusoidal instability goes to completion in minimum time are found and indicate that inclusion of the driving factors causes the optimum to diverge substantially from the locus of maximum growth rates as predicted by linear theory. Core axial velocities are also investigated and found to be high compared with previous research.

Jentink, H. W. and Bogue, R. K.

"OPTICAL AIR FLOW MEASUREMENTS FOR FLIGHT TESTS AND FLIGHT TESTING OPTICAL AIR FLOW METERS"

RTO-MP-SCI-162, 2005, Paper 11, Neuilly-sur-Seine, France

Optical air flow measurements can support the testing of aircraft and can be instrumental to in-flight investigations of the atmosphere or atmospheric phenomena. Furthermore, optical air flow meters potentially contribute as avionics systems to flight safety and as air data systems. The qualification of these instruments for the flight environment is where we encounter the systems in flight testing. An overview is presented of different optical air flow measurement techniques applied in flight and what can be achieved with the techniques for flight test purposes is reviewed. All in-flight optical airflow velocity measurements use light scattering. Light is scattered on both air molecules and aerosols entrained in the air. Basic principles of making optical measurements in flight, some basic optical concepts, electronic concepts, optoelectronic interfaces, and some atmospheric processes associated with natural aerosols are reviewed. Safety aspects in applying the technique are shortly addressed. The different applications of the technique are listed and some typical examples are presented. Recently NASA acquired new data on mountain rotors, mountain induced turbulence, with the ACLAIM system. Rotor position was identified using the lidar system and the potentially hazardous air flow profile was monitored by the ACLAIM system.

"ON THE RELATIONSHIP BETWEEN THE VORTEX FORMATION PROCESS AND CYLINDER WAKE VORTEX PATTERNS"

Journal of Fluid Mechanics, Vol. 519, 2004, pp. 161-181.

The idea of vortex formation time, originally developed for vortex ring formation, is extended to bluff-body flows. Effects related to characteristic vortex formation time are shown for both the cylinder

starting from rest and the cylinder undergoing forced oscillations in a steady flow. By looking at how wake vortices are formed when the cylinder is accelerated from rest, it is found that similarities exist between the formation process for wakes and for vortex rings. This formation process is then observed for forced oscillating cylinders, where the characteristic formation time interacts with the oscillation period. Frequently observed bluff-body phenomena will be recast considering the vortex formation process.

Jeong, J. and Hussain, F.

"ON THE IDENTIFICATION OF A VORTEX"

J. of Fluid Mech., Vol. 285, February 1995, pp. 69-94

Considerable confusion surrounds the longstanding question of what constitutes a vortex, especially in a turbulent flow. This question, frequently misunderstood as academic, has recently acquired particular significance since coherent structures (CS) in turbulent flows are now commonly regarded as vortices. An objective definition of a vortex should permit the use of vortex dynamics concepts to deduce CS, to explain formation and evolutionary dynamics of CS, to explore the role of CS in turbulence phenomena, and to develop viable turbulence models and control strategies for turbulence phenomena. We propose the definition of a vortex in an incompressible flow in terms of the eigenvalues of the symmetric tensor $S/\sup 2/ + \Omega / \sup 2/$; here S and Ω are respectively the symmetric and antisymmetric parts of the velocity gradient tensor $\text{Del } u$. This definition captures the pressure minimum in a plane perpendicular to the vortex axis at high Reynolds numbers, and also accurately defines vortex cores at low Reynolds numbers, unlike a pressure-minimum criterion. We compare our definition with prior schemes/definitions using exact and numerical solutions of the Euler and Navier-Stokes equations for a variety of laminar and turbulent flows. In contrast to definitions based on the positive second invariant of $\text{Del } u$ or the complex eigenvalues of $\text{Del } u$, our definition accurately identifies the vortex core in flows where the vortex geometry is intuitively clear.

"WAKE EFFECTS ON AEROELASTIC STABILITY OF HINGELESS AND BEARINGLESS ROTORS"

Journal of Aircraft, Vol. 50, No. 6, November-December 2013, pp. 1938-1943.

In the present work, a study of the wake effects on the aeroelastic stability of hinge-less and bearing-less helicopter rotors was investigated in forward flight. A nonlinear beam model based on the large deflection theory was employed to evaluate the aeroelastic responses. To calculate the air loads of the rotor blades, three different aerodynamic approaches were used: a 2-D quasi steady with a Drees linear inflow model, the blade element theory (BET) with a Drees linear inflow model, and the BET with a free-wake method. As a result of the differences in the aerodynamic methods, the results of the periodic tip deflection exhibited discrepancies. In addition, the flap, lag, and torsion damping values obtained from the stability analyses of the hinge-less rotor blades were compared with those from previous studies. The lag damping obtained from the BET with the free-wake method, which differs by

at least 14.6 percent at low forward speeds, had lower values than the other approaches. At a low advance ratio, the damping values were significantly influenced by the wake effect. For this reason, it was clearly seen that the discrepancies of the damping values disappeared as the forward speed increased. Moreover, comparisons of the lag damping values of the bearing-less rotor blade obtained using the present analysis with experiments and other types of analyses exhibited reasonable agreement with some notable differences emanating from the wake effects. Therefore, it is concluded that the wake effects should be considered in order to obtain an accurate estimation of the aeroelastic stability.

"NUMERICAL AND EXPERIMENTAL STUDY OF FLOW STRUCTURE OF LOW-ASPECT RATIO WING"

Journal of Aircraft, Vol. 41, No. 5, September-October 2004, pp. 1196-1201

Unsteady aerodynamic characteristics of a low-aspect-ratio elliptic wing with an E-174 airfoil are studied by numerically solving unsteady incompressible Navier-Stokes equations. Two phenomena have been found: The first phenomenon is found at angle of attack larger than 11 deg, where the flow around the wing becomes bilateral asymmetric. This phenomenon is caused by tip vortices' destabilization. Tip vortices' destabilization is due to interaction between a secondary separated vortex and the tip vortices. The second phenomenon is found at angle of attack larger than 33 deg, where a large separated vortex stays above the wing, forming a stationary vortex. The stationary vortex is thought to be related to the vertical component of the tip vortices. Experimental flow visualization has verified the phenomena found in the numerical simulation.

"A SURVEY OF THE SCATTERING CHARACTERISTICS AND DETECTION OF AIRCRAFT WAKE VORTICES"

Journal of Radars, Vol. 6, 2017, pp. 1-20.

Aircraft wake vortex is a pair of strong counter-rotating vortices and has attracted considerable attention in various fields including aviation safety and atmospheric physics. The characteristics and detection of wake vortex act as the basis for both behavior prediction as well as hazard assessment.

This paper provides a short survey of the characteristics and detection researches. Initially, the wake vortex is classified as clear-air wake vortex (i.e., wake turbulence and contrail) and precipitation wake vortex (i.e., under rainy, foggy, or snowy condition). Subsequently, the dynamics and scattering are introduced, and the main verdicts are: the radar (radio detection and ranging) scattering of wake vortex is relatively weak under clear air conditions, but the Lidar (Light detection and ranging) scattering is appreciable owing to the presence of particles such as aerosols. Wake vortices under precipitation conditions and contrails possess relatively good radar reflectivity owing the strong scattering characteristics of precipitation droplets and ice crystals. Furthermore, we have introduced a joint detection scheme of Lidar and radar for wake vortex along with parameter-retrieval algorithms. Finally, we have presented our conclusions and intended future research.

"LES FOR INTERACTION OF WINGTIP VORTEX AND WAKES"

AIAA Paper No. 2007-724, Reno, NV, January 2007

Large eddy simulation with filtered-structured-function sub-grid model and implicit large eddy simulation (ILES without explicit sub-grid model) using high-order accuracy and high-resolution compact scheme have been performed on the tip vortex shedding from a rectangular half-wing with a NACA 0012 airfoil section and a rounded wing tip. The formation of the tip vortex and its initial development in the boundary layer and the near field wake are investigated and analyzed in detail. The physics, why the tip vortex, which is originally turbulent in the boundary layer, is relaminarized and becomes stable and laminar rapidly after shedding in the near field, is revealed by this simulation. The computation also shows the widely used second order sub-grid model is not consistent to six-order compact scheme and would degenerate the six-order LES results to second order. Therefore, high order schemes, grid refinement and six order sub-grid models are critical to LES approaches.

Jiang, L., Cai, J. and Liu, C.

"LES FOR NEAR FIELD WAKES BEHIND JUNCTION OF WING AND PLATE"

Journal of Hydrodynamics, Vol. 18, Issue 3, Supplement 1, July 2006, pp. 270-274

Large eddy simulation with high-order accuracy and high resolution has been performed on the tip vortex shed from a rectangular half-wing with a NACA 0012 airfoil section and a rounded wing tip. The formation of the tip vortex and its initial development in the near field are studied and analyzed in details.

Jiang, L., Cai, J. and Liu, C.

"LARGE EDDY SIMULATION OF WING TIP VORTEX IN THE NEAR FIELD"

Technical Report 2007-13, September 2007, University of Texas, Arlington, TX

Large eddy simulation with filtered-structure-function sub-grid model and implicit large eddy simulation (ILES without explicit sub-grid model) using high-order accuracy and high-resolution compact scheme have been performed on the tip vortex shedding from a rectangular half-wing with a NACA 0012 airfoil section and a rounded wing tip. The formation of the tip vortex and its initial development in the boundary layer and the near field wake are investigated and analyzed in detail. The physics, why the tip vortex, which is originally turbulent in the boundary layer, is relaminarized and becomes stable and laminar rapidly after shedding in the near field, is revealed by this simulation. The computation also shows the widely used second order sub-grid model is not consistent to six-order compact scheme and would degenerate the six-order LES results to second order. Therefore, high order schemes, grid refinement and six order sub-grid models are critical to LES approaches.

"DETECTION AND VISUALIZATION OF VORTICES"

Visualization Handbook, edited by C. Johnson and C. Hansen, Academic Press, 2004, pp. 287-301.

Throughout the past decade, there has been a steady stream of publications about vortex detection. The paper presents an overview of nine detection algorithms that are representative of the state-of-the-art. Each detection algorithm is classified based on how it defines a vortex, whether it is Galilean invariant, and the local or global nature of its identification process. Although many of the algorithms share similarities, each has its own advantages and disadvantages. A recently developed verification algorithm, that can be used in conjunction with any detection method, was also overviewed, as well as various techniques for visualizing detected vortices. Although much progress has been made towards detecting vortices in steady flow fields, there is still a paucity of methods that can do the same in unsteady (time-varying) flow fields. None of the detection methods described in this paper can adequately address all of the issues unique to unsteady vortical flows. A major challenge will be to develop efficient and robust vortex detection and tracking algorithms for unsteady flow fields.

"INFLUENCE OF TOPOGRAPHY AND WAKES ON WIND TURBULENCE: MEASUREMENTS AND INTERPRETATION OF RESULTS"

Wind Energy, Vol. 14, Issue 7, October 2011, pp. 895-908.

To perform detailed calculations of dynamic loads on wind turbines due to turbulence, a precise wind simulator is needed. International standards give guidelines to generate a synthetic wind for a flat terrain in the absence of wakes. Measurements in complex terrain and under wake effects have been analyzed with the purpose of establishing some modifications to those guidelines that improve the simulated wind turbine characteristics. A modification of the spectrum shape is proposed for locations affected by wind turbine wakes. Modifications are also proposed for the ratios of standard deviations and the turbulence lengths, which give a tendency to turbulence isotropy, as the complexity of the

terrain and wake effects become more relevant. The parameter called normalized turbulence intensity is introduced to quantify the 'complexity' of a location.

Jimenez, J.

"STABILITY OF A PAIR OF CO-ROTATING VORTICES"

Phys. Fluids, Vol. 18, No. 11, November 1975, pp. 1580-1581

The linear stability of a pair of co-rotating vortex filaments is studied with a view toward clarifying the behavior of these pairs in the shear layer. The configuration is found to be stable within the long wave approximation.

Jimenez, J. M. and Smits, A. J.

"TIP AND JUNCTION VORTICES GENERATED BY THE SAIL OF A YAWED SUBMARINE MODEL AT LOW REYNOLDS NUMBERS"

Journal of Fluids Engineering, Vol. 133, March 2011, pp. 034501-1 to 034501-4.

Results are presented on the behavior of the tip and junction vortices generated by the sail of a SUBOFF submarine model at yaw angles from 6 deg. to 17 deg. for a Reynolds number of 94,000 based on model length. The measurements were conducted in a water channel on a spanwise plane 1.3 chord lengths downstream from the trailing edge of the sail. In the vicinity of the sail hull junction, the pressure of streamwise vortices in the form of horseshoe or necklace vortices locally dominates the flow. As the yaw angle is increased from 6 deg. to 9 deg., the circulation of the sail tip vortex increases, and is in good accordance with predictions from finite wing theory. However, as the yaw angle is further increased, the sail boundary layer separates with an overall drop in circulation. In contrast, the circulation value for the junction vortex increases with yaw angle, and only drops slightly at the highest yaw angle.

"HELICOPTER WAKE ENCOUNTERS IN THE CONTEXT OF RECAT-EU"

43rd European Rotorcraft Forum, Paper 512, September 2017, Milan, Italy.

This work presents a first attempt to apply the RECAT-EU (European Wake Turbulence Categorization and Separation Minima) methodology of fixed-wing aircraft separation to helicopters. The approach is based on a classification of helicopters in categories using their rotor diameter and weight combined with wake comparisons between different classes of fixed-wing aircraft and helicopters. Where necessary the upset caused by a wake encounter to a simple helicopter model is used to establish safe separation distances. The work is based on a very limited amount of data for wake strengths but shows that the principles of the RECAT-EU methodology are directly applicable to helicopters at least for landing and take-off. This research calls for further measurements of helicopter wakes with modern

methods so that the suggested separation distances can be further ascertained and ultimately refined allowing for better and safer integration of fixed and rotary-wing traffic at airports.

"TRAILING VORTEX STRENGTH ATTENUATION VIA CHIPPED WINGTIP SHAPES"

AIAA Paper 2013-2656, June 2013, San Diego, CA.

The shedding of strong vortices generated at the wingtip during take off and landing can cause substantial safety issue to the following aircraft. To avoid the vortex wake hazard from the leading aircraft, a chipped wingtip shape is proposed as a new concept and its conceptual validity is examined through systematic wind tunnel studies. The flow structure of the vortex wakes behind chipped wingtip shapes are measured by using particle image velocimetry (PIV) at $Re = 1,060,000$. Aerodynamic forces of chipped wingtip shapes are also measured to supplement the PIV results. It is found that the trailed vortices of chipped wingtip shapes are substantially attenuated compared with those of the baseline wingtip shape. Counter-rotating vortices generated by chipped wingtip shape significantly weakens the main wingtip vortex strength in the far field. A series of parametric study has been performed to evaluate the chip shape parameters such a chip aspect ratio, spacing from wingtip edge and area percentage. From the results it is concluded that despite a slight increase of the drag, chipped wingtip shape can successfully alleviate the peak tangential velocity and vorticity strength of the trailed vortices.

Jing, F., Kanso, E. and Newton, P. K.

"INSIGHTS INTO SYMMETRIC AND ASYMMETRIC VORTEX MERGERS USING THE CORE GROWTH MODEL"

Physics of Fluids, Vol. 24, 2012, pp. 073101-1 - 073101-17.

We revisit the two-vortex merger problem (symmetric and asymmetric) for the Navier-Stokes equations using the core growth model for vorticity evolution coupled with the passive particle field and an appropriately chosen time-dependent rotating reference frame. Using the combined tools of analyzing the topology of the streamline patterns along with the careful tracking of passive fields, we highlight the key features of the stages of evolution of vortex merger, pinpointing deficiencies in the low-dimensional model with respect to similar experimental/numerical studies. The model, however, reveals a far richer and delicate sequence of topological bifurcations than has previously been discussed in the literature for this problem, and, at the same time, points the way towards a method of improving the model.

Johannes, R. P.

"AIRCRAFT WAKE TURBULENCE CONTROLLABILITY EXPERIMENT"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 547-559.

The object of the experiment was to evaluate the effectiveness of a properly mechanized automatic control system in minimizing aircraft upset and improving the controllability which can result from wake turbulence encounter. The in-flight experiment consisted of two flights of approximately three hours duration each, wherein the B-52 test aircraft was flown in formation with a C-141 and explored the wake turbulence generated.

Johansson, B. C. A.

"COMPRESSIBLE FLOW ABOUT HELICOPTER ROTORS"

Vertica, Vol. 2, No. 1, pp. 1-9

Two theoretical methods for helicopter rotors or propellers in subsonic flow are presented, namely a lifting-line theory for a helicopter rotor in vertical climb, hovering or in slow descent, or a propeller in steady forward flight or operating statically, and a disk approximation for a helicopter rotor in forward flight or a propeller in yaw. In both methods the compressibility of the air is considered. In the second case, the rotor is approximated by a disk of continuous thrust and in-plane force distributions, which are assumed to be known. Its wake is represented by a semi-infinite cylinder of distributed vorticity. Formulas for the induced velocity field are derived.

Johansson, L. C., Wolf, M. and Hedenstrom, A.

"A QUANTITATIVE COMPARISON OF BIRD AND BAT WAKES"

Journal of the Royal Society Interface, Vol. 7, 2009, pp. 61-66.

Qualitative comparison of bird and bat wakes has demonstrated significant differences in the structure of the far wake. Birds have been found to have a unified vortex wake of the two wings, while bats have a more complex wake with gradients in the circulation along the wingspan, and with each wing generating its own vortex structure. Here, we compare quantitative measures of the circulation in the far wake of three bird and one bat species. We find that bats have a significantly stronger normalized circulation of the start vortex than birds. We also find differences in how the circulation develops during the wingbeat as demonstrated by the ratio of the circulation of the dominant start vortex and the total circulation of the same sense. Birds show a more prominent change with changing flight speed and a relatively weaker start vortex at minimum power speed than bats. We also find that bats have a higher normalized wake loading based on the start vortex, indicating higher relative induced drag and therefore less efficient lift generation than birds. Our results thus indicate fundamental differences in the aerodynamics of bird and bat flight that will further our understanding of the evolution of vertebrate flight.

Johansson, P. B. V.

"THE AXISYMMETRIC TURBULENT WAKE"

PhD Thesis, 2002, Chalmers University of Technology, Goteborg, Sweden.

This thesis presents a theoretical and experimental study of the turbulent axisymmetric wake. In the theoretical part, an equilibrium similarity solution of the far wake was derived that was found to admit to two different solutions for this flow. The high Reynolds number solution predicts that the flow grows as the cube root of the distance downstream, whereas the low Reynolds number solution grows as the square root of the downstream distance. None of these solutions had unambiguously been confirmed in earlier work. The analysis also provided necessary criteria for when to expect either solution. In the experimental part, data was obtained by hot-wire anemometry using arrays of 13 and 15 probes. For the first time, experimental data was proven to behave like the high Reynolds number equilibrium similarity solution predicted. These multi-point probe rakes were also used to measure cross-spectra in cross-sections of the flow from 10 to 150 disk diameters downstream.

Johari, H. and Durgin, W. W.

"DIRECT MEASUREMENT OF CIRCULATION USING ULTRASOUND"

Experiments in Fluids, Vol. 25, 1998, pp. 445-454

Ultrasound time-of-flight methods employing counter-propagating ultrasonic pulses are utilized for the direct measurement of circulation in vortical flows. Two schemes are described here which involve either a single straight path or a closed path. Both techniques are shown to result in time differences, between the counter-propagating pulses around the path, linearly proportional to the circulation enclosed by the ultrasound path. The ultrasound methods of circulation measurement do not require calibration constants and can be non-invasive. The reliability of the closed path ultrasound method was assessed by comparing the measured circulation values with those calculated from the lift measurements of a NACA 0012 airfoil. Two examples are also presented where the closed path ultrasound method has been applied to the flow over a delta wing and a free-surface vortex in a cylindrical tank.

Johari, H. and Durgin, W. W.

"ULTRASONIC MONITORING METHOD AND SYSTEM FOR WAKE TURBULENCE USEFUL AT RUNWAYS"

US Patent 6,062,076, May 2000.

Two techniques for detecting vortices and their associated circulation are disclosed. The first is termed a closed path configuration, and the second is termed the dual path configuration. These techniques are useable for the detection of wake turbulence especially in the vicinity of airport runways, which results from wing tip vortices generated by aircraft during take-off and landing. The systems are similar in that they use ultrasonic measurement techniques to determine the circulation about defined areas. The circulation is reflective of the vorticity associated with trailing vortices, which are manifest within the area.

Johari, H. and Moreira, J.

"DIRECT MEASUREMENT OF DELTA-WING VORTEX CIRCULATION"

AIAA Journal, Vol. 36, No. 12, December 1998, pp. 2195-2203.

The circulation around a closed path encompassing the primary vortex of stationary delta wings has been investigated using a novel ultrasound technique. Ultrasonic pulses propagating in clockwise and counterclockwise directions enclosed a fixed path that was positioned perpendicular to the delta-wing root chord line. Circulation in the plane of the closed path then was determined from the transit-time difference between the clockwise and counterclockwise pulses. Half-delta wings with sweep angles of 60 and 70 deg were tested over a range of angles of attack up to 38 deg and 52 deg, respectively, and at chordwise distances of 35, 50, 65, and 80 percent from the wing apexes. Circulation increased monotonically with angle of attack for both sweep angles until it reached a maximum value, beyond which the total circulation decreased or remained nearly constant. The angle of attack associated with the maximum circulation is correlated with conditions resulting in feeding sheet interaction on the symmetry plane. At any angle of attack, circulation increased approximately linearly with increasing chordwise location as long as the feeding-sheet interaction was not present. Normalizing circulation by freestream velocity and local semispan collapsed the data at angles of attack prior to the interaction. The rate of circulation increase along the wing increased with angle of attack for both sweep angles. Vortex breakdown does not appear to have any direct influence on the total circulation of delta-wing vortices.

"EXPERIMENTAL AND COMPUTATIONAL INVESTIGATION OF THE FLOW BEHIND A C-130 WITH TAILGATE DOWN"

AIAA Paper 2002-0713, January 2002, Reno, NV.

This paper presents a comparison of computational fluid dynamics and an experimental analysis of the unsteady flow behind a C-130 with tailgate down. One of the primary missions of the C-130 Hercules is deployment of airborne paratroopers using a static line system to deploy the parachutes. However, if the static line fails to deploy the paratroopers may get caught and injured in the separation/recirculation region aft of the cargo bay ramp. A detailed experimental and computational understanding of the nature of the flow has been initiated at the US Air Force Academy to identify solutions to this problem. An unstructured grid modeling the full aircraft with 6,200,000 cells was created, and an unsteady Navier Stokes solution was performed, matching the experimental Reynolds number. The experimental analysis involves laser light sheet and dye flow visualization coupled with particle image velocimetry. The potential solutions of extending a large plate/extended ramp out of the cargo bay ramp as well as using bleed doors along the fuselage are identified and examined.

Johnson Jr, E. J.

"TOLERABLE ERRORS IN MEAN EDR FOR WAKE TURBULENCE APPLICATIONS"

AIAA Paper 2017-4241, June 2017, Denver, CO.

The prediction of aircraft wake turbulence lifetimes has been identified as potentially the primary user of mean Eddy Dissipation Rate (EDR) data derived from aircraft-based observations. This paper develops estimates for the error in EDR values that can be tolerated without affecting the prediction of wake vortex lifetimes by more than 5 percent across the range of EDR values operationally significant for potential wake turbulence applications. These estimates were used by the FAA to develop performance standards for algorithms computing EDR from aircraft derived data. The FAA performance standards are being leveraged by RTCA Special Committee 206 to develop performance guidelines and requirements for algorithms computing EDR to ensure operationally comparable results under all conditions normally encountered in routine aeronautical operation.

Johnson, A.

"TRENDS IN WAKE VORTEX INCIDENTS"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 9-1 - 9-12

An analysis of 140 incidents involving wake vortex turbulence over the past 7 years was undertaken to detect trends in these reports. After processing the files, patterns appeared. It was found that most wake vortex incidents occur when a plane of the 'large' weight class is preceded by a plane of the 'heavy' class. Moreover, a large fraction of the incidents with the heavy/large and the large/large combination had the required spacing required by federal regulations, and most of the incidents happened in the landing/approach phase of the plane's flight, below 1000'.

Johnson, D. E.

"DEVELOPMENT OF A TERMINAL SENSOR FOR HAZARDOUS WEATHER AND WAKE TURBULENCE DETECTION"

Annual Assembly Meeting and Technical Symposium Proceedings, Radio Technical Commission for Aeronautics, 1984, pp. 149-158.

It is pointed out that real time weather information for Federal Aviation Administration (FAA) air traffic control (ATC) purposes comes currently from ATC surveillance radars. However, existing surveillance radars have three severe limitations for weather detection use. One limitation is related to an optimization of the radars for aircraft detection, because such an optimization degrades the weather detection capability. The fan beam antenna of the surveillance radars causes inaccuracies in weather indications, while the third limitation is the restriction of the surveillance radars to the provision of reflectivity information. This situation has led the FAA to conduct research and development activities concerning the use of Doppler radars. Attention is given to the FAA weather radar requirements, activities in support of the Next Generation Weather Radar (NEXRAD), wind shear and wake turbulence detection, and aspects of data collection.

Johnson, H.

"NONLINEAR DYNAMICS OF WAKE VORTICES"

PhD Thesis, December 2016, University of Paris-Saclay, Ecole Polytechnique, Paris, France.

Aircraft wakes have been the subject of extensive research for several decades as it poses economic, safety and environmental issues. The wake is composed of powerful counter-rotating vortices that persist long after the aircraft has passed. In this thesis, the nonlinear dynamics of aircraft wake vortices is investigated through Direct Numerical Simulation. The aim is to explore the nonlinear effects on wake vortex behavior and evaluate the potential for the anticipated destruction of the vortices through optimal perturbation. First the disruptive potential of the linear optimal perturbation of the flow is evaluated by applying it with increasing initial amplitude and observing the nonlinear response of the flow. With sufficient yet reasonable initial amplitude, the linear optimal perturbation halves the life-span of the vortex pair by accelerating the loss of coherence of the vortices after the linking phase. Next the nonlinear gradient-based optimization tool that was developed during the thesis is validated by reproducing existing results concerning a simple vortical flow: an isolated two-dimensional vortex. In doing so new nonlinear optimization results are obtained and analyzed. It is shown that the 2D nonlinear optimal perturbation of an isolated vortex can induce considerably greater transient growth than the linear optimal. In some cases, the nonlinear optimal causes a transition to a quasi-steady asymmetric state, bypassing the natural axisymmetrization process. The effect of the vortex vorticity profile on the optimal perturbations is also studied. Vortices with sharper profiles experience far greater linear perturbation growth, however the nonlinear growth is significantly inferior. Finally, the nonlinear optimal perturbation analysis of the isolated vortex is extended to three dimensions. Although the 3D nonlinear optimal perturbations produce less growth than their linear counterparts, they can lead to quasi-permanent high energy states.

"ON THE SPREAD AND DECAY OF WIND TURBINE WAKES IN AMBIENT TURBULENCE"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012055-1 - 012055-8.

The decay of the downstream wake turbine plays an important role in the performance of a wind farm. The spread and decay of a wake depend both on wake meandering (advection of the wake as a whole) and wake diffusion (widening of the wake within its meandering frame of reference). Both of these effects depend strongly on the intensity of the ambient turbulence relative to the velocity deficit in the wake, and on the integral length scale of the turbulence relative to the wake width. Recent theory, which we review here, shows how intense large-scale turbulence can lead to a rapid $1/(x^2)$ decay in the time-averaged centerline velocity deficit, as compared to a $1/x$ decay for smaller scale turbulence, where x is distance downstream. We emphasize in this paper that common wind farm models do not predict this rapid decay. We present new experimental measurements of the velocity deficit downstream of a porous disc in relatively large-scale ambient turbulence which

corroborate predictions of a $1/(x \text{ squared})$ decay, and we show theoretically that the commonly used k-epsilon model does not capture this effect. We further show that a commercial CFD package, configured to match our experiments and employing the k-epsilon model, fails to predict such rapid decay. We conclude that steady simulations of wind turbine wake dynamics are insufficient for informing wind farm layout optimization.

"SIMPLIFIED AIRCRAFT-BASED PAIRED APPROACH: CONCEPT DEFINITION AND INITIAL ANALYSIS"

NASA/TP-2013-217994, January 2013, NASA Langley Research Center, Hampton, VA.

Simplified Aircraft-based Parallel Approach (SAPA) is an advanced concept proposed by the Federal Aviation Administration (FAA) to support dependent parallel approach operations to runways with lateral spacing closer than 2500 ft. At the request of the FAA, NASA performed an initial assessment of the potential performance and feasibility of the SAPA concept, including developing and assessing an operational implementation of the concept and conducting a Monte Carlo wake simulation study to examine the longitudinal spacing requirements. The SAPA concept was shown to have significant operational advantages in supporting the pairing of aircraft with dissimilar final approach speeds. The wake simulation study showed that support for dissimilar final approach speeds could be significantly enhanced using a two-phase altitude-based longitudinal positioning requirement, with larger longitudinal positioning allowed for higher altitudes out of ground effect and tighter longitudinal positioning defined for altitudes near and in ground effect. While this assessment is preliminary and there are several operational issues still to be examined, it has shown the basic SAPA concept to be technically and operationally feasible.

Johnson, W.

"MODEL FOR VORTEX RING STATE INFLUENCE ON ROTORCRAFT FLIGHT DYNAMICS"

4th Decennial Specialist's Conference on Aeromechanics, American Helicopter Society, January 2004, San Francisco, CA.

The influence of vortex ring state (VRS) on rotorcraft flight dynamics is investigated, specifically the vertical velocity drop of helicopters and the roll-off of tiltrotors encountering VRS. The available wind tunnel and flight test data for rotors in vortex ring state are reviewed. Test data for axial flow, nonaxial flow, two rotors, unsteadiness, and vortex ring state boundaries are described and discussed. Based on the available measured data, a VRS model is developed. The VRS model is a parametric extension of momentum theory for calculation of the mean inflow of a rotor, hence suitable for simple calculations and real-time simulations. This inflow model is primarily defined in terms of the stability boundary of the aircraft motion. Calculations of helicopter response during VRS encounter were performed, and good correlation is shown with the vertical velocity drop measured in flight tests. Calculations of tiltrotor response during VRS encounter were performed, showing the roll-off behavior characteristic of

tiltrotors. Hence it is possible, using a model of the mean inflow of an isolated rotor, to explain the basic behavior of both helicopters and tiltrotors in vortex ring state.

Johnson, W.

"INFLUENCE OF WAKE MODELS ON CALCULATED TILTROTOR AERODYNAMICS"

American Helicopter Society Aerodynamics, Acoustics, and Test and Evaluation Technical Specialists Meeting, January 2002, San Francisco, CA.

Comparisons of measured and calculated aerodynamic behavior of a tiltrotor model are presented. The test of the Tilt Rotor Aeroacoustic Model (TRAM) with a single, 1/4-scale V-22 rotor in the German-Dutch Wind Tunnel (DNW) provides an extensive set of aeroacoustic, performance, and structural loads data. The calculations were performed using the rotorcraft comprehensive analysis CAMRAD II. Presented are comparisons of measured and calculated performance and air loads for helicopter mode operation, as well as calculated induced and profile power and wake geometry. The focus of this paper is on the further development of wake models for tiltrotors in helicopter mode operation. Three tiltrotor wake models are considered, characterized as the rolled-up, multiple-trailer, and multiple-trailer with consolidation models. By using a free wake geometry calculation method that combines the multiple-trailer wake model with a simulation of the tip vortex formation process (consolidation), good correlation of the calculations with TRAM measurements is obtained for both performance and for air loads.

Johnson, W. A.

"MATHEMATICAL MODEL FOR HUMAN PILOT BEHAVIOR DURING A WAKE VORTEX ENCOUNTER UPSET"

TR-1025-4/2, May 1975, Systems Tech. Inc., Hawthorne, CA.

This report documents the results of a pilot modeling effort to determine the roll control behavior of a human pilot during a wake vortex encounter upset. Data for the pilot modeling analysis was obtained from a six-degree-of-freedom moving-base, piloted simulation of vortex encounters at NASA Ames Research Center.

Johnson, W. A. and Myers, T. T.

"A MODEL FOR HUMAN PILOT BEHAVIOR DURING WAKE VORTEX ENCOUNTER UPSETS"

FAA-RD-76-8, April 1976, Systems Technology Inc., Hawthorne, CA.

A model for pilot behavior is needed to more completely analyze the consequences (including hazard assessment) of wake vortex encounter upsets during final approach. Such a model has been developed to describe a pilot's roll control behavior during a vortex upsets. This model resulted from abstracting the salient characteristics of the many vortex encounters recorded during two moving-base piloted simulations at NASA Ames Research Center. The model allows for several discrete modes of behavior

and includes an associated set of switching logics. The model is the result of a lengthy sequence of analytical steps; however, a retracing of these steps is not included here. Rather, only a description of the resulting model and several example applications are presented.

Johnson, W. A. and Rediess, H. A.

"STUDY OF CONTROL SYSTEM EFFECTIVENESS IN ALLEVIATING VORTEX WAKE UPSETS"

AIAA Paper No. 1973-0833, Key Biscayne, FL, 1973.

The problem of an airplane being upset by encountering the vortex wake of a large transport on takeoff or landing is currently receiving considerable attention. This paper describes the technique and results of a study to assess the effectiveness of automatic control systems in alleviating vortex wake upsets. A six-degree-of-freedom nonlinear digital simulation was used for this purpose. The analysis included establishing the disturbance input due to penetrating a vortex wake from an arbitrary position and angle. Simulations were computed for both a general aviation airplane and a commercial jet transport. Dynamic responses were obtained for the penetrating aircraft with no augmentation, and with various command augmentation systems. The results of this preliminary study indicate that it is feasible to use an automatic control system to alleviate vortex encounter upsets.

Johnson, W. A. and Teper, G. L.

"ANALYSIS OF VORTEX WAKE ENCOUNTER UPSETS"

NASA CR-127491, August 1974, Systems Tech. Inc., Hawthorne, CA

The problem of an airplane being upset by encountering the vortex wake of a large transport on takeoff or landing is currently receiving considerable attention. This report describes the technique and result of a study to assess the effectiveness of automatic control systems in alleviating vortex wake upsets. A six-degree-of-freedom nonlinear digital simulation was used for this purpose. The analysis included establishing the disturbance input due to penetrating a vortex wake from an arbitrary position and angle. Simulations were computed for both a general aviation airplane and a commercial jet transport. Dynamic responses were obtained for the penetrating aircraft with no augmentation, and with various command augmentation systems, as well as with human pilot control. The results of this preliminary study indicate that attitude command augmentation systems can provide significant alleviation of vortex wake upsets; and can do it better than a human pilot.

Johnson, W. A., Teper, G. L. and Rediess, H. A.

"STUDY OF CONTROL SYSTEM EFFECTIVENESS IN ALLEVIATING VORTEX WAKE UPSETS"

Journal of Aircraft, Vol. 11, No. 3, March 1974, pp. 148-154

The problem of an airplane being upset by encountering the vortex wake of a large transport on takeoff or landing is currently receiving considerable attention. This paper describes the technique and

results of a study to assess the effectiveness of automatic control systems in alleviating vortex wake upsets. A six-degree-of-freedom nonlinear digital simulation was used for this purpose. The analysis included establishing the disturbance input due to penetrating a vortex wake from an arbitrary position and angle. Simulations were computed for both a general aviation airplane and a commercial jet transport. Dynamic responses were obtained for the penetrating aircraft with no augmentation, and with various command augmentation systems. "WIND TUNNEL MEASUREMENTS AND CALCULATIONS OF AERODYNAMIC INTERACTIONS BETWEEN TILTROTOR AIRCRAFT"

AIAA Paper 2003-0047, January 2003, Reno, Nevada.

Wind tunnel measurements and calculations of the aerodynamic interactions between two tiltrotor aircraft in helicopter mode are presented. The measured results include the roll moment and thrust change on the downwind aircraft, as a function of the upwind aircraft position (longitudinal, lateral, and vertical). Magnitudes and locations of the largest interactions are identified. The calculated interactions generally match the measurements, with discrepancies attributed to the unsteadiness of the wake and aerodynamic forces on the airframe. To interpret the interactions in terms of control and power changes on the aircraft, additional calculations are presented for trimmed aircraft with gimbaled rotors.

Johnstone, E. H.

"AIRCRAFT WING VORTEX DEFLECTOR"

US Patent 3,974,986, August 1976.

An aircraft wing vortex deflector constituting means for intercepting at least part of the spiral flow of air around the tips of the wings during flight and directing the intercepted air rearwardly in a manner and direction tending to dissipate vortices in the wake of the aircraft.

Joly, L. and Reinaud, J. N.

"THE MERGER OF TWO-DIMENSIONAL RADIALLY STRATIFIED HIGH-FROUDE-NUMBER VORTICES"

J. Fluid Mech., Vol. 582, 2007, pp. 133-151

We investigate the influence of density inhomogeneities on the merger of two co-rotating two-dimensional vortices at infinite Froude number. In this situation, buoyancy effects are negligible, yet density variations still affect the flow by pure inertial effects through the baroclinic torque. We first re-address the effects of a finite Reynolds number on the interaction between two identical Gaussian vortices. Then, by means of direct numerical simulations, we show that vortices transporting light fluid

in a heavier counterpart merge from further distances than vortices in a uniform density medium. On the other hand, heavy vortices only merge from small separation distances. We measure the critical distance of the vortex radii to their initial separation distance. It departs from the homogeneous threshold of 0.22 in response to increasing density contrasts between the vortices and their surroundings. An analysis of the contribution of the baroclinic vorticity to the dynamics of the flow is detailed and explains the observed behavior. This analysis is completed by a simple model based on point vortices that mimics the flow. It is concluded that vortices carrying light fluid are more likely to generate large-scale structures than heavy ones in an inhomogeneous fluid.

Jones, D. N.

"INTRODUCTION TO JET-ENGINE EXHAUST AND TRAILING VORTEX WAKES"

TR-226, April 1970, Air Weather Service (MAC), USAF, Scott Air Force Base, IL.

This report is a result of a survey of the immediately available literature on aircraft wakes and is a general representation of techniques and problems involved. Approximate relations are used for their simplicity and to define areas dangerous to flight.

Jones, J. P.

"THE CALCULATION OF THE PATHS OF VORTICES FROM A SYSTEM OF VORTEX GENERATORS AND A COMPARISON WITH EXPERIMENT"

ARC Report CP-361, March 1955, University of Southampton, Southampton, England.

A method is described for the calculation of the paths of the trailing vortices from a system of counter-rotating vortex generators, and a comparison is made with some experimental results obtained in a water tunnel. The method can be adapted to other configurations of generators arranged to produce rows of vortices close to a plane surface.

Jones, J. P. and Noak, M.

"SOME PROBLEMS IN THE NUMERICAL SOLUTION OF VORTEX MOTION EQUATIONS"

Proceedings of 3rd CAL/AVLABS Symposium, Aerodynamics of Rotor, Wing and V/STOL Aircraft, Vol. III, June 1969.

The results of some flow visualization experiments on the trailing vortices from a model helicopter rotor are presented. It was found that the wake contraction was a cyclic phenomenon dependent on the number of blades. Its precise cause could not be ascertained but was probably due to interference between the blade bound vortices and the trailing vortices in the rotor wake. An investigation was conducted into some of the problems encountered when attempting to solve numerically the equations governing vortex motion.

"DYNAMICS OF THE VORTEX CORE DURING PITCHING OF A HIGH-SWEEP DELTA WING"

AIAA Paper No. 2007-1284, Reno, NV, January 2007

In the present work, the pitch-up of a 70-degree sweep delta wing is modelled computationally. The dynamics of the vortex core generated near the wing leading edge, during transitions to vortex breakdown, is observed. The intention is to test theories for breakdown derived from more confined geometries to the delta wing vortex breakdown. Accordingly, the dynamics of the vortex is tracked in terms of the appearance of negative azimuthal vorticity, and transitions in criticality of the vortex core. It is confirmed that the onset of breakdown is preceded in time and space by the generation of negative azimuthal vorticity, consistent with analyses for more confined geometries. Consideration of the criticality criterion, in the form of the helix angle, shows that the chordwise location of breakdown is consistent with the transition of the vortex from a supercritical to subcritical flow.

Jones, M. I. and Bender, E. E.

"CFD-BASED COMPUTER SIMULATION OF OPTICAL TURBULENCE THROUGH AIRCRAFT FLOWFIELDS AND WAKES"

AIAA Paper No. 2001-2798, Anaheim, CA, June 2001

Recent results for Lockheed Martin Aeronautics CFD-based aero-optical analysis of unsteady aerodynamic flow fields are presented. An unsteady CFD analysis of a fuselage/turret configuration is described. The unsteady density fields obtained from the CFD analysis are used to perform aero-optical analysis of laser beams propagating from the turret. Analysis includes time-varying wavefront error (WFE) maps, far-field laser burn patterns, Zernike fitting coefficient values and Zernike spectra for aperture X-tilt, Y-tilt, defocus and astigmatism, and WFE RMS values and RMS spectra.

Jones, R. H.

"HOW THE COURTS LOOK AT WAKE TURBULENCE"

FAA Symposium on Turbulence, Federal Aviation Administration, 1971, p. 23

Wake turbulence aircraft accidents over the years have resulted in law suits against the Government for the alleged negligence of the control tower operator. Recent cases have broadened and extended the liability of the U.S. Government for the negligence of its air traffic controllers in wake turbulence accident cases.

Jones, R. T. and Lasinski, T. A.

"EFFECT OF WINGLETS ON THE INDUCED DRAG OF IDEAL WING SHAPES"

NASA TM-81230, September 1980, NASA Ames Research Center, Moffett Field, CA.

A conventional wing having a given lift and a limited span achieves minimum induced drag when the spanwise distribution of lift is elliptical. However, if the limitation on span is removed and replaced by a structural constraint on the integrated bending moments, Prandtl found that a 10-percent reduction of induced drag can be achieved by a 10-percent increase of wing span accompanied by a more highly tapered loading. In the present report, we have extended such calculations to wings having vertical tip extensions or winglets. It is found that essentially the same result can be obtained by a 15-percent vertical extension. Thus, it appears that with ideal wing shapes similar reductions of induced drag can be achieved by either horizontal or vertical tip extensions.

"POTENTIAL 1090 EXTENDED SQUITTER SUPPORT OF WAKE VORTEX/METEOROLOGY APPLICATIONS"

Report MTR130464, October 2013, Mitre Corporation, McLean, VA.

The Automatic Dependent Surveillance-Broadcast (ADS-B) 1090-Megahertz Extended Squitter message broadcast requirements supporting Wake Vortex and Meteorology data updates are derived from the 'Aircraft Derived Meteorological Data via Data Link for Wake Vortex, Air Traffic Management and Weather Applications -- Operational Services and Environmental Definition (OSED)' (DO-338). Evaluation of the OSED proposed alternatives is based on these requirements as well as an examination of the potential impact of these alternatives on ADS-B users. Criteria for this impact assessment are the 'ADS-B Traffic Surveillance Systems and Applications ADS-B Minimum Aviation System Performance Standards (MASPS)' (DO-338) requirements for state vector updates. Expected performance estimates in specified interference environments use The MITRE Corporation 1090 MHz C0-channel Interference Model. Model validation and expected performance in several interference scenarios proposed by the FAA's 1090 MHz Spectrum Mitigation Alternatives Working Group are described.

"AIRCRAFT TRAILING VORTEX INSTABILITIES"

International Council of the Aeronautical Sciences Paper 74-34, Haifa, Israel, 1974. (Also, TEES 600-74-01)

A summary is given of the results of flight test studies of trailing vortices carried out at Texas A&M University. The instability of a pair of trailing vortices due to mutual interaction is fully discussed and theoretical predictions of the wavelength of the vortex oscillations that develop in the far wake of an airplane are compared with values determined from photographic records of the wake behavior of a DeHavilland Beaver DHC-2 aircraft. The different types of instability that can develop with single vortices are also considered, including vortex bursting phenomenon that occurs with vortices that

separate from the leading edges of highly swept wings at incidence. A technique for inducing earlier breakdown and dissipation of the vortices than would occur normally is described.

"AIRLOADS AND MOMENTS ON AN AIRPLANE FLYING OVER A PAIR OF INCLINED TRAILING VORTICES"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 523-545

When an aircraft flies across the wake of a preceding one, it is subjected to changing air loads and moments induced by the trailing vortices of the first aircraft. The purpose of this paper is to investigate the magnitude and characteristics of the time dependent aerodynamic forces so produced. The problem is reduced to finding the appropriate vorticity distribution at each stage of the aircraft's flight over the trailing vortices. This can be done approximately by using a modified lifting line theory or, more accurately, by lifting surface theory.

Jordan, A. R.

"PRESSURE AND VORTICITY TRANSIENTS FROM SUMMER STORMS AND AIRCRAFT"

J. Appl. Meteorology, Vol. 19, October 1980, pp. 1223-1233.

Pressure, wind, and vorticity have been studied on the microscale and mesoscale for a variety of features including plumes, vortices, dust devils, and gust front from thunderstorms along with aircraft-generated vortices. Results confirm the fact that negative-pressure pulses result from updrafts associated with convective elements, both rotational and non-rotational. It is shown that wake vortices from aircraft at take-off and landing have similar features with naturally occurring vortices even though the axes of the wake vortices are initially almost horizontal. It is also shown that a high-sensitivity pressure sensor in combination with suitable wind sensors can be used to determine the diameter and orbital velocity of the vortex flow near the ground where a potential hazard to flight may exist.

Jordan, Jr., F. L.

"FLOW VISUALIZATION OF THE WAKE OF A TRANSPORT AIRCRAFT MODEL WITH LATERAL-CONTROL OSCILLATIONS"

NASA TM-84623, June 1983, NASA Langley Research Center, Hampton, VA

An exploratory flow visualization study conducted in the Langley Vortex Research Facility to investigate the effectiveness of lateral control surface oscillations as a potential method for wake vortex attenuation on a 0.03 scale model of a wide body jet transport aircraft is described. Effects of both asymmetric surface oscillation (control surfaces move as with normal lateral control inputs) and symmetric surface oscillation (control surfaces move in phase) are presented. The asymmetric case simulated a flight maneuver which was previously investigated on the transport aircraft during NASA/FAA flight tests and which resulted in substantial wake vortex attenuation. Effects on the model

wake vortex systems were observed by propelling the model through a two-dimensional smoke screen perpendicular to the model flight path. Results are presented as photographic time histories of the wake characteristics recorded with high speed still cameras. Effects of oscillation on the wake roll up are described in some detail, and the amount of vortex attenuation observed is discussed in comparative terms. Findings were consistent with flight test results in that only a small amount of rotation was observed in the wake for the asymmetric case. A possible aerodynamic mechanism contributing to this attenuation is suggested.

"STATUS OF AERIAL APPLICATIONS RESEARCH IN THE LANGLEY VORTEX RESEARCH FACILITY AND THE LANGLEY FULL-SCALE WIND TUNNEL"

AIAA Paper No. 1978-1481, Los Angeles, CA, August 1978

The Langley Research Center is currently engaged in basic research to improve aerial applications technology. As part of this program, Langley's Vortex Research Facility and Full-Scale Wind Tunnel play lead roles in aircraft systems research to improve aircraft aerodynamics and dispersal systems efficiency, and in studies of aircraft wake-dispersal interactions to improve drift control and dispersal transport. In the Vortex Research Facility, small-scale models of agricultural airplanes are tested and numerical methods are utilized to study interactions between the airplane wake and the dispersed spray and granular materials. Methods are being developed to measure and predict dispersal transport and ground deposition with the objective of modifying wake characteristics and dispersal techniques to obtain interactions more favorable to wide, uniform deposition patterns and reduced drift. In the Full-Scale Wind Tunnel, full-scale agricultural airplanes and dispersal systems for both liquid and solid applications are evaluated to improve aircraft aerodynamics and dispersal systems efficiency. This paper presents the program status in these two facilities with emphasis on wake interactions and dispersal systems research.

Jordan, P. F.

"SPAN LOADING AND FORMATION OF WAKE"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 207-227

Classical analyses of aircraft wake formation assume that the wing span loading is (essentially) elliptic, and that in consequence the wake starts out being (essentially) flat. This assumption is incorrect: actual span loadings contain a logarithmic term, and in consequence there is an infinite upwash directly behind the wing just inside the wing tips. This explains why the aircraft wake rolls up faster than the classical analyses predict.

Jordan, P. F.

"STRUCTURE OF BETZ VORTEX CORES"

Journal of Aircraft, Vol. 10, No. 11, November 1973, pp. 691-693

In 1932 Betz proposed a principle of momentum conservation which leads to an unambiguous description of the structure of the major (the inviscid) part of the trailing vortex. In the present note, the analysis by which one calculates this structure for a wing with an arbitrary (but known) spanwise lift distribution is drastically simplified. Thus, an easier access is provided for discussions of questions like that of single versus multiple vortex pairs, of the effect of the detailed vortex structure on its stability, and such.

"VORTEX AND METEOROLOGICAL MEASUREMENTS AT DALLAS/FT. WORTH AIRPORT"

AIAA Paper No. 1999-0760, Reno, NV, January 1999.

As part of NASA's Aircraft Vortex Spacing System (AVOSS), Lincoln Laboratory conducted meteorological and wake vortex data collection at Dallas/Ft. Worth (DFW) airport in 1997. A mobile continuous-wave coherent CO₂ laser radar was utilized to detect and track vortices generated by landing aircraft. Associated meteorological data were acquired by an extensive array of weather sensors. The DFW deployment is described here along with a preliminary analysis of vortex data. Vortex measurements from a 1995 lidar deployment in Memphis are also included in the analysis.

Josserand, Ch. and Rossi, M.

"THE MERGING OF TWO CO-ROTATING VORTICES: A NUMERICAL STUDY"

European Journal of Mechanics B/Fluids, Vol. 26, 2007, pp. 779-794

The merging of two-dimensional co-rotating vortices is analyzed through direct numerical simulations at large Reynolds numbers. It is shown how the Reynolds number affects each of the three phases that characterize this phenomenon. In the first phase, we examine the merging onset and focus on its definition. During the second rapid phase, the contributions of various flow regions upon the dynamics of a vortex are quantitatively studied. These regions are respectively the companion vortex, the filaments and an intermediate zone between vortices and filaments. The third phase is interpreted in terms of an advection diffusion process. Finally, the final profile and circulation of the merged vortex is determined: the two thirds of the total circulation of the two initial vortices is contained in the newly formed vortex.

"NUMERICAL CAPTURE OF WING TIP VORTEX IMPROVED BY MESH ADAPTATION"

International Journal for Numerical Methods in Fluids, Vol. 67, 2011, pp. 8-12.

This paper presents a mesh adaptation procedure linked to a finite volume solver, the goal of which is to increase the precision of the numerical simulation of a wing tip vortex flow. The adaptation scheme is applied to hexahedron meshes and hybrid meshes made up of tetrahedrons and prisms. To evaluate the ability of each type of element to capture the physics of a tip vortex, a specific test case is studied and results obtained numerically from this test case are compared with experimental results. The error estimator of the adaptation scheme is derived from a solution scalar variable. It is shown that the element anisotropy as well as the adaptation algorithms used have an impact on the precision of the solution. Adaptation of hexahedrons allows a better capture of the tip vortex far from the vortex root, even though the adaptation of those hexahedrons barely changes the number of nodes used to achieve a specified precision contrary to the adaptation of hybrid meshes.

Journade, J.

"NUMERICAL WAKE VORTEX CHARACTERIZATION"

AIAA Paper No. 2003-3815, Orlando, FL, June 2003

This paper deals with the achievements in wake characterization and prediction obtained at Airbus by means of a devoted computational tool based upon vortex particle methods. The code, called WaVES (Wake Vortex Extended Simulation), can be initialized either by an aircraft geometry (lifting surface model), or a load distribution or vorticity plane. It is capable of simulating wakes up to several tens of spans downstream, in 2D or 3D, with unsteady or stationary behaviors. To deal with long time computations, the 3D version has been implemented with several features. First a fast tree code approach has been developed to reach reasonable computational cost, a specific redistribution strategy is used which preserves the vortex sheet geometry, and an advancing frozen domain is used to save CPU time for stationary computations. Validation examples in 2D up to 50 spans and in 3D up to 10 spans illustrate the good behavior of the method.

"THREE-DIMENSIONAL STABILITY OF PERIODIC ARRAYS OF COUNTER-ROTATING VORTICES"

Physics of Fluids, Vol. 14, No. 2, February 2002, pp. 732-743

We study the temporally developing three-dimensional stability of a row of counter-rotating vortices defined by the exact solution of Euler's equations proposed by Mallier and Maslowe [Phys. Fluids 5, 1074 (1993)]. Based on the symmetries of the base state, the instability modes are classified in two types, symmetric and anti-symmetric. We show that the row is unstable to two-dimensional symmetric perturbations leading to the formation of a staggered array of counter-rotating vortices. For long wavelengths, the anti-symmetric mode is shown to exhibit a maximum amplification rate at small wave numbers whose wavelengths scale mainly with the period of the row. This mode could be interpreted as due to the Crow-type of instability extended to the case of a periodic array of vortices. For short wavelengths, symmetric and anti-symmetric instability modes are shown to have comparable growth rates, and the shorter the wavelength, the more complex the structure of the eigenmode. We show

that this short wavelength dynamic is due to the elliptic instability of the base flow vortices, and is well modeled by the asymptotic theory of Tsai and Widnall. The effect of varying the Reynolds number was also found to agree with theoretical predictions based on the elliptic instability.

Jumper, E. J. and Nelson, R. C.

"COMPUTING THE NEAR-FIELD DYNAMICS OF THE WAKE"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 95-104

The presentation will describe a modified discrete-vortex computational method developed at Notre Dame for computing the near-field dynamics of a wake issuing from a lift-producing wing. The method considers both the effect of the wing-bound, lift-producing circulation, and the fact that the wake (streamwise) vortices are not infinite but begin at the wing. The method uses the wing's spanwise load distribution as an input and computes the deformation and trajectory of the wake from its initial span-aligned geometry at the wing to its 'ultimate' wake geometry approximately four spans downstream from the wing. From this point, the dynamics of the full wake may continue to be computed; however, the presentation will describe our method of computing the continued wake dynamics with a simpler description of the wake. The criteria for determining how far downstream is sufficiently far to consider the geometric form of the wake to be its 'ultimate' form will also be discussed. A study using these computational methods of the wake produced by injecting additional discrete vortices into the wake at the wing will be described along with some of the conclusions drawn from the study.

"GLRT DETECTORS FOR AIRCRAFT WAKE VORTICES IN CLEAR AIR"

Chinese Journal of Aeronautics, Vol. 23, 2010, pp. 698-706.

In this article, radar echoes of aircraft wake vortices are modeled as weighted sums of the frequency components of the echoes with a special covariance matrix for the weighted coefficients. With a proposed detection scheme, two generalized likelihood ratio test (GLRT) detectors are derived respectively for aircraft wake vortices with time-varying and time-invariant Doppler spectra. Then the analytical expressions for detection and false alarm probabilities of the detectors are derived and three factors are investigated which mainly influence the detection performance, i.e., the Doppler extension and uncertainty of the aircraft wake vortex, and the number of the detection cells. The results indicate that, the signal-to-noise ratio (SNR) loss induced by Doppler extension is generally several decibels. The SNR loss due to Doppler uncertainty is approximately proportional to the logarithm of the number of spectrum lines in the uncertain Doppler spectrum intervals. For a large number of detection cells, the SNR gain is approximately proportional to the square root of the number of the detection cells.

Jung, J., Choi, W. and Lee, S.

"EFFECT OF THE BLADE INNER-TIP POSITION ON THE GENERATION OF TWIN VORTICES"

J. Aircraft, Vol. 45, No. 2, 2008, pp. 728-732

The effect of the chordwise inner-tip position was examined with conceptually designed blades that generate twin tip vortices. The three-dimensional Navier-Stokes solver HeliNA was used for flow field analysis. The trailing-tip blade showed higher performance and it was due to the lower sectional torque near the inner tip. Both blades generated a separated twin-vortex structure. The inner vortex of the trailing-tip blade was generated in a similar way to the conventional tip vortex, but that of the leading-tip blade was formed with a more distributed vorticity structure. The strength of the inner-tip vortex was weaker than the outer-tip vortex in hover. The difference of circulation between the inner and outer vortices was increased in the trailing-tip blade and was decreased in the leading-tip blade as thrust increased.

Jung, S. N., Sa, J. H., You, Y. H., Park, J. S. and Park, S. H.

"LOOSE FLUID-STRUCTURE COUPLED APPROACH FOR A ROTOR IN DESCENT INCORPORATING FUSELAGE EFFECTS"

Journal of Aircraft, Vol. 50, No. 4, July-August 2013, pp. 1016-1026.

A loose coupling approach is used to combine a comprehensive structural-dynamics code CAMRAD II and a computational fluid dynamics solver KFLOW to validate the data and to identify the effect of fuselage on the aeroelastic behavior of the second higher harmonic rotor acoustic test rotor. The computations are made using isolated rotor and rotor-fuselage models. To demonstrate the effect of a fuselage, the shaft tilt angles remain identical for both configurations. A good correlation has been obtained with the present computational fluid dynamics/comprehensive structural dynamics method. It is observed that a rotor-fuselage model improves the correlation significantly in terms of magnitudes and phases of the air loads solution. All the blade-vortex interaction peaks are captured accurately, and the phase shift in the section normal forces improves significantly, with the inclusion of a fuselage. The sources of improvements are investigated, considering the vorticity distributions and induced velocity fields of a rotor. It is revealed that the upwash pattern due to a fuselage is not restricted locally but propagates to considerable portion of the disk. Numerical results indicate that the upwash is responsible to lift up vortices at the zone of interest for a reduced miss distance, which results in a stronger blade-vortex interaction for improved correlations.

Jung, U. and Breitsamter, C.

"AERODYNAMIC WAKE INVESTIGATIONS OF HIGH-LIFT TRANSPORT AIRCRAFT WITH DEPLOYED SPOILERS"

ICAS Poster 2010-P2.25, September 2010, Nice, France.

Commercial Transport Aircraft (CTA) make use of spoilers in the approach phase. In doing so, the aerodynamic wake of the CTA's wing is highly influenced by the deployed spoilers, potentially leading to

horizontal tail plane (HTP) buffet. Mean and turbulent flow field quantities downstream of a CTA model's wing are investigated experimentally to evaluate the near field wake. The detailed half model features slats, aileron and flaps in high-lift approach configuration. Spoiler configurations comprise a baseline configuration with no spoilers deployed, a configuration with outboard conventional spoilers deployed 30 degrees, and two configurations, with two types of unconventional outboard spoilers. The experiments are performed in Wind Tunnel A at the Technical University of Munchen. Angles of attack are chosen for each configuration corresponding to a lift coefficient of 1.5. The freestream velocity is set to 50 m/s corresponding to a Reynolds number of 1,000,000. Two stream wise positions are chosen to evaluate the evolution of the wake from near the trailing edge of the wing to the tail of the model. Stereo Particle Image Velocimetry is used to measure the velocity distribution in the wake planes. At selected positions of the planes additional velocity measurements are taken by means of Constant Temperature Hot-Wire Anemometry. These time-resolved measurements serve to conduct a spectral analysis. It is shown that the wake of none of the three investigated spoiler configurations does impose a significant increase of vertical turbulence intensity on the HTP; neither broadband nor narrowband.

Jung, Y. and Seath, D. D.

"SPANWISE DISPLACEMENT OF A LINE VORTEX ABOVE A WING - A SIMPLE CALCULATION SCHEME"

Journal of Aircraft, Vol. 25, No. 5, May 1988, pp. 476-478

When a wing encounters a concentrated tip vortex, its aerodynamic characteristics are substantially altered due to nonlinear interaction. While the vortex affects the wing loads, the wing in turn affects the vortex path through its vorticity field. It is generally believed that some kind of iteration scheme is necessary to account for the mutual influence between the vortex and the wing trailing vorticity and, thus, to obtain an acceptable vortex path and its effect on induced air loads. The present method is based on the lifting line solution of the spanwise load distribution.

Jung, Y. W. and Park, S. O.

"VORTEX-SHEDDING CHARACTERISTICS IN THE WAKE OF AN OSCILLATING AIRFOIL AT LOW REYNOLDS NUMBER"

Journal of Fluids and Structures, Vol. 20, Issue 3, April 2005, pp. 451-464

An experimental investigation was carried out to study the unsteady characteristics of vortex shedding in the near wake of an oscillating airfoil. The airfoil was given a harmonic pitching motion about the quarter-chord axis at four reduced frequencies: 0.1, 0.2, 0.3, and 0.4. The mean incidence and the oscillating amplitude were 0 degrees and 3 degrees, respectively. The velocity in the wake was measured by hot-wire anemometry. Smoke-wire visualization was also carried out to investigate the link between the boundary layer flow and the shedding frequency variation. To analyze the frequency characteristics of the vortex shedding, we composed a short-time spectrum by the autoregressive (AR) method and a moving window. It was found that the shedding frequency in the wake of oscillating airfoil was much different from that for the case of steady airfoil at a given angle of attack, implying

that the state of the boundary layer dictated the vortex-shedding characteristics. The vortex-shedding frequency was found to vary with the phase angle of oscillation, not with the angle of attack, for a given reduced frequency. The range of variation of the shedding frequency was diminished as the reduced frequency of oscillation increased.

Jurdic, V., Joseph, P. and Antoni, J.

"INVESTIGATION OF ROTOR WAKE TURBULENCE THROUGH CYCLOSTATIONARY SPECTRAL ANALYSIS"

AIAA Journal, Vol. 47, No. 9, September 2009, pp. 2022-2030.

The present paper introduces cyclo-stationary spectral analysis as a new approach to analyze the turbulence velocity measurements generated by a rotor. To apply this technique, a random signal should have periodic statistical characteristics and should be suitable for many rotating mechanical systems as shown in recent studies. However, this method has never been applied on rotor velocity measurements. Via a Wigner-Ville representation, the instantaneous power spectra of the turbulence in the wakes and in between the wakes will be depicted and analyzed. The usefulness of the technique applied to rotor-generated turbulence is that it can separate the spectrum of the turbulence in between the wakes from that in the wake with a much greater frequency resolution than conventional spectral analysis.

Jurkovich, M. S. and Hummer, C. J.

"UNDERSTANDING THE FLOWFIELD BEHIND A TANKER AIRCRAFT"

AIAA Paper 2018-0536, January 2018, Kissimmee, FL.

The capabilities of the Kestrel flow solver with Cartesian off-body Adaptive Mesh Refinement are utilized in support of aerial refueling simulation with one aircraft in proximity behind another. Comparison to flight test data is used to demonstrate the achievable accuracy of Computational Fluid Dynamics (CFD) analysis for capturing the delta forces and moments on a tanker aircraft due to the proximity of a large receiver aircraft. The study also determined the set of options which minimize numeric dissipation in the vortex core, and tested resolving the wake vortex to the aft boundary of the computational domain. Best practices are proposed for utilizing CFD in tanker/receiver modeling while minimizing demand for computational resources.

Justus, C. G. and Johnson, D. L.

"THE NASA/MSFC GLOBAL REFERENCE ATMOSPHERIC MODEL: 1999 VERSION (GRAM-99)"

NASA TM-209630, May 1999, Marshall Space Flight Center; Huntsville, AL.

The latest version of Global Reference Atmospheric Model (GRAM-99) is presented and discussed. GRAM-99 uses either (binary) Global Upper Air Climatic Atlas (GUACA) or (ASCII) Global Gridded Upper Air Statistics (GGUAS) CD-ROM data sets, for 0-27 km altitudes. As with earlier versions, GRAM-99

provides complete geographical and altitude coverage for each month of the year. GRAM-99 uses a specially-developed data set, based on Middle Atmosphere Program (MAP) data, for 20-120 km altitudes, and NASA's 1999 version Marshall Engineering Thermosphere (MET-99) model for heights above 90 km. Fairing techniques assure smooth transition in overlap height ranges (20-27 km and 90-120 km). GRAM-99 includes water vapor and 11 other atmospheric constituents (O₃, N₂O, CO, CH₄, CO₂, N₂, O₂, O, A, He and H). A variable-scale perturbation model provides both large-scale (wave) and small-scale (stochastic) deviations from mean values for thermodynamic variables and horizontal and vertical wind components. The small-scale perturbation model includes improvements in representing intermittency ('patchiness'). A major new feature is an option to substitute Range Reference Atmosphere (RRA) data for conventional GRAM climatology when a trajectory passes sufficiently near any RRA site. A complete user's guide for running the program, plus sample input and output, is provided. An example is provided for how to incorporate GRAM-99 as subroutines in other programs (e.g., trajectory codes).

Justus, C. G., Jeffries III, W. R., Yung, S. P. and Johnson, D. L.

"THE NASA/MSFC GLOBAL REFERENCE ATMOSPHERIC MODEL-1995 VERSION (GRAM-95)"

NASA TM-4715, August 1995, Marshall Space Flight Center; Huntsville, AL.

The latest version of the Global Reference Atmospheric Model (GRAM-95) is presented and discussed. GRAM-95 uses the new Global Upper Air Climatic Atlas (GUACA) CD-ROM data set, for 0- to 27-km altitudes. As with earlier versions, GRAM-95 provides complete geographical and altitude coverage for each month of the year. Individual years 1985 to 1991 and a period-of-record (1980 to 1991) can be simulated for the GUACA height range. GRAM-95 uses a specially developed data set, based on Middle Atmosphere Program (MAP) data, for the 20- to 120-km height range, and the NASA Marshall Engineering Thermosphere (MET) model for heights above 90 km. Fairing techniques assure a smooth transition in the overlap height ranges (20 to 27 km and 90 to 120 km). In addition to the traditional GRAM variables of pressure, density, temperature and wind components, GRAM-95 now includes water vapor and 11 other atmospheric constituents (O₃, N₂O, CO, CH₄, CO₂, N₂, O₂, O, A, He, and H). A new, variable-scale perturbation model provides both large-scale and small-scale deviations from mean values for the thermodynamic variables and horizontal and vertical wind components. The perturbation model includes new features that simulate intermittency (patchiness) in turbulence and small-scale perturbation fields. The density perturbations and density gradients (density shears) computed by the new model compare favorably in their statistical characteristics with observed density perturbations and density shears from 32 space shuttle reentry profiles. GRAM-95 provides considerable improvement in wind estimates from the new GUACA data set, compared to winds calculated from the geostrophic wind relations previously used in the 0- to 25-km height range. The GRAM-95 code has been put into a more modular form, easier to incorporate as subroutines in other programs (e.g., trajectory codes). A complete user's guide for running the program, plus sample input and output, is provided.

Kaarlonen, K. and Laine, S.

"THE EFFECT OF THE REYNOLDS NUMBER ON THE WING VORTICES"

ICAS-2002-2.2.2, Toronto, Canada, September 2002

Wind tunnel experiments have shown that the vortex system of a delta-wing configuration with rounded leading edges, ELAC-1, depends on the Reynolds number. The purpose of this study was to examine the Reynolds number effect by using a Navier-Stokes flow solver with two advanced turbulence models, an explicit algebraic Reynolds stress model and a kappa-omega SST model.

Kaden, A. and Luckner, R.

"MODELING WAKE VORTEX ROLL-UP AND VORTEX-INDUCED FORCES AND MOMENTS FOR TIGHT FORMATION FLIGHT"

AIAA Paper 2013-5076, August 2013, Boston, MA.

Migratory birds that fly in tight formation use the upwash of the leading birds to save energy. Aircraft can use the same principle to save fuel. To date, commercial aircraft do not fly in tight formation because of unresolved technical and operational issues. However, increasing fuel cost and environmental constraints are drivers to investigate tight formation flight and the potential fuel savings. For such investigations a good knowledge of the vortex-induced velocities and the effect on the encountering aircraft is fundamental. In research on safe separation distances the vortex far field (more than 40 wingspans behind the generating aircraft) is modeled with a pair of straight vortices. This paper addresses a method to model the wake vortex roll-up that occurs in the near field (up to 15 wingspans behind the generating aircraft) using discrete vortex filaments. The motion of these filaments due to the mutual velocity induction is simulated numerically, followed by the calculation of the resulting induced velocities in a second step. To find an appropriate set of simulation parameters, the computed velocities are compared with those induced by a validated wake vortex velocity model. An already existing wake vortex encounter simulation software is improved to model the wake vortex roll-up. First simulation results are presented.

Kadlec, P. W.

"FLIGHT DATA ANALYSIS OF THE RELATIONSHIP BETWEEN ATMOSPHERIC TEMPERATURE CHANGE AND CLEAR AIR TURBULENCE"

AMS/AIAA Paper No. 66-365, March 1966, Los Angeles, CA.

To determine what atmospheric temperature changes can be used to detect clear air turbulence at jet altitudes, data were collected during one year on 146 flights by riding as an extra crew member in the cockpit of airline and military jet aircraft. In addition, an aircraft flight data recorder and air data system on one DC-8 were modified to collect static air temperature information using an improved temperature sensor. From flight observations using a portable temperature change instrument and the flight recorder data, a rate of temperature change of 1.0 deg C per minute was found to be the most useful criterion for correctly indicating clear air turbulence. Since the inception of manned flight in

powered aircraft, the rapid and constant advance in the performance capabilities of airplanes has forced the aeronautical meteorologist to develop new concepts of atmospheric behavior. The current stage in the evolution of flight is dominated by jet aircraft, traveling near the speed of sound at altitudes above 25,000 feet. With the rapidly expanding numbers of operational jet aircraft and the associated increased frequency of pilot reports of CAT encounters, research meteorologists have become concerned with the relationship of clear air turbulence to specific synoptic features in the atmosphere. Although forecasting techniques have greatly improved, the predicted geographical areas and vertical depths of CAT remain too extensive. Atmospheric soundings normally taken only once every 12 hours by the rather widely separated stations of the radiosonde network, impose basic limitations on the degree of forecasting skill that may be developed. Therefore, in order to pinpoint an area of turbulence with greater accuracy, an airborne instrument is needed to warn of the proximity of Cat in much the same manner that radar warns the pilot of thunderstorms. Ideally, the prospect of an airborne device which could probe ahead of a moving aircraft and detect areas of clear air turbulence would be the most practical method of avoiding it. Such a device, used in conjunction with the turbulence forecast, would enable jet flight crews to avoid or minimize the discomfort and possible hazard which Cat now imposes.

"A NEW MICROWAVE TEMPERATURE PROFILER -- FIRST MEASUREMENTS IN POLAR REGIONS"

Thirteenth ARM Science Team Meeting Proceedings, April 2003, Broomfield, CO.

Temperature inversions are a ubiquitous feature of the high latitude atmospheric boundary layer (ABL). In Polar Regions, the temperature inversion is a complicated phenomenon involving interactions between surface radiative cooling, subsidence, and warm air advection. In the period 1997-2002, several microwave temperature profilers were used to measure temperature inversion parameters at one of the three sites of the U.S. Department of Energy (DOE) Atmospheric Radiation Measurement (ARM) Program, located at the North Slope of Alaska (NSA). These instruments provided continuous, unattended observation of the ABL thermal structure. However, the vertical resolution was not large enough to measure the low-level lifted inversions, which were observed in the spring period by radiosondes. In 2001, the Russian scientific production company ATTEX, in cooperation with the Dutch Company Kipp and Zonen, produced a new microwave temperature profiler for Polar regions, MTP-5P (P stands for Polar), with improved vertical resolution.

"AIRCRAFT WAKE VORTEX OBSERVATIONS IN HONG KONG"

Journal of Radars, Vol. 6, 2017, pp. 1-10.

The Hong Kong International Airport (HKIA) is among the busiest airports in the world, with total aircraft movements exceeding 400,000 in 2016. The Hong Kong Observatory (HKO), provider of aviation meteorological services to HKIA, has recently begun making the first sets of aircraft wake

vortex observations at HKIA using short-range LIDARs. This paper briefly describes the preliminary observation results obtained from field measurements between 2014 and 2016, and discusses the way forward on the monitoring and prediction of wake vortex behavior in Hong Kong.

"UP TO 12 KM VERTICAL WIND PROFILING USING MITSUBISHI ELECTRIC'S LONG RANGE LIDAR"

19th Coherent Laser Radar Conference (CLRC), Paper P31, June 2018, Okinawa, Japan.

A new function of Mitsubishi Electric's long range lidar for vertical wind profiling has been developed. The observation performance evaluation was carried out by KARI, and the result shows that the measurable height of up to 12 km in no precipitation condition was demonstrated. The correlation coefficient of wind speed and direction between the lidar and radio sonde are also shown. The result implies the expanding use of wind lidars for high altitude wind sensing.

"VORTEX DISTORTION DURING VORTEX-SURFACE INTERACTION IN A MACH 3 STREAM"

AIAA Paper No. 93-0761, January 1993, Reno, NV.

An experimental study has been conducted in a Mach 3 stream to investigate supersonic vortex behavior upon interacting with a solid lifting surface placed in its passage. The experimental scheme involved positioning a two-dimensional wedge surface downstream of a slender semi-span vortex-generator wing section such that the generated trailing tip vortices interacted with the downstream wedge surface. The experimental setup was arranged so that interactions resulted in a close encounter of the vortex core and the wedge leading edge. Spark shadow photographs of the flow field along with chord-wise pressure measurements on the wedge surface were used to study the interaction problem. In their most organized form, distortion of stream-wise vortices upon interacting with the surface was found to result in formation of unsteady detached shock fronts followed by an apparent slip surface separating a subsonic region from a supersonic zone. The interaction was found to depend strongly on vortex strength and vortex proximity to the wedge leading edge and the generated flow field was found to be highly unsteady.

Kalkhoran, I. M.

"EXPERIMENTAL INVESTIGATION OF THREE-DIMENSIONAL VORTEX-AIRFOIL INTERACTION IN A SUPERSONIC STREAM"

Poly-AE 95-3, July 1995, Polytechnic University, Brooklyn, NY.

An experimental study of the interaction between stream-wise vortices and a two-dimensional surface was conducted in a Mach 2.5 flow. The influence of oblique shock wave intensity on the inherently three-dimensional interaction was examined for vortices of variable strength. Planar laser

sheet visualizations of the flow field generated by the interaction at several distances downstream of the wedge leading edge were performed to gain an understanding of vortex behavior at distances further downstream. Results indicated that the interaction of a moderate strength vortex with an oblique shock wave leads to the formation of a steady separated shock structure upstream of the oblique shock front. Planar laser sheet visualization of the flow field revealed an expansion of the vortex core in crossing a strong oblique shock front. The vortical structure was observed to persist along the entire chord of the shock generating wedge but was seen to diffuse with distances downstream of the wedge leading edge. Measurements of the vortex center above the wedge surface indicated that immediately downstream of the normal portion of the bulged-forward shock wave the vortex center was parallel to the direction of the free stream flow.

"VORTEX DISTORTION DURING VORTEX-SURFACE INTERACTION IN A MACH 3 STREAM"

AIAA Journal, Vol. 32, No. 1, January 1994, pp. 121-129.

An experimental study has been conducted in a Mach 3 wind tunnel to investigate the behavior of supersonic vortices as they interact with a wedge surface placed in their passage. The experimental setup was arranged so that interactions resulted in a close encounter of the vortex core and the wedge leading edge. Spark shadow photographs of the flow field along with pressure measurements on the wedge surface were used to study the interaction problem. In their most organized form, distortion of streamwise vortices upon interacting with the wedge was found to result in formation of symmetric detached shock fronts far upstream of the wedge leading edge followed by an apparent slip surface separating a subsonic region from a supersonic zone. Interaction experiments leading to substantial changes in the structure of vortices revealed that the supersonic vortex distortion has strong resemblances to the incompressible 'B-breakdown' reported in the literature. Experimental results also indicate that the interaction strongly depends on the vortex strength and vortex proximity to the wedge leading edge, and the generated flow field was found to be highly unsteady. Interaction of concentrated streamwise vortices with the oblique shock formed over the wedge surface resulted in formation of a locally three-dimensional shock wave with a limited subsonic region downstream of the shock.

"AN EXPERIMENTAL INVESTIGATION OF THE PERPENDICULAR VORTEX-AIRFOIL INTERACTION AT TRANSONIC SPEEDS"

PhD Thesis, Univ. of Texas, Arlington, TX, 1987

Extensive experimental studies were conducted in the UTA High Reynolds Number Transonic Wind Tunnel facility. Experimental investigations of the compressible trailing vortex system were performed by means of a thorough probing of the viscous core of the vortex system. Detailed flow field measurements and contour plots of the total pressure field in the neighborhood of the vortex core are presented. Comprehensive experimental studies were conducted to investigate the pressure

distribution on a C141 and a NACA 0012 airfoil sections for a range of transonic flow conditions. Transonic vortex airfoil interaction tests at Mach numbers ranging from 0.68-0.90 and airfoil chord Reynolds numbers of 3.5-6 million were conducted to simulate the helicopter rotor blade vortex interaction problem. The interaction scheme involves positioning a lifting wing (vortex generator) upstream of an airfoil so that the trailing vortex interacts with the downstream airfoil. The interacting airfoils included a symmetric NACA 0012 and a two-dimensional C-141 (NACA 65 series) airfoil section. The effects of vortex strength, vortex height above the downstream airfoil, Mach number and Reynolds number on the pressure distribution of the downstream airfoil, and the normal force coefficients were studied and the quantitative results are presented. The results obtained from these experiments indicate a substantial change in the pressure distribution of the downstream airfoil, a spanwise drift of the vortex core after interacting with the airfoil, and a high degree of unsteadiness in the vicinity of the vortex viscous core.

Kalkhoran, I. M. and Paek, C.

"EXPERIMENTAL STUDY OF A WEAK VORTEX-NORMAL SHOCK INTERACTION"

AIAA Journal, Vol. 42, No. 6, 2004, pp. 1264-1267

To expand upon the results of previous normal shock wave-vortex interaction studies, an experimental investigation of the interaction between a weak vortex and an otherwise normal shock wave was carried out in a Mach 2.49 flow. Measurements of the flow properties in the core region of the weak vortex indicated reduced total pressures, a wakelike axial Mach-number distribution, and a Burgers-like swirl profile. These parameters contained identical trends to those measured for moderate and strong vortices but with much lower intensities. These measurements further revealed a significant reduction of the axial Mach number in the vortex generator wake where the measured axial Mach number was seen to be lower than that at the vortex axis. Interaction of the weak vortex with a normal shock front revealed a local bulging of the shock wave in the upstream direction. The upstream bulging of the shock wave was seen to be more pronounced in the wake region where the Mach number was a minimum. Examination of the generated flow field did not reveal a vortex distortion pattern comparable to the supersonic vortex breakdown observed during previous shock wave-vortex interaction studies.

"AIRFOIL PRESSURE MEASUREMENTS DURING OBLIQUE SHOCK WAVE-VORTEX INTERACTION IN A MACH 3 STREAM"

AIAA Paper No. 1992-2631, June 1992, Palo Alto, CA.

An experimental investigation of the interaction of discrete vortices and oblique shock waves was conducted in a Mach 3 blowdown wind tunnel. An instrumented two-dimensional wedge airfoil section was placed downstream of a semi-span wing section so that the trailing tip vortex would interact with the shock wave formed over the downstream test airfoil. The experiments were designed to simulate

interaction of streamwise vortices from upstream sections with shock waves formed over aft surfaces as might be encountered in supersonic flight of aircraft and missiles. The influence of vortex strength and vortex-airfoil vertical separation distance on the interaction was examined. The flow field generated was found to be highly unsteady and a substantial change in the pressure distribution of the downstream airfoil was observed. Furthermore, the interaction of strong vortices with the oblique shock waves over the test airfoil resulted in formation of unsteady shock waves far upstream of the airfoil leading edge.

Kalkhoran, I. M. and Sforza, P. M.

"AIRFOIL PRESSURE MEASUREMENTS DURING OBLIQUE SHOCK-WAVE/VORTEX INTERACTION IN A MACH 3 STREAM"

AIAA Journal, Vol. 32, No. 4, April 1994, pp. 783-788

An experimental investigation of the interaction between stream-wise discrete vortices and oblique shocks formed over a two-dimensional wedge surface was conducted in a Mach 3 blowdown wind tunnel. An instrumented two-dimensional wedge section was placed downstream of a semispan wing so that the trailing tip vortex would arbitrarily interact with the shock wave formed over the wedge surface. The experiments were designed to simulate interaction of streamwise vortices from upstream bodies with shock waves formed over aft surfaces as might be encountered in supersonic flight of aircraft and missiles. The influence of vortex strength and vortex-airfoil vertical separation distance on the interaction was examined. The flow field generated was found to be highly unsteady, and a substantial change in the pressure distribution on the downstream airfoil was observed. The interaction of a strong vortex with the oblique shock wave over the downstream wedge section resulted in formation of an unsteady detached shock wave upstream of the wedge leading edge. Furthermore, when the vortex approached the wedge leading edge, formation of a detached shock wave occurred further upstream of the section leading edge.

"ASPECTS OF SHOCK WAVE-INDUCED VORTEX BREAKDOWN"

Progress in Aerospace Sciences, Vol. 36, 2000, pp. 63-95

In this article, we discuss supersonic vortex breakdown when sufficiently strong streamwise vortices encounter otherwise planar, normal and oblique shock fronts as well as solid surfaces placed in their passages. The dramatic destruction of a streamwise vortex during supersonic vortex interactions reveals a vortex breakdown similar in many ways to the well-documented incompressible vortex bursting. The main features of supersonic vortex breakdown include formation of a spherically blunt-nosed conical shock, and a vortex core, which upon crossing the apex of the conical shock expands into a subsonic turbulent conical region. A notable characteristic of the supersonic vortex breakdown is the formation of an entropy-shear layer separating an inner subsonic zone containing the burst structure from the surrounding supersonic flow. Numerical, experimental, and analytical studies of shock

wave/vortex interactions are discussed and results from wind tunnel studies involving head-on collision of supersonic vortices with solid surfaces are presented.

"EXPERIMENTAL STUDY OF SHOCK-VORTEX INTERACTION IN A MACH 3 STREAM"

AIAA Paper No. 1991-3270, September 1991, Baltimore, MD.

An experimental investigation of interactions between tip vortices and shock waves of various strength was conducted in the Mach 3 blowdown supersonic wind tunnel at Polytechnic University. The interaction scheme involved positioning a shock wave generator upstream of a semispan wing vortex generator such that tip vortices generated from the lifting surface arbitrarily interacted with shock waves. The resulting interaction was found to be highly unsteady and the observed structure of the flow varied appreciably with shock wave strength. For the case of tip vortices intersecting bow shock waves in front of blunt bodies, formation of conical shock waves were observed.

"INTERACTION OF SUPERSONIC WING TIP VORTICES WITH A NORMAL SHOCK"

AIAA Paper No. 1995-2283, San Diego, CA, June 1995

An experimental study involving interaction of concentrated streamwise wing tip vortices and normal shock fronts was carried out in a Mach 2.49 flow. The interaction scheme involved positioning a vortex-generator wing section upstream of a pilot-type normal shock inlet such that the wing tip vortices interacted with the normal shock formed in front of the inlet. The vortex strength was varied by

placing the vortex generator wing at different angles of attack while a normal shock was created by adjusting the mass flow rate passing through the inlet. Spark shadowgraphs, laser sheet planar visualizations, and pitot pressure measurements of the flow field indicated a significant change in the structure of streamwise vortices generated by the vortex generator wing at 5 and 10 deg angle of attack upon encountering a normal shock discontinuity. Results of the investigation showed that the interactions lead to the formation of an unsteady conical shock wave far upstream of the inlet as well as a highly turbulent flow downstream for both vortices. Pitot pressure measurements using a fast response pressure transducer in conjunction with the spark shadowgraphs revealed a bimodal feature of the flow field. The frequency of oscillation of the generated structure was found to be higher for increased vortex strength.

Kalkhoran, I. M., Smart, M. K. and Betti, A.

"INTERACTION OF SUPERSONIC WING-TIP VORTICES WITH A NORMAL SHOCK"

AIAA Journal, Vol. 34, No. 9, Sept. 1996, pp. 1855-1861.

An experimental study involving interaction of concentrated streamwise wing-tip vortices and normal shock fronts was carried out in a Mach 2.49 flow. The interaction scheme involved positioning a vortex-generator wing section upstream of a pitot-type normal shock inlet such that the wing-tip vortices interacted with the normal shock formed in front of the inlet. The vortex strength was varied by placing the vortex generator wing at different angles of attack while a normal shock was created by adjusting the mass flow rate passing through the inlet. Spark shadowgraphs, laser sheet planar visualizations, and pitot pressure measurements of the flow field indicated a significant change in the structure of streamwise vortices generated by the vortex generator wing at 5.7- and 10.4-deg angle of attack upon encountering a normal shock discontinuity. Results of the investigation showed that the interactions lead to the formation of an unsteady conical shock wave far upstream of the inlet as well as a highly turbulent flow downstream for both vortices. Pitot pressure measurements using a fast response pressure transducer in conjunction with the spark shadowgraphs revealed a bimodal feature of the flow field. The frequency of oscillation of the generated structure was found to be higher for increased vortex strength. Measurements of pitot pressure in the vortex core in the absence of a shock wave revealed high-frequency oscillations that were attributed to the vortex meandering phenomenon.

"PLANAR LASER SHEET VISUALIZATION OF OBLIQUE SHOCK WAVE/VORTEX INTERACTION"

AIAA Paper No. 96-0046, Jan. 1996, Reno, NV.

Planar laser sheet visualizations of the flow field generated by the interaction of a streamwise wing tip vortex and a strong oblique shock front at several distances downstream of a shock generating wedge were performed in a Mach 2.49 flow. The experimental scheme involved positioning a two-dimensional wedge surface downstream of a vortex generator wing section so that the wing-tip vortex interacts with the planar oblique shock front. The results of the investigation revealed an expansion of

the vortex core in crossing a strong oblique shock front. The maximum vortex core diameter was seen to occur at a distance of 12.7 mm downstream of the wedge leading edge while at distances further downstream, the vortex core diameter remained approximately constant. The vortical structure was observed to persist along the entire chord of the shock generating wedge but was seen to diffuse with distances downstream of the wedge leading edge. Measurements of the vortex position relative to the wedge surface indicated that immediately downstream of the normal portion of a bulged-forward shock wave, the vortex axis was parallel to the direction of the freestream flow. On the other hand, the vortex was observed to travel parallel to the wedge surface at distances downstream of the wedge mid-chord position. The conical structure which forms as a result of vortex distortion was found to be sensitive to downstream disturbances in a manner similar to the incompressible vortex breakdown.

Kalkhoran, I. M., Smart, M. K. and Wang, F. Y.

"SUPERSONIC VORTEX BREAKDOWN DURING VORTEX/CYLINDER INTERACTION"

J. Fluid Mech., Vol. 369, March 1998, pp. 351-380

The head-on interaction of a supersonic streamwise vortex with a circular cylinder reveals a vortex breakdown similar in many ways to that of incompressible vortex breakdown. In particular, the dramatic flow reorganization observed during the interaction resembles the conical vortex breakdown reported by Sarpkaya (1995) at high Reynolds number. In the present study, vortex breakdown is brought about when moderate and strong streamwise vortices encounter the bow shock in front of a circular cylinder at Mach 2.49. The main features of the vortex/cylinder interaction are the formation of a blunt-nosed conical shock with apex far upstream of the undisturbed shock stand-off distance, and a vortex core which responds to passage through the apex of the conical shock by expanding into a turbulent conical flow structure. The geometry of the expanding vortex core as well as the location of the conical shock apex are seen to be strong functions of the incoming vortex strength and the cylinder diameter. A salient feature of the supersonic vortex breakdown is the formation of an entropy-shear layer, which separates an interior subsonic zone containing the burst vortex from the surrounding supersonic flow. In keeping with the well-established characteristics of the low-speed vortex breakdown, a region of reversed flow is observed inside the turbulent subsonic zone.

Kalkhoran, I. M., Wang, F. Y., Milanovic, I. and Smart, M. K.

"SUPERSONIC VORTEX BREAKDOWN DURING VORTEX/CYLINDER INTERACTION"

1997 ASME Fluids Engineering Division Summer Meeting, June 1997

An experimental study involving the interaction between streamwise vortices of various strength with circular cylinders in a supersonic stream has been carried out. The interaction scheme involved positioning a vortex-generator wing section upstream of a circular cylinder such that the wing-tip vortices interacted with the cylinder. Spark shadowgraphs, surface oil visualization, pitot and static pressure measurements of the flow field indicated a significant change in the structure of streamwise vortices because of the encounter. The vortex/cylinder interaction experiments lead to formation of a

highly turbulent conical structure surrounded by a conical shock wave far upstream of the interacting cylinder. The scale of the conical structure containing the burst vortex as well as the intensity of interaction leading to vortex breakdown are seen to be strong functions of the vortex strength. Like the well-established characteristics of incompressible vortex breakdown, a region of reversed flow and formation of stagnation points are observed inside of the highly turbulent conical region. Interaction experiments leading to vortex breakdown are seen to have many characteristics of supersonic vortex distortion observed during normal shock wave/vortex interaction with one notable exception i.e., the generated flow field is seen to be globally steady during the present study. The significant upstream influence observed during the interaction is a unique feature of supersonic vortex breakdown partly due to wake-like axial Mach number distribution in the vortex core and its streamwise evolution. The extent of the burst structure and the scale of the conical shock were found to depend on the cylinder size indicating a strong influence of the downstream boundary on supersonic vortex breakdown.

"EXPERIMENTAL INVESTIGATION OF THE PERPENDICULAR ROTOR BLADE-VORTEX INTERACTION AT TRANSONIC SPEEDS"

AIAA Journal, Vol. 30, No. 3, March 1992, pp. 747-755.

Transonic perpendicular rotor blade-vortex interaction tests at Mach numbers ranging from 0.68 to 0.9 and Reynolds numbers (based on airfoil chord) of 3.8-5.5 million were conducted in the UTA high-Reynolds number, transonic Ludwig-tube wind tunnel. The scheme involved positioning a lifting wing (vortex generator) upstream of an instrumented NACA 0012 airfoil so that the trailing vortex interacted with the downstream airfoil. Tests were performed at several vortex strengths as well as several vortex core heights above the downstream airfoil. The results obtained from these experiments indicate that a substantial change in the pressure distribution of the downstream airfoil occurs, but most of the effects were confined to the leading 30 percent of the airfoil chord. A spanwise drift of the vortex core as it passes over the trailing airfoil, similar to results obtained previously in low-speed wind tunnel tests, as well as a high degree of unsteadiness in the vicinity of the vortex center were observed.

Kalogiros, J. A. and Wang, Q.

"AERODYNAMIC EFFECTS ON WIND TURBULENCE MEASUREMENTS WITH RESEARCH AIRCRAFT"

Journal of Atmospheric and Oceanic Technology, Vol. 19, October 2002, pp. 1567-1576.

Flow distortion is a major issue in the measurement of wind turbulence with gust probes mounted on a nose boom, at the radome, or under the wing of research aircraft. In this paper, the effects of both propellers of a turboprop aircraft and of the aircraft vortex system on the pressure and wind velocity measurements near the nose of the aircraft are examined. It is shown that, for a turboprop aircraft, the sensors mounted near the nose are affected directly (slipstream) or indirectly (lift increase) by the propellers. The propeller effects are more significant for pressure sensors located ahead of the propellers on the fuselage and are less significant for the small local flow angles measured at the nose

of the aircraft. The first case is clearly realized during in-flight calibration maneuvers performed by a turboprop aircraft. A major flow distortion, which seriously affects the vertical wind velocity measurements near the nose of an aircraft, is the upwash induced mainly by the wing-bound vortex. Also, low energy of the vertical wind component in the inertial subrange for scales larger than the fuselage diameter is usually observed in aircraft measurements. This is shown to be the result of not considering the decrease of the upwash correction with eddy frequency (or no need for such a correction in the inertial subrange) caused by the aerodynamic delay and the response of the wing vortex to turbulence. The level of energy in the inertial subrange of the vertical wind component is significant because it is commonly used for the estimation of the dissipation rate of turbulence kinetic energy. A method to estimate this frequency variable correction and correct the spectra or the time series of the estimated vertical wind component is described. Data from low-level flight legs with a Twin Otter aircraft show that this correction may result in about a 20 percent correction of the variance of the vertical wind component and a 5 percent correction of the vertical turbulent fluxes.

"MODELING SUBSCALE ROTOR WAKE IN GROUND EFFECT WITH ACCURATE TURBULENT LENGTH SCALES"

AIAA Journal, Vol. 55, No. 9, September 2017, pp. 3085-3094.

An accurate prediction of the tip vortex flow field is required to understand the viscous interaction of the rotor wake and ground prevalent during helicopter brownout. To achieve this goal, a compressible, structured, overset Reynolds-averaged Navier-Stokes-based solver is used to simulate a subscale rotor in ground effect. Novel mesh-gridding techniques are used to avoid prohibitive computational costs. The Reynolds-averaged Navier-Stokes equations solved with the Spalart-Allmaras turbulence model show that a smeared-out flow field at an early wake, ages due to excessive turbulence levels. To further investigate that the source of a smeared rotor wake is the use of turbulence modeling, the computations are performed with laminar flow assumption that show a preserved rotor wake field for longer wake ages. However, an accurate understanding of the cause of brownout requires an accurate prediction of turbulence levels. Therefore, a hybrid Reynolds-averaged Navier-Stokes/large-eddy simulation methodology such as delayed detached-eddy simulation is explored. The flow field obtained from the delayed detached-eddy simulation methodology still does preserve the rotor wake. Because the wake capturing grids are highly anisotropic, a modified length scaling is used. The delayed detached-eddy simulation-based length scale with correction for anisotropic grids helps in preserving the rotor wake and shows a close agreement with experimental results.

"COMPARING DIFFERENT CFD WIND TURBINE MODELLING APPROACHES WITH WIND TUNNEL MEASUREMENTS"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012056-1 - 012056-13.

The performance of a model wind turbine is simulated with three different CFD methods: actuator disk, actuator line and a fully resolved rotor. The simulations are compared with each other and with measurements from a wind tunnel experiment. The actuator disk is the least accurate and most cost-efficient, and the fully resolved rotor is the most accurate and least cost-efficient. The actuator line method is believed to lie in between the two ends of the scale. The fully resolved rotor produces superior wake velocity results compared to the actuator models. On average it also produces better results for the force predictions, although the actuator line method had a slightly better match for the design tip speed. The open source CFD tool box, OpenFOAM, was used for the actuator disk and actuator line calculations, whereas the market leading commercial CFD code, ANSYS/FLUENT, was used for the fully resolved rotor approach.

"MODELING AND SIMULATION OF WAKE ENCOUNTER FOR A FIGHTER AIRCRAFT"

International Journal of Aerospace Innovations, Vol. 4, Number 3 and 4, 2012, pp. 65-74.

This paper addresses the development of six degrees of freedom model for simulation of flight in the wake of a similar class aircraft. The aircraft considered in this study is a high-performance fighter with full authority flight control laws. Apart from the aerodynamic effects, the flight dynamic model also includes a model of the air data system and the feedback control laws. The model is used to study the effect of wake on the flight dynamic response of the aircraft with and without effect of wake on the air data system feedback variables like angle of attack, angle of sideslip and static pressure.

"INFLUENCE OF TIP SHAPE ON STRUCTURE OF WING-TIP VORTEX AT LOW REYNOLDS NUMBERS"

Proceedings ASME 2009 Fluids Engineering Division Summer Meeting, FEDSM2009-78230, August 2009, Vail, CO.

An important phenomenon in three-dimensional flow over a wing is the existence of wingtip vortices. It has significant effects on the aerodynamics of flying vehicles. In this computational study, we

investigate the effects of geometry of the wingtip on the structure of the wing-tip vortices. Here, we consider a rectangular half-wing with NACA0012 airfoil as cross section. The aerodynamic coefficients and the flow-field variables are computed at low Reynolds numbers below 50,000. As the edge-shape parameter is increased the wing tip vortex is weakened. This influence is higher at higher values of Reynolds number. But, the increase of angle of attack does not change the shape or rate of this increase.

Kambe, T.

"VORTEX SOUND WITH SPECIAL REFERENCE TO VORTEX RINGS; THEORY, COMPUTER SIMULATIONS, AND EXPERIMENTS"

Aeroacoustics, Vol. 9, Nos. 1 and 2, 2010, pp. 51-89.

This is a review paper on vortex sound with special reference to vortex rings and sound emission detected in experimental tests. Any unsteady vortex motion excites acoustic waves. From the fundamental conservation equations of mass, momentum, and energy of fluid flows, one can derive a wave equation of aerodynamic sound. The wave equation of acoustic pressure can be reduced to a compact form, called the equation of vortex sound. This equation predicts sound generation by unsteady vortex motions. On the other hand, based on the matched asymptotic expansion (using the multipole expansions), one can derive a formula of wave pressure excited by time-dependent vorticity field localized in space. The theoretical predictions are compared with experimental observations and direct computer simulations. The systems considered are, head-on collision or oblique collision of two vortex rings, vortex-cylinder interaction, vortex-edge interaction, and others. Scaling laws of the pressure of emitted sound are predicted by the theory and compared with experimental observations. Comparison between theories and observations shows excellence of the theoretical predictions. Direct numerical simulations are reviewed briefly for sound generation by collisions of two vortex rings and that by a cylinder immersed in a uniform stream (aeolian tones). Vortex sound in superfluid is also reviewed about experimental observations and computational studies on the basis of the Gross-Pitaevski equation.

Kambe, T. and Minota, T.

"SOUND RADIATION FROM VORTEX SYSTEMS"

Journal of Sound and Vibration, Vol. 74, No. 1, 1981, pp. 61-72.

Sound radiation from a localized, weakly compressible flow in an inviscid fluid is investigated. A matching method enables the surrounding acoustic field to be related to the local eddy flow associated with a system of compact vortices. By using an asymptotic expansion of the velocity potential associated with the vorticity distribution, a general expression for the acoustic pressure is found to depend linearly on the vorticity, in accord with the theories of Mohring and Obermeier. This scheme is applied to an interacting system of coaxial circular vortex rings, and in particular two examples are

presented of the time histories of the radiated acoustic pressures which are generated by interactions of two identical vortex rings, in 'head-on collision' and in 'mutual threading' respectively.

Kambe, T. and Oo, U. M.

"SCATTERING OF SOUND BY A VORTEX RING"

Journal of the Physical Society of Japan, Vol. 50, No. 10, October 1981, pp. 3507-3516

Following the theory of aerodynamic sound scattering, a general formula of the scattered sound pressure is presented for a case of a plane harmonic wave incident upon a flow field localized in space. The expression is valid even when the flow is time-dependent and applied to the scattering by a vortex ring in translational motion. The scattering amplitude and cross-section are determined numerically under the condition of slow motion. They depend not only on the incident wavelength, but also on the direction of the vortex motion with respect to the incident wave. The scattering power of the vortex ring is compared with that of a solid sphere of the same size. In the present analysis, no restriction is imposed about the magnitude of the incident wavelength so far as the scattered wave is a small perturbation to the incident one.

"DEVELOPMENT OF WIND SENSING COHERENT DOPPLER LIDAR AT MITSUBISHI ELECTRIC CORPORATION FROM LATE 1990S TO 2013"

17th Coherent Lidar Conference, June 2013, Barcelona, Spain.

Since late 1990s, we have been developing the wind sensing coherent Doppler LIDARs. In the history of wind lidar, we have offered the following world-first topics, (1) wind sensing using eye-safe (1.5 micron) wavelength region, (2) instrumentation of compact fiber-based lidar, (3) product release of the fiber-based pulsed lidar, (4) middle-range (8 km) wind sensing with the high power fiber amplifier, (5) long-range (10 km) and real-time wind sensing using eye-safe wavelength, and (6) ultra-long-range (more than 30 km) wind sensing. Here, we introduce these topics and shortly describe about our future perspectives.

"EFFECTS OF EXHAUST PLUME TEMPERATURE ON VORTEX-WAKE/GROUND INTERACTION"

AIAA Paper No. 1998-2525, Albuquerque, NM, June 1998

The effect of exhaust plume temperature on the vortex-wake decent, separation and rebound near the ground is investigated. The three-dimensional, compressible Navier-Stokes (NS) equations are solved numerically. The implicit, upwind, Roe flux-differencing, finite volume scheme is used. The computations of vortex-wake/exhaust plume interaction with the ground are carried out using overlapping zonal method for long distances downstream. Typical velocity profiles of a tip vortex for Boeing 757 and Boeing 747, with and without exhaust plume temperature profiles, are used for inflow boundary conditions. The vortex-wake is subjected to crosswind flow and both upwind and downwind vortices are considered. The results of the vortex-wake decent, separation and rebound with and without exhaust plume are compared with each other.

"COMPUTATION OF COMPRESSIBLE QUASI-AXISYMMETRIC SLENDER VORTEX FLOW AND BREAKDOWN"

Computer Physics Communications, Vol. 65, 1991, pp. 164-172.

Analysis and computation of steady, compressible, quasi-axisymmetric flow of an isolated, slender vortex are considered. The compressible Navier-Stokes equations are reduced to a simpler set by using the slenderness and quasi-axisymmetric assumptions. The resulting set along with a compatibility equation are transformed from the diverging physical domain to a rectangular computational domain. Solving for a compatible set of initial profiles and specifying a compatible set of boundary conditions, the equations are solved using a type-differencing scheme. Vortex breakdown locations are detected by the failure of the scheme to converge. Computational examples include isolated vortex flows at different Mach numbers, external axial-pressure gradients, and swirl ratios. Excellent agreement is shown for a bench-mark case between the computed results using the slender vortex equations and those of a full Navier-Stokes solver.

Kandil, O. A., Adam, I. and Wong, T.-C.

"FAR-FIELD TURBULENT VORTEX-WAKE/EXHAUST PLUME INTERACTION FOR SUBSONIC AND HSCT AIRPLANES"

AIAA Paper No. 1996-1962, New Orleans, LA, June 1996

Computational study of the far-field turbulent vortex-wake/exhaust plume interaction for subsonic and high-speed civil transport (HSCT) airplanes is carried out. The Reynolds-averaged Navier-Stokes (NS) equations are solved using the implicit, upwind, Roe-flux-differencing, finite-volume scheme. The two-equation shear stress transport model of Menter is implemented with the NS solver for turbulent-flow calculation. For the far-field study, the computations of vortex-wake interaction with the exhaust plume of a single engine of a Boeing 727 wing in a holding condition and two engines of an HSCT in a

cruise condition are carried out using overlapping zonal method for several miles downstream. These results are obtained using the computer code FTNS3D. The results of the subsonic flow of this code are compared with those of a parabolized NS solver known as the UNIWAKE code.

"HYBRID VORTEX METHOD FOR LIFTING SURFACES WITH FREE VORTEX FLOW"

AIAA Paper No. 1980-0070, January 1980, Pasadena, CA.

A Nonlinear Hybrid Vortex method (NHV-method) has been developed for predicting the aerodynamic characteristics of wings exhibiting leading- and side-edge separations. This method alleviates the drawbacks of the Nonlinear Discrete Vortex method, also known as the multiple line vortex method. The NHV-method combines continuous-vorticity and vortex-line representations of the wing and its separated free shear layers. Continuous vorticity is used in the near-field calculations, while discrete vortex-lines are used in the far-field calculations. The wing and its free shear layers are divided into quadrilateral vortex panels having second-order vorticity distributions. The aerodynamic boundary conditions and continuity of the vorticity distributions are satisfied at certain nodal points on the vortex panels. An iterative technique is used to satisfy these conditions to obtain the vorticity distribution and the wake shape. Distributions and total aerodynamic loads are then calculated.

"COMPUTATION OF STEADY AND UNSTEADY COMPRESSIBLE QUASI-AXISYMMETRIC VORTEX FLOW AND BREAKDOWN"

AIAA Paper No. 1991-0752, January 1991, Reno, NV.

The unsteady, compressible Navier-Stokes equations are used to compute and analyze compressible quasi-axisymmetric isolated vortices. The Navier-Stokes equations are solved using an implicit, upwind, flux-difference splitting finite-volume scheme. The developed three-dimensional solver has been verified by comparing its solution profiles with those of a slender, quasi-axisymmetric vortex solver for a subsonic, isolated quasi-axisymmetric vortex in an unbounded domain. The Navier-Stokes solver is then used to solve for a supersonic quasi-axisymmetric vortex flow in a configured circular duct. Steady and unsteady vortex-shock interactions and breakdown have been captured. The problem has also been calculated using the Euler solver of the same code and the results are compared with those of the Navier-Stokes solver. The effect of the initial swirl has been tentatively studied.

Kandil, O. A., Kandil, H. A. and Liu, C. H.

"SUPERSONIC QUASI-AXISYMMETRIC VORTEX BREAKDOWN"

AIAA Paper No. 1991-3311, September 1991, Baltimore, MD.

An extensive computational study of supersonic quasi-axisymmetric vortex breakdown in a configured circular duct is presented. The unsteady, compressible, full Navier-Stokes (NS) equations are used for the present computational study. The NS equations are solved for quasi-axisymmetric flows using an implicit, upwind, flux-difference splitting, finite-volume scheme. The quasi-axisymmetric solutions are time accurate and are obtained by forcing the components of the flow field vector to be equal on two axial planes, which are near each other. The computational study addresses the effect of the Reynolds number, for laminar flows, on the evolution and persistence of vortex breakdown. The effect of boundary conditions at the duct exit on vortex breakdown is also studied. Finally, the effect of swirl ratio at the duct inlet is investigated.

Kandil, O. A., Kandil, H. A. and Liu, C. H.

"CRITICAL EFFECTS OF DOWNSTREAM BOUNDARY CONDITIONS ON VORTEX BREAKDOWN"

AIAA Paper No. 1992-2601, June 1992, Palo Alto, CA.

The unsteady, compressible, full Navier-Stokes equations are used to study the critical effects of the downstream boundary conditions on the supersonic vortex breakdown. The present study is applied to two supersonic vortex breakdown cases. In the first case, quasi-axisymmetric supersonic swirling flow is considered in a configured circular duct, and in the second case, quasi-axisymmetric supersonic swirling jet, that is issued from a nozzle into a supersonic jet of lower Mach number, is considered. For the configured duct flow, four different types of downstream boundary conditions are used, and for the swirling jet flow from the nozzle, two types of downstream boundary conditions are used. The solutions are time accurate which are obtained using an implicit, upwind, flux-difference splitting, finite-volume scheme.

Kandil, O. A., Kandil, H. A. and Liu, C. H.

"THREE-DIMENSIONAL SUPERSONIC VORTEX BREAKDOWN"

AIAA Paper No. 1993-0526, January 1993, Reno, NV.

Three-dimensional, supersonic vortex-breakdown problems in bound and unbound domains are solved. The solutions are obtained using the time-accurate integration of the unsteady, compressible, full Navier-Stokes equations. The computational scheme is an implicit, upwind, flux-difference splitting, finite-volume scheme. Two vortex-breakdown applications are considered in the present paper. The first is for a supersonic swirling jet which is issued from a nozzle into a supersonic uniform flow at a lower Mach number than that of the swirling jet. The second is for a supersonic swirling flow in a configured circular duct. In the first application, an extensive study of the effects of grid fineness, shape and grid-point distribution on the vortex breakdown is presented. Four grids are used in this study and they show a substantial dependence of the breakdown bubble and shock wave on the grid used. In the second application, the bubble-type and helix-type vortex breakdown have been captured.

"EFFECTS OF COUPLED AND UNCOUPLED BENDING TORSION MODES ON TWIN-TAIL BUFFET RESPONSE"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

In this paper, the interactions of unsteady vortex-breakdown flow of a 76-degree sharp-edged delta wing with the vertical twin-tail configuration of Washburn et. al. is computationally produced and investigated. The formulation of the problem consists of three sets of governing equations along with certain initial and boundary conditions. The first set is the unsteady, compressible, Reynolds-averaged Navier-Stokes equations. The second set consists of the aeroelastic equations for coupled or uncoupled bending and torsional responses of the twin tail. The third set consists of equations for deforming the grid due to the deflections of the twin tail in bending and torsion. These sets are sequentially solved accurately in time at each time step.

Kandil, O. A., Wong, T.-C. and Liu, C. H.

"ANALYSIS AND COMPUTATION OF TRAILING VORTICES AND THEIR HAZARDOUS EFFECTS"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 36-1 - 36-24

The thin-layer, Reynolds-averaged, Navier-Stokes equations along with an implicit, upwind, flux-difference splitting, finite-volume scheme are used to compute the vortex wake of a large-aspect-ratio wing. A C-O grid with grid stretching at the wing leading, trailing and side edges is used to solve for the wing and its near-vortex wake flows. The computed surface-pressure distribution is validated by comparison with a set of experimental data. Next, a relatively small trailing wing, in comparison with the leading wing, having a large aspect ratio is introduced in the near-vortex wake of the leading wing. The trailing wing grid has also been stretched at critical interference locations. The interacting-wing problem is recomputed using the solution of the previous isolated-wing problem as the initial condition. Fixing the downstream separation distance, the spanwise location of the trailing wing is varied to simulate two flow interference problems. The first problem is called the 'along-track penetration through vortex center' and the second is called the 'along-track penetration between vortices'.

Kandil, O. A., Wong, T.-C. and Liu, C. H.

"TURBULENT FLOW OVER A 747/747 GENERATOR/FOLLOWER CONFIGURATION AND ITS DYNAMIC RESPONSE"

AIAA Paper No. 1994-2383, Colorado Springs, CO, June 1994

The multidisciplinary interaction of the aerodynamics and rigid-body dynamics between a single tip vortex (representing a 747-generator wing) and a trailing wing (representing a 747-follower wing) is computationally investigated. The three-dimensional computational model consists of a tip vortex with

prescribed location and flow profiles in the inlet boundary of the computational domain, and a 747-follower wing with prescribed location relative to the generator tip vortex and prescribed mass-moment of inertia around the wing axis of symmetry. Keeping the follower wing stationary, the problem is solved for the flow field using the Reynolds-averaged, Navier-Stokes (NS) equations. With this solution serving as initial conditions, the follower wing is released to roll under the effect of the rolling moment induced by the generator tip vortex. At each time step, the NS equations and the dynamics equation for rolling motion are solved sequentially for the flow field, the rolling moment and the follower wing rolling motion.

"PREDICTION OF NEAR- AND FAR-FIELD VORTEX-WAKE TURBULENT FLOWS"

AIAA Paper 1995-3470-CP, Baltimore, MD, August 1995

Prediction of both the near- and far-field vortex-wake turbulent flows are presented. The Reynolds-averaged Navier-Stokes (NS) equations are solved using the implicit, upwind Roe-flux-differencing scheme. The turbulence models of Baldwin and Lomax, one-equation model of Spalart and Allmaras and two-equation shear stress transport model of Menter are implemented with the NS solver for turbulent-flow calculation. For the near-field study, computations are carried out on a fine grid for a rectangular wing with a NACA-0012 airfoil section and a rounded tip. The wing has an aspect ratio of 1.5 and is mounted inside a wind tunnel at an angle of attack of 10 degrees. The focus of study is the tip-vortex development, the near vortex wake roll-up, and validating the results with the available experimental data. For the far-field study, the computations of vortex-wake interaction with the exhaust plume of a single engine are carried out using overlapping zonal method for a long distance downstream of a Boeing 727 wing in a holding condition. The results are compared with those of an incompressible parabolized NS solver known as the UNIWAKE code.

"MASS TRANSFER ENHANCEMENT BY LONGITUDINAL VORTICES"

Heat and Mass Transfer, Vol. 32, 1997, pp. 163-166.

From numerical and experimental investigations, it has been recently established that convective heat transfer can be dramatically enhanced by the generation of longitudinal vortices in the flow. The phenomenological similarity between heat and mass transfer suggests that longitudinal vortices should increase also mass transfer. The mixing between two parallel streams of two components in a rectangular channel with and without a pair of rectangular winglets as vortex generators has been numerically investigated. The results show that one pair of vortex generators can increase the global mixing by more than 50 for laminar flow. This global mixing has been defined as the sum of the square of the differences of concentrations.

Kanki, B. G.

"DYNAMIC SPACING HUMAN FACTORS"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 500-508

The dynamic spacing human factors project is part of the Aircraft-ATC System integration element of the NASA Terminal Area Productivity program. The goal of the research is to investigate human factors issues related to the effect of Aircraft Vortex Spacing System (AVOSS) technologies on air traffic controllers. AVOSS technologies are presumed to make it possible to reduce separation standards in the terminal area under specified meteorological conditions. To take advantage of reduced spacing, controllers will be required to shift from one set of standards to another depending on dynamically changing conditions. Human factors issues include controller limitations to incorporating dynamic changes (e.g., adequate transition time, acceptable workload), the identification of controller strategies for accommodating shifting standards, and consistency with current practices, training, policies, and regulations. In addition, it is critical to address the way the AVOSS technologies will interface with the Air Traffic Management system. The research incorporates an integrated approach utilizing both simulation and field research methods. A preliminary simulation study produced the following results: Controllers were able to achieve reduced separation during training but not during test runs when the separations shifted in the standard-to-reduced matrix direction. However, there was a great amount of controller performance variability which could be attributed to differences in skill, strategies and/or length of run effects.

Kantha, H. L., Lewellen, W. S. and Durgin, F. W.

"QUALITATIVE RESPONSES OF A VORTEX CORE TO TIP BLOWING AND INTERSECTING AIRFOILS"

ASRL TR 153-4, August 1971, MIT Aeroelastic and Structures Research Laboratory, Cambridge, MA.

This investigation deals with the qualitative responses of a trailing vortex core to changes in its convective velocity produced in two different ways, (a) by injection of air into the vortex core and (b) by the flow field of a lifting surface in the path of the core. Flow pictures of the vortex core and vorticity measurements in the core show that an axial momentum injection of approximately 35 percent of the total wing drag alters the vortex structure and behavior quite drastically by effectively inducing a more rapid dispersion of the vorticity in the core. The data indicates that the phenomenon is governed by the rate of injection of the momentum rather than the mass flow rate as reported recently by Reinhart. There also seems to be an optimum rate of injection beyond which increased injection does not bring about equally significant changes in the vortex core. Flow patterns of the region of interaction between the flow field of a lifting surface and the vortex core show two modes of vortex response: (a) the vortex core bends, following the streamline shape until it intercepts the wake of the wing where it is abruptly dispersed, or (b) the vortex core may be sliced into two smaller vortices when the vortex hits the leading edge of the wing.

Kantha, H. L., Lewellen, W. S., and Durgin, F. H.

"RESPONSE OF A TRAILING VORTEX TO AXIAL INJECTION INTO THE CORE"

Journal of Aircraft, Vol. 9, No. 3, March 1972, pp. 254-256

The present investigation demonstrates that axial injection into the core of a vortex can indeed beneficially spread out the vorticity concentrated in it and prematurely age it. It further shows that the phenomenon is more nearly governed by the momentum flux of injection than by mass flow. A suitable value of injection for which substantial changes are produced in the vortex core appears to correspond to roughly 0.35. Despite the relatively high value of injection needed, this provides a possibly feasible way to disperse trailing vortices, since all of the injection required may be obtained by a redistribution of thrust.

Kantha, L.

"DECAY OF AIRCRAFT WAKE VORTICES UNDER DAYTIME FREE CONVECTIVE CONDITIONS"

Journal of Aircraft, Vol. 47, No. 6, Nov.-Dec. 2010, pp. 2159-2164.

The study suggests that separation times can be prudently lowered based on actual measured values of the turbulence kinetic energy dissipation rate. Doppler lidars may therefore play a critical role in enhancing the handling capacity of busy airports around the world, since they provide the capability to remotely measure the turbulence kinetic energy dissipation rate all along the flight corridor. Strong daytime convective conditions are often associated with good visibility; hence, visual flight rules prevail, and separation distances are reduced upon request by the pilots. However, the separation distances (times) could also be reduced under poor visibility and instrument flight rules, in particular, category 1 conditions.

Kantha, L. H.

"EMPIRICAL MODEL OF TRANSPORT AND DECAY OF WAKE VORTICES BETWEEN PARALLEL RUNWAYS"

Journal of Aircraft, Vol. 33, No. 4, July-August 1996, pp. 752-760

This article describes a simple empirical model for the transport and decay of aircraft trailing wake vortices between parallel runways in a turbulent atmosphere. It is suitable for applications to both single and closely spaced parallel runways. The model includes the influence of ambient turbulence on the decay rate of the wake vortices as well as the effect of crosswind shear. Well-known Monin-Obukhov similarity laws in the lower atmospheric boundary layer are used to compute the ambient shear and turbulence. Vortex bounce that occurs near the ground is also parameterized in the model. The results show that ambient shear plays an important role in vortex decay and transport. Atmospheric stability also affects the fate of these vortices, but with stable stratification having a much larger effect than convective heating of the atmospheric boundary layer. These results may prove useful for a better understanding of the factors that affect the transport and decay of aircraft wake vortices near the ground in the presence of crosswinds in a turbulent atmosphere.

Kantha, L. H.

"EMPIRICAL MODEL OF TRANSPORT AND DECAY OF AIRCRAFT WAKE VORTICES"

Journal of Aircraft, Vol. 35, No. 4, July-August 1998, pp. 649-653

An earlier empirical model of the transport and decay of aircraft wake vortices has been extended to include the effect of the decrease in the vortex circulation caused by ambient turbulence and shear, the shear-induced tilt of the vortex oval, and the initial roll-up phase. In addition to simulating the vortex bounce frequently observed near the ground, the model is now formulated to simulate the accelerated decay of the downwind vortex in crosswind shear, which often leads to the phenomenon of a lone surviving vortex. The ambient crosswind shear produces a vortex pair tilt with the downwind vortex being higher at normal crosswind speeds. Quite high crosswinds are needed to tilt the vortex in the other direction, where the upwind vortex is higher.

Kao, D. L.

"AUTOMATED VORTEX CORE ANALYSIS FOR MULTI-ZONE NUMERICAL FLOW SIMULATIONS"

AIAA Paper No. 2011-3679, June 2011, Honolulu, Hawaii.

An automated approach is implemented to perform data analysis of vortex cores extracted from numerical flow simulations. The new approach generates contiguous vortex core lines in multi-zone grids. Then, several interactive techniques are presented that extract quantitative data such as cross-flow velocity profiles and vortex core diameter. The approach provides a faster way of analyzing flow features than is possible using conventional post-processing tools. Furthermore, it provides a new way of analyzing vortex cores.

Kao, D. L. and Chaderjian, N. M.

"AUTOMATIC TIP VORTEX CORE PROFILING FOR NUMERICAL FLOW SIMULATIONS OF ROTORCRAFT IN HOVER"

AIAA Paper No. 2010-4752, June 2010, Chicago, IL.

An automated approach is presented that extracts visual and quantitative data from vortex cores produced by Navier-Stokes simulations of rotorcraft in hover mode. This approach extracts contiguous rotor tip vortex-core trajectories, cross-flow velocity profiles, and vortex-core diameter variation with wake age (azimuthal angle). This automated approach is faster and more accurate than a conventional manual approach. Moreover, this new approach allows for an efficient way to quantitatively compare vortex-core profiles from different flow simulations, e.g., grid resolution studies, and validate computed results with experimental data.

"VISUALIZATION AND ANALYSIS OF VORTEX FEATURES IN HELICOPTER ROTOR WAKES"

AIAA Paper 2013-1162, January 2013, Grapevine, TX.

Vortex interactions in helicopter rotor wakes are visualized using enhanced flow visualization techniques, which in turn play a crucial role in understanding the dynamics of these complex flows. Iso-surfaces are clipped in a 3D volume to reduce visual clutter. Flow textures are improved to highlight vortical flow structure and vortex-wake interactions. These visualization techniques are applied to three Computational Fluid Dynamics (CFD) simulations of helicopter flow fields. The presented techniques provide a good depiction of rotor tip vortices in these flows.

Kao, D. L., Smith, K. L. and Liu, Z.

"TRACKING BLADE TIP VORTICES FOR NUMERICAL FLOW SIMULATIONS OF HOVERING ROTORCRAFT"

AIAA Paper 2018-1175, January 2018, Kissimmee, FL.

Blade tip vortices generated by a helicopter rotor blade are a major source of rotor noise and airframe vibration. The noise and vibration occur when a vortex passes close to, and interacts with, a rotor blade. Accurate prediction of Blade Vortex Interaction (BVI) remains a challenge for Computational Fluid Dynamics (CFD). Although considerable research has been devoted to BVI noise reduction and experimental techniques for measuring the blade tip vortices in a wind tunnel, there are only a handful of post-processing tools available for extracting vortex core lines from CFD simulation data. To obtain the vortex core radius, most of these tools require the user to manually select a vortex core to perform the calculation. Furthermore, none of these tools provide an ability to track the growth of a vortex core, which is a measure of how quickly the vortex diffuses over time. This paper introduces an automated approach for tracking the core growth of a blade tip vortex from CFD simulations of rotorcraft in hover. The proposed method enables effective quantification and visualization of blade tip vortices in helicopter rotor wakes.

Kao, H. C.

"BODY-VORTEX INTERACTION, SOUND GENERATION AND DESTRUCTIVE INTERFERENCE"

NASA TM-2000-210239, August 2000, NASA Glenn Research Center at Lewis Field, Cleveland, OH.

It is generally recognized that the interaction of vortices with downstream blades is a major source of noise production. To analyze this problem numerically, a two-dimensional model of inviscid flow together with the method of matched asymptotic expansions is proposed. The method of matched asymptotic expansions is used to match the inner region of incompressible flow to the outer region of compressible flow. Because of incompressibility, relatively simple numerical methods are available to treat multiple vortices and multiple bodies of arbitrary shape. Disturbances from vortices and bodies propagate outward as sound waves. Due to their interactions, either constructive or destructive interference may result. When it is destructive, the combined sound intensity can be reduced,

sometimes substantially. In addition, an analytical solution to sound generation by the cascade-vortex interaction is given.

Kao, H. C.

"BODY-VORTEX INTERACTION, SOUND GENERATION, AND DESTRUCTIVE INTERFERENCE"

AIAA Journal, Vol. 40, No. 4, April 2002, pp. 652-660.

It is generally recognized that the interaction of vortices with downstream blades is a major source of noise production. To analyze this problem numerically, a two-dimensional model of inviscid flow, together with the method of matched asymptotic expansions, is proposed. The method of matched asymptotic expansions is used to match the inner region of incompressible flow to the outer region of compressible flow. Because of incompressibility, relatively simple numerical methods are available to treat multiple vortices and multiple bodies of arbitrary shape. Disturbances from these vortices and bodies propagate outward as sound waves. Because of their interactions, either constructive or destructive interference may result. When it is destructive, the combined sound intensity can be reduced, sometimes substantially.

"DYNAMICS OF FLAP SIDE-EDGE VORTICES"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

One dominant source of airframe noise is situated at the side edge of an extended wing flap. Oscillation of the vortical structure at the flap side-edge has been proposed by various authors as one possible mechanism of sound generation. The objective of the present study is to reduce this noise by blowing air into the vortical structure. The basic idea behind this concept is to displace or destroy the vortical structure, reducing the surface pressure level and thus the amplitude of the radiated sound. To investigate the technical feasibility, particle image velocimetry (PIV) and sound pressure level measurements are performed on a swept constant chord half model. The PIV measurements yield a rather complicated and unsteady vortical structure which confirms the assumption of a noise source at the flap side-edge. The vortical structure can be almost completely dispersed by blowing, thus resulting in a significant reduction of the sound pressure level.

Kaplan, M. L.

"MULTI-SCALE OBSERVATIONAL AND NUMERICAL MODELING STUDIES OF THE TURBULENCE ENVIRONMENT"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 15, 2016, Springer International Publishing Switzerland, pp. 299-316.

In this chapter, the focus will be on diagnosing multi-scale dynamical and thermodynamical processes that produce a favorable environment for aviation turbulence. In particular, the chapter will describe possible links among circulations at multiple scales of atmospheric motion that likely are favorable for the downscale generation of severe aviation turbulence. The chapter will be composed of three sections: (1) a synoptic/meso-alpha scale observational analysis of a broad cross section of turbulence accidents and the larger scale flow patterns that likely create a favorable mesoscale environment for the development of the turbulence event, (2) numerical simulations of the downscale dynamic/thermodynamic focusing of a favorable turbulence environment including the intersection of features at the synoptic, meso-alpha ($L = 200\text{-}2000\text{ km}$), and meso-beta ($L = 20\text{-}200\text{ km}$) scales of motion, and (3) an example of an operational mesoscale numerical model-based turbulence forecasting system and its implications for how it can be employed to determine the processes resulting in an environment which organizes severe aviation turbulence. These three sections are based upon research in Kaplan et al. (Characterizing the severe turbulence environments associated with commercial aviation accidents, 2004; Meteorol. Atmos. Phys. 88:129-152, 2005a; Meteorol. Atmos. Phys. 88:153-175, 2005b; Meteorol. Atmos. Phys. 94:235-270, 2006). We conclude with a summary and synthesis of a multi-scale paradigm for the downscale organization of a favorable aviation turbulence environment.

"A TERMINAL AREA PBL PREDICTION SYSTEM AT DALLAS-FORT WORTH AND ITS APPLICATION IN SIMULATING DIURNAL PBL JETS"

Bull. Amer. Met. Society, Vol. 81, No. 9, September 2000, pp. 2179-2204

A state-of-the-science meso-beta-scale numerical weather prediction model is being employed in a prototype forecast system for potential operational use at the Dallas-Fort Worth International Airport (DFW). The numerical model is part of a unique operational forecasting system being developed to support the National Aeronautics and Space Administration's (NASA) Terminal Area Productivity Program. This operational forecasting system will focus on meso-beta-scale aviation weather problems involving planetary boundary layer (PBL) turbulence, and is named the Terminal Area PBL Prediction System (TAPPS). TAPPS (version 1) is being tested and developed for NASA to improve 1-6 h terminal area forecasts of wind, vertical wind shear, temperature, and turbulence within both stable and convective PBLs at major airport terminal areas. This is being done to enhance terminal area productivity, that is, aircraft arrival and departure throughput, by using the weather forecasts as part of the Aircraft Vortex Spacing System (AVOSS). AVOSS is dependent upon nowcasts or short-period forecasts of wind, temperature, and eddy dissipation rate so that the drift and dissipation of wake vortices can be anticipated for safe airport operation. This paper describes the numerical modeling system, which has three basic components: the numerical model, the initial data stream, and the postprocessing system.

Kaplan, M. L., Lin, Y.-L., Ringley, C. J., Brown, Z. G., Kiefer, M. T., Suffern, P. S. and Hoggarth, A. M.

"WAKE VORTEX ENVIRONMENT SIMULATIONS FROM A TERMINAL AREA PBL PREDICTION SYSTEM (TAPPS)"

AIAA Paper No. 2006-1074, Reno, NV, January 2006.

This paper describes the development of a system to predict wake vortex environmental climatologies at major airports. This research model represents the precursor to a modeling system that ultimately could be run in real time to predict the atmospheric environment that controls wake vortex translation and dissipation. In this paper we will describe the most recent efforts to validate the numerical modeling system against field experiment observations compiled by NASA during the Aircraft Vortex Observation and Spacing System (AVOSS) field experiment held at Dallas-Fort Worth International Airport (DFW) on 15-19 September 1997. The paper will first describe the numerical modeling system followed by the results of the validation of simulations against available rawinsonde and boundary layer observations surrounding and at DFW.

"A TERMINAL AREA PBL PREDICTION SYSTEM FOR DFW"

AIAA Paper No. 1999-0983, Reno, NV, January 1999

A state-of-the-science mesoscale numerical weather prediction model is being tested in a prototype mode for potential operational use in support of NASA's Terminal Area Productivity (TAP) Program at the Dallas-Fort Worth (DFW) International Airport. The numerical model is the key component of a mesoscale weather prediction system named the Terminal Area PBL Prediction System (TAPPS). TAPPS is being developed and tested for NASA to improve short period forecasts of wind, wind shear, temperature, and turbulence within stable and convective planetary boundary layers (PBL). This is being done to enhance terminal area productivity by using the weather forecasts as part of the Aircraft Vortex Spacing System (AVOSS). In this paper we describe the real time numerical modeling system which has three basic components: (i) the numerical model, (ii) the initial data stream, and (iii) the postprocessing system. We also compare the results of several case study simulations with data collected from a field program held during September 1997 at DFW. During this field program, detailed local measurements of the PBL as well as the entire troposphere were taken in an effort to verify the numerical model results. Comparisons indicate that the numerical model is capable of accurately simulating the vertical wind shear structure during the diurnal evolution of the planetary boundary layer. Special emphasis in comparisons between the numerical model and observations are placed on the dynamics of the Great Plains nocturnal low-level jet, which represents the dominant low-level wind shear-production mechanism during many synoptic scale weather regimes.

"THE APPLICATION OF MESOSCALE NUMERICAL WEATHER PREDICTION MODELS TO THE TERMINAL AREA AND EXAMPLES FROM MEMPHIS 1995 FIELD DATA"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 430-459

This presentation will focus on the new weather forecast system which is designed to support AVOSS, i.e., the Terminal Area Planetary boundary layer Prediction System (TAPPS). The system will be described in terms of its two primary components which represent state-of-the-science mesoscale numerical weather prediction models. The first component is the Mesoscale Atmospheric Simulation System (MASS). This numerical model is designed to simulate phenomena which have spatial scales > 100 km and temporal scales of 3 hours or greater. It is initialized from synoptic scale data including radiosonde, wind profiler, satellite, radar, and surface observations. MASS will then act to provide the initial and lateral boundary conditions for a cloud/LES scale numerical model known as the Terminal Area Simulation System (TASS). TASS then enables the forecast system to be applied to the county scale/aviation terminal area for time periods of < 3 hours with a specific focus on predicting localized planetary boundary layer phenomena. One of the most important aspects of short period local terminal weather is the problem of rapidly developing low-level jet streams. These wind maxima can have a dramatic effect upon the transport and dynamics of wake vortices just above the earth's surface.

"WAKE VORTICITY MEASUREMENTS FOR LOW ASPECT RATIO WINGS AT LOW REYNOLDS NUMBER"

Journal of Aircraft, Vol. 44, No. 1, January-February 2007, pp. 241-251

Trailing vortex structure of low aspect ratio wings was studied in a water tunnel at Reynolds numbers of 8000 and 24,000 using dye injection and digital particle image velocimetry in cross-flow planes in the near wake, for rectangular, semi-elliptical, and delta-wing planforms. The velocity data were used to calculate lift via circulation and effective span, and the results were compared with force balance measurements and classical inviscid theory. The objectives of the study were to assess how low-Reynolds number effects might affect the measurement of lift coefficient from tip-vortex circulation, how well the measurements fit the various theoretical models of lift curve slope for low aspect ratio wings, and the extent to which planform shape affects lift coefficient while aspect ratio and planform area are kept constant. All models were thin flat plates with square edges. For the conditions studied, apparent viscous effects on vorticity integrations in the wake were small, resulting in good agreement between lift coefficient values inferred from the measurements, the force balance data, and the classical inviscid formulas. Whereas the three wings exhibited distinctly different wake structures, lift curve slopes were similar.

Kaplan, S. M., Altman, A. and Ol, M.

"ANGLE OF ATTACK AND PLANFORM EFFECTS ON FLAT PLATE TRAILING VORTICES AT LOW REYNOLDS NUMBERS"

AIAA Paper No. 2006-246, Reno, NV, January 2006

Tip vortices of low aspect ratio wings were studied in a water tunnel at Reynolds numbers of 8000 and 24,000, with dye injection and digital particle image velocimetry in crossflow planes in the near wake, for rectangular, semi-elliptical and delta-wing planforms. The velocity data were used to calculate lift via circulation, and the results were compared with direct force measurements. The objectives of the study were to assess how low Reynolds number effects might affect the classical measurement of lift coefficient from tip-vortex circulation, how well the measurements fit the slender wing theory lift curve slope, and the extent to which planform shape affects lift coefficient while aspect ratio and area are kept constant. All models were thin flat plates with square edges. For the range of streamwise locations and angles of attack studied, apparent viscous effects on vorticity in the wake were small, resulting in good agreement between lift coefficient values inferred from the measurements, the force balance data, and the classical inviscid formulas.

"A MODEL FOR THE FORMATION OF 'OPTIMAL' VORTEX RINGS TAKING INTO ACCOUNT VISCOSITY"

Physics of Fluids, Vol. 17, August 2005, pp. 087101-1-087101-.

The evolution of a viscous vortex ring from thin to thick-cored form is considered using an improved asymptotic solution, which is obtained after impressing a spatially uniform drift on the first-order solution of the Navier-Stokes equations. The obtained class of rings can be considered as the viscous analog solution to the Norbury vortices and classified in terms of the ratio of their initial outer radius to the core radius. The model agrees with the reported theoretical and experimental results referring to the post-formation and the formation stages. By using the matching procedure suggested earlier and the obtained properties of the viscous vortex ring, it is found that when the length-to-diameter aspect ratio L/D reaches the limiting value 4.0 ('formation number'), the appropriate values of the normalized energy and circulation become around 0.3 and 2.0, respectively. An approach that enables to predict the 'formation number' is proposed.

Kaplanski, F., Fukumoto, Y. and Rudi, Y.

"REYNOLDS-NUMBER EFFECT ON VORTEX RING EVOLUTION IN A VISCOUS FLUID"

Physics of Fluids, Vol. 24, 2012, pp. 033101-1 - 033101-13.

It is known that the cross section of the vortex ring core takes an approximately elliptical shape with increasing Reynolds number. In order to model this feature, the functional form of a vortex ring solution of the Stokes equations is modified to be able to model higher Reynolds number rings. The model introduces two nondimensional parameters that govern the shape of the vortex core: d greater than or equal to 1 and b greater than or equal to 1. Based on this modification, new expressions for the translation velocity, energy, circulation, and stream function are derived for a wide range of section ellipticity that are specific to such vortices. To validate the model, the data adapted from the numerical study of vortex ring at Reynolds number 1400 performed by Danaila and Helie is used. In this case, the appropriate values of d and b are calculated by equating the normalized energy and circulation of the

theoretical vortex to the corresponding values obtained from the numerical data. The model provides a good prediction of the ring velocity evolution at high Reynolds numbers.

"A GENERALIZED VORTEX RING MODEL"

Journal of Fluid Mechanics, Vol. 622, 2009, pp. 233-258.

A conventional laminar vortex ring model is generalized by assuming that the time dependence of the vortex ring thickness L is given by the relation $L = a \text{ times } t \text{ to the } b \text{ power}$, where a is a positive number and b is greater than or equal to $1/4$ and less than or equal to $1/2$. In the case in which $a = \text{the square root of } 2\nu$, where ν is the laminar kinematic viscosity, and $b = 1/2$, the predictions of the generalized model are identical with the predictions of the conventional laminar model. In the case of $b = 1/4$ some of its predictions are similar to the turbulent vortex ring models, assuming that the time-dependent effective turbulent viscosity is equal to $L \text{ times } L \text{ prime}$. This generalization is performed both in the case of a fixed vortex ring radius R and increasing vortex ring radius. In the latter case, the so-called second Saffman's formula is modified. In the case of fixed R , the predicted vorticity distribution for short times shows a close agreement with a Gaussian form for all b and compares favorably with available experimental data. The time evolution of the location of the region of maximal vorticity and the region in which the velocity of the fluid in the frame of reference moving with the vortex ring centroid is equal to zero is analyzed. It is noted that the locations of both regions depend upon b , the latter region being always further away from the vortex axis than the first one. It is shown that the axial velocities of the fluid in the first region are always greater than the axial velocities in the second region.

Kaplanskii, F. B. and Rudi, Y. A.

"EVOLUTION OF A VISCOUS VORTEX RING"

Fluid Dynamics, Vol. 36, No. 1, 2001, pp. 16-25

The velocity field inside a viscous vortex ring and its overall velocity are obtained based on an existing solution of the Stokes equation for the vorticity in a moving coordinate system. It is shown that these characteristics of the motion relate the results obtained earlier for limiting times and are confirmed by the experimental data. The effect of the initial Reynolds number on the development of the vortex ring is analyzed by constructing entrainment diagrams.

"FORMATION, STRUCTURE, AND DEVELOPMENT OF NEAR-FIELD WING TIP VORTICES"

Proc. IMechE, Vol. 222, Part G, 2008, pp. 13-22.

The current experimental study investigates the details of the formation, structure, and development of wing tip vortices that are generated by an airfoil of NACA0012 profile having a rectangular planform

of 151 mm chord using the particle image velocimetry technique. Experiments have been carried out at different angles of attack, which affect the vortex strength, vortex size, tangential velocity, and vorticity distribution along the downstream stations at chord lengths ranging from $x/c = 0.1$ to 1.6 , at a fixed free-stream velocity of 212 mm/s corresponding to the Reynolds number, $Re = 32000$ based on the chord length. The radius of the vortex core is found to vary approximately between 5 and 7.5 per cent of the chord length of the wing. The results show that the flow around the tip is dominated by the structures of multiple vortices. The maximum normalized tangential velocity increases with increasing angle of attack. The peak magnitude of the tangential velocity is about 15 per cent of the free-stream velocity for an angle of attack of 4° , whereas it is about 40 per cent of the free-stream velocity for 12° .

Karcher, B.

"AVIATION-PRODUCED AEROSOLS AND CONTRAILS"

Surveys in Geophysics, Vol. 20, 1999, pp. 113-167.

Liquid and solid particles in the plumes of jet aircraft cruising in the upper troposphere and lower stratosphere lead to the formation of ice clouds (contrails), modify the microphysical properties of existing cirrus clouds, and provide sites for heterogeneous chemical reactions. Characterization of aviation-produced particles in terms of physico-chemical properties is an important step in assessing the global impact of aircraft emissions upon atmospheric chemistry and climate parameters. Chemistry and microphysics of the gas-aerosol system in aircraft plumes and its evolution in the atmosphere is a field of intense research. This paper reviews the current knowledge (mid-1998) and outlines possible atmospheric implications.

Karkehabadi, R.

"AERODYNAMIC INTERFERENCE OF A LARGE AND A SMALL AIRCRAFT"

J. Aircraft, Vol. 41, No. 6, Nov.-Dec. 2004, pp. 1424-1429

The influence of wake from a leading aircraft, Boeing 757, on a following aircraft, Cessna 750 Citation X, is investigated using the unsteady vortex lattice method. The effect of the wakes from both wings and each other is considered and the new position of the wakes from both aircraft calculated. As the midspan of the Cessna wing approaches the Boeing 757 trailing vortex core, the roll moment increases to its maximum value. Strong changes appear in aerodynamic loads of the Cessna as it moves near the Boeing 757's wake. Rapid change occurs as the Cessna moves in transverse or vertical directions near the Boeing's wake. The unsteady aerodynamic loads on wings moving along different paths are calculated. The Boeing 757's wake strongly affects the aerodynamic loads and the wake of the Cessna. Also included in the present results are numerical simulations of wakes and velocity vectors in the Trefftz plane detailing the influence of the wake from the leading aircraft, the Boeing 757.

Karkehabadi, R.

"WIND TUNNEL MEASUREMENTS OF HAZARD POSED BY LIFT-GENERATED WAKES"

J. Aircraft, Vol. 32, No. 2, November-December 2004, pp. 1424-1429

The influence of wake from a leading aircraft, Boeing 757, on a following aircraft, Cessna 750 Citation X, is investigated using the unsteady vortex lattice method. The effect of the wakes from both wings and each other is considered and the new position of the wakes from both aircraft calculated. As the midspan of the Cessna wing approaches the Boeing 757 trailing vortex core, the roll moment increases to its maximum value. Strong changes appear in aerodynamic loads of the Cessna as it moves near the Boeing 757's wake. Rapid change occurs as the Cessna moves in transverse or vertical directions near the Boeing's wake. "TIME EVOLUTION OF THE VORTEX BETWEEN AN AIR INLET AND THE GROUND"

AIAA Paper No. 2000-0990, Reno, NV, January 2000

The flow near the inlet of a gas turbine engine intake located close to the ground is studied through Large Eddy Simulations (LES). The suction through the air inlet induces a vortex system, which is not only turbulent but also contains larger unsteady vortices. These vortices can be characterized through their geometrical shape and characteristic frequencies. The latter parameter discloses that there are several different modes of vortex systems. The transitions among the modes have been verified to be independent of the numerical parameters of the LES. We also notice that some of the vortices have a tendency of moving fluid from ground up into the air-intake. These vortices have a time dependent strength and 'origin' near the ground. The LES results have been compared qualitatively to experimental data reported in the literature. Our results indicate that LES can capture the details found in the experiments.

Karpatne, A.

"INVESTIGATION OF TIP VORTEX APERIODICITY IN THE WAKE OF A HELICOPTER IN HOVER"

MS Thesis, August 2012, University of Texas, Austin, Texas.

Previous research has indicated aperiodicity in the position of tip vortices emitted from a helicopter rotor blade in hover. The objective of the current study is to develop an analysis of the tip vortex aperiodicity in hover and to validate it with measurements on a reduced-scale, 1m diameter, four-bladed rotor. A 'vortex ring emitter model' (VREM) was developed to study the statistics of the tip vortices emitted from a rotor blade during hover. To better model the rotor wake, several independent vortex blobs were used to describe a vortex ring. An empirical model for viscosity was also considered

which helped model the core radius growth of the vortex ring with vortex age. A parametric analysis was then performed to obtain a comprehensive qualitative and quantitative convergence study of the time step, viscosity parameter, initial core size, number of rings shed, number of blobs and overlap factor. It was observed that the solution converged rapidly for all the parameters used. The locations of tip vortex cores for vortex ages ranging from 0 to 260 degrees were measured on the reduced-scale rotor using a stereo PIV system. The blade loading for the reduced scaled rotor was 0.044 and the blade rotational speed was 1520 RPM, which corresponds to a tip Reynolds number of 248,000. The 95 percent confidence region for the position of tip vortex cores exhibited an anisotropic, aperiodic pattern, approximating an ellipse. It was seen that the principal axis of this ellipse appeared to be aligned perpendicular to the slipstream boundary. The analytical model showed good correlation with experimental data in terms of the orientation and extent of the anisotropy. Moreover, an estimate of the total thrust produced and spanwise loading along the rotor blade was also obtained and compared with Blade Element Momentum Theory (BEMT). It was seen that by using more blobs to represent a vortex ring, the solution converged to the BEMT estimate..

"DYNAMIC RESPONSE TO WAKE ENCOUNTER"

AIAA Paper 2013-1921, April 2013, Boston, MA.

Wake vortices generated by an aircraft might cause severe structural dynamic response of an aircraft that encounters the wake while its strength is still high. Realistic wake-encounter cases might adversely affect the mission of the crossing aircraft or yield critical structural design loads cases. A numerical scheme for calculating the response of aeroelastic systems in such cases is presented. The new scheme is utilized in the Dynresp code for industrial dynamic loads calculations, taking advantage of its computational efficiency, feedback-loop capabilities and applicability with most general gust inputs, local aerodynamic outputs, and control-system architecture. The WESDE preprocessor that calculates the wake-induced incidence angles at the aerodynamic panels in arbitrary crossing parameters is also presented. The response formulation with new gust inputs is shown to be significantly different than that of standard gust-response schemes. Frequency-domain solutions and FFT schemes are combined for an efficient, robust and adequately accurate numerical process for massive industrial applications. Propeller-engine 1P load effects are included. Unsteady aerodynamic lag effects are shown to be especially important in fast wake encounter, and well represented by feedback filters that approximate Kussner's sharp-edge gust function by rational functions in the Laplace domain. Numerical examples with a generic transport aircraft and with the A400M military transport show well-behaved a-symmetric modal solutions. Very good comparisons are shown between numerical and A400M flight-test results.

Karwal, A. K.

"WAKE VORTEX FLIGHT TESTING IN RECENT EU RESEARCH PROGRAMS"

17th SFTE (EC) Symposium, June 2006, Amsterdam, The Netherlands

Predominantly driven by the need to increase airport capacity, but punctuated by the topical discussion on adequate separation criteria behind larger aircraft such as the An-225, A380 and the future B747-800, several European research programs have been launched aimed at expanding the knowledge of wake vortices and their effect on the overall safety level of the air transport system. These programs are designated by telltale acronyms such as M-FLAME, C-WAKE, WakeNet, S-WAKE, I-WAKE, ATC-WAKE, WAKEOP, AWIATOR, CREDOS and FAR-WAKE. In these programs different experimental techniques (such as the use of wind tunnel, water tank, ground lidar and catapult facilities, CFD computations, piloted simulations, and flight trials) are applied as tools to investigate vortex characteristics, to determine the effects of active or passive wake vortex control (alleviation) devices and to assess the impact on flight safety of a wake encounter. A few of these research programs (notably S-WAKE, I-WAKE, and AWIATOR) included actual flight tests to determine the correlation between the mentioned techniques with full-scale results and to get measurements that are difficult to obtain in a laboratory environment. NLR aircraft have participated in these programs, the paper will discuss practical issues related to aircraft instrumentation, test preparation and execution and some results of the flight test programs that were performed. Upcoming developments in the field of wake vortex flight testing are addressed as well.

Kashevarov, A. V., Potapov, Y. F. and Stasenko, A. L.

"NUMERICAL INVESTIGATION OF CHEMICALLY REACTING JETS OF AN AIRLINER AT LOW ALTITUDES"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 303-309

The work presents numerical investigation of the spatial-temporal evolution of chemically reacting components in an axisymmetric jet of an aircraft's engine, which are of interest both from a standpoint of airport ecology and as potential tracers for wake visualization by use of resonance sounding. Characteristic photochemical reactions were also taken into consideration. Computations were performed for a B-747-type aircraft flying at sea level.

Kashitani, M., Kita, Y., Suzuki, H., Yamaguchi, Y., Date, H. and Takita, Y.

"A FUNDAMENTAL STUDY ON AIRCRAFT MODEL BY WAKE MEASUREMENTS IN LOW-SPEED WIND TUNNELS"

AIAA Paper 2013-1022, January 2013, Grapevine, TX.

In this paper, the drag prediction method (wake integration method) based on the momentum conservation theorem was applied to the aerodynamic investigations on aircraft model. The wake survey of the model is performed to obtain the basic data to evaluate how applicable the technique is to aerodynamic tests in a relatively small low-speed wind tunnel. In this case, it is important to

investigate the effect of the measurement interval by the wake survey. The aircraft model is the same geometry model that was used for the correction wind tunnel test previously. The free-stream velocity is kept to be 30 m/s. The Reynolds number based on the mean aerodynamic chord length is $Re = 270,000$. The results are shown as follows. The section lift coefficient of 20 mm measurement interval shows the good agreement with the result of 5 mm interval. And as for the spanwise induced drag coefficient distribution, the distribution of 20 mm interval does not show quantitative agreement with the result of 5 mm interval. On the lift coefficient, the data of the wake measurement of 20 mm and 5 mm interval shows the good agreement with the results of the balance system. In the detail consideration, the result of 5 mm interval is 2.6 percent closer to the result by the balance system than the result of 20 mm interval. This difference of the present experimental data may be considered the effect of the flow unsteadiness and the measurement interval.

Kasim, K. A., Mat, S., Ishak, I. S. and Said, M.

"EFFECTS OF PROPELLER LOCATIONS ON THE VORTEX SYSTEM ABOVE DELTA-SHAPED UAV MODEL"

ICAS-2016-0162, September 2016, Daejeon, Korea.

The flow above delta wing is complicated and dominated by a very complex vortex structure. This study investigates the effects of propeller locations on the aerodynamic characteristics above a 55-degree sharp-edged non-slender delta wing UAV model. The experiments were conducted in a closed circuit UTM-LST wind tunnel at speeds of 20 and 25 m/s. In this project the propeller is located at three different locations namely; front, middle and rear. The result obtained from this experiment was compared with the clean wing configuration. The effects of propeller locations, angle of attack, Reynolds number and propeller advance ratio on the aerodynamic characteristics of this generic UAV model are discussed in this paper. The experimental data highlights an impact of propeller locations on lift, drag, moment and vortex system of the UAV. The results also showed that the propeller advance ratio, J influence the vortex system above UAV wing.

"WAKE MEASUREMENTS OF A MULTI-MW WIND TURBINE WITH COHERENT LONG-RANGE PULSED DOPPLER WIND LIDAR"

Journal of Atmospheric and Oceanic Technology, Vol. 27, September 2010, pp. 1529-1532. 47.

Long-range Doppler wind light detection and ranging (lidar) measurements at a wind turbine were carried out for the first time. The turbine was of the type Areva M5000 and is located at a site near the coastline in Bremerhaven, in the northern part of Germany. This wind turbine is the prototype for the German offshore test site 'alpha ventus' and has a rated power of 5 MW. Information about the ambient wind field before and after this multimegawatt wind turbine was obtained. In this paper the measurement technique is discussed and the results of measurements in the diurnal layer and in the stable nocturnal boundary layer are shown. The main focus of this work is to determine the reduction of the wind speed at certain distances downstream from the rotor.

Kasper, S., Burke, T., Rapski, J. and Saneholtz, N.

"AERODYNAMICS OF FORMATION FLIGHT FOR UAVS"

AIAA Paper 2016-1285, January 2016, San Diego, CA.

The upwash generated from wingtip vortices from a lead aircraft can be utilized by a suitably positioned trailing aircraft to obtain essentially 'free' lift. This free lift means it requires a smaller angle of attack to maintain altitude, thus reducing drag, which in turn leads to reduced fuel consumption and increased range and endurance. The unmanned aspect of a UAV relieves safety constraints that exist with human flight. In particular, unmanned aircraft can fly closer to other vehicles, thus benefitting from the stronger vortices closer to the lead aircraft. This idea was expanded to combine the upwash of two leading aircraft positioned side by side, such that the counter rotating vortices will have sections of upwash that coincide with each other and will therefore be stronger than the upwash from only one leading aircraft. This project measured the effects that the combined vortices have on the trailing UAV and compared those results to a similar test with only one lead aircraft. This project includes both an experimental and a computational study of vortex effects. Experimental lift and drag measurements of the trailing vehicle were taken in a wind tunnel at varying trailing distances, using both one and two leading wings. The wings were concurrently modeled and evaluated in ANSYS Fluent at wind tunnel conditions. Wind tunnel results were used to validate computational results at wind tunnel conditions, and then the computational study was expanded to actual cruise conditions.

"TIME-RESOLVED STEREOSCOPIC PIV MEASUREMENT OF UNSTEADY WINGTIP FLOWFIELD"

AIAA Paper No. 2012-0035, January 2012, Nashville, Tennessee.

Time-Resolved Particle Image Velocimetry (TR-PIV) which can measure velocity fields at sampling rate of 10 kHz or higher sampling rate is now widely applied to practical flow problems. The TR-PIV provides the two-dimensional distributions of the spectrum of the velocity fluctuation because it can measure the two-dimensional velocity distributions at high sampling rate. But flow fields in industrial wind tunnel applications are three dimensional. Three-dimensional velocity measurement is strongly needed. The objective of this research is to develop time-resolved stereoscopic PIV system for industrial wind tunnels and to apply the system to unsteady wingtip flow field on a single rectangular wing. The objective flow fields are unsteady, not uniform, and strongly influenced by a probe. Generally, it is difficult to measure such unsteady velocity fields. For example, hot wire anemometer which is widely used for unsteady velocity measurement is not suitable for the objective flow field due to the intrusiveness. The time-resolved stereoscopic PIV can measure such flow fields precisely because it is not intrusive. Thus, the time-resolved stereoscopic PIV is suitable to investigate the objective flow fields. Time-resolved stereoscopic PIV system was developed for industrial wind tunnel testing. Unsteady wingtip velocity field was measured by the time-resolved stereoscopic PIV system in JAXA 2m x 2m low-speed wind tunnel. The wingtip vortices behavior of NACA0012 rectangle wing model was investigated. Finally, the power spectrum density distributions of the velocity fluctuation were shown

to clarify the vortex behavior and to demonstrate the effectiveness of the time-resolved stereoscopic PIV data to specify the unsteady flow phenomena.

"DATA MINING FOR THE ADVECTION DATABASE OF WAKE VORTICES"

AIAA Paper No. 2010-7989, Toronto, Canada, August 2010.

Advection database of wake vortices was constructed based on the Doppler lidar measurements at Sendai Airport to understand the relations among measurement, weather factors and behavior of wake vortex. The advection database of wake vortex consists of three measurement factors and fifteen weather factors as variables to determine the wake vortex behavior. However, the extraction of correlations from the high-dimensional data is difficult in general. Therefore, in this paper, data mining was employed as an efficient approach to extract relations among the variables from the advection database of wake vortex. As a first step of the data mining, redundant measurement, weather factors were removed through Spearman rank method, then Self-Organizing Map was created to find correlations among the measurement, weather factors and wake vortex behavior. Next, the measurement, weather factors which have larger influences to the behavior of the wake vortex were identified by Analysis of Variance. Finally, rough set theory revealed the specific rules of measurement, weather factors to determine wake vortex behavior.

Kato, N., Ohkuma, T., Kim, J. R., Marukawa, H. and Niihori, Y.

"FULL SCALE MEASUREMENTS OF WIND VELOCITY IN TWO URBAN AREAS USING AN ULTRASONIC ANEMOMETER"

Journal of Wind Engineering and Industrial Aerodynamics, Vol. 41, 1992, pp. 67-78.

This paper describes the results obtained from the measurements of the characteristics of wind turbulence in urban areas using ultrasonic anemometers. The data used in this paper is what which was gained from the year-long observation extending from January 1990 through December 1990 and during two typhoons No. 8922 and No. 9011. The values of the turbulence intensity at a height of less than 100m were approximately 10 15 percent larger than those recommended for corresponding urban areas by the AIJ standard, in which the specified power index of the wind profile is set at 0.3. The shape of the power spectral density for the u component agrees fairly well with the shape of the Karman type spectrum. The power spectral density of the v component is quite similar to the Karman type spectrum for the u component.

Katz, J.

"CLASSICAL AND POTENTIAL-FLOW AERODYNAMICS DO WE NEED THEM?"

AIAA Paper 2019-0864, January 2019, San Diego, CA.

Nowadays, computational tools for solving the flow over complex objects are widely available and easily connected to basic design tools. This allows iterative engineering analysis and design without using classical ideal flow models. Furthermore, most of the classical solutions rely on complex, and often lengthy, mathematical formulation, not very exciting when presented in the classroom. However, those simple models were successful in predicting many important features of the flow-field, as in the case of the flow over wings. On the other hand, efforts to reduce graduation times, forced curriculum planners to reevaluate the need for teaching classical aerodynamics. In the following discussion, an effort is made to explain why those methods work, what are the resulting conclusions, and respond to the frequently asked question about the method convergence and validation. Also, when educating engineers, simple models (e.g., ideal flow models) are needed to predict design trends and thereby shortening preliminary design cycles.

Katz, J. and Galdo, J. B.

"EFFECT OF ROUGHNESS ON ROLLUP OF TIP VORTICES ON A RECTANGULAR HYDROFOIL"

Journal of Aircraft, Vol. 26, No. 3, March 1989, pp. 247-253

Experiments focusing on the development of a tip vortex on a rectangular NACA-66 hydrofoil have been performed in a towing tank. The study consists of flow visualization by illuminating with a laser sheet and by disturbing fluorescing dye in the water. It also includes surface pressure measurements, particularly around the tip. The experiments have been performed with a smooth surface, and by painting a layer of roughness elements with characteristic sizes of 250 and 500 micron. The observations demonstrate that the physical dimensions of the tip vortex are not affected significantly by the surface roughness, whereas the surface pressure, particularly just under the tip vortex, changes substantially. This observation leads to the conclusion that an increase in the surface roughness reduces the strength of the tip vortex. The flow visualization experiments also demonstrate that for all the roughness sizes, the tip vortex dimensions increase with the incidence angle and decreases as the velocity is increased. In addition, the study demonstrates that the flow is unsteady and that the tip region is dominated by multiple secondary vortex structures. A series of sample photographs demonstrating these phenomena is provided.

Katz, J. and Maskew, B.

"UNSTEADY LOW-SPEED AERODYNAMIC MODEL FOR COMPLETE AIRCRAFT CONFIGURATIONS"

Journal of Aircraft, Vol. 25, No. 4, April 1988, pp. 302-310.

A method for converting steady-state, potential-flow based panel methods into a time-dependent mode is derived and applied to several test cases. For this development, an improved vortex wake model was constructed that was also suitable for simulating the leading-edge separation of slender wings at high angles of attack. Computed flow-field simulations are presented for various unsteady and

high-angle-of-attack conditions, involving geometries such as simple wings, rotors, and complete aircraft configurations.

"BEHAVIOR OF VORTEX WAKES FROM OSCILLATING AIRFOILS"

J. Aircraft, Vol. 15, No. 12, December 1978, pp. 861-863

The vortex wake of an oscillating airfoil has long been studied, and it is now well known that under certain conditions strong nonlinear interactions can develop. This appears in the form of agglomerations of vortex elements resulting in discrete concentrations of vorticity which can then be analyzed as separate vortices. In this Note, we present a simple and rapid numerical technique for calculation of the time-dependent growth and evolution of wakes. The parameters influencing the rollup are examined and the ranges of reduced frequencies for which such instabilities occur are determined.

"AIRCRAFT WAKE VORTEX DETECTION TRIALS WITH C-BAND INSTRUMENTATION RADAR"

Twenty-eighth Conference on Radar Meteorology, Austin, TX, September 7-12, 1997, Preprints, American Meteorological Society, 1997, pp. 163-164

Detection of wingtip vortices by radar in a range of weather conditions is desirable. Experimental trials have been conducted by the FAA to identify the most reliable techniques for discriminating wingtip vortex radar echoes from wind-generated echoes; attention was given to the dependence of vortex signatures on flow orientation relative to the radar beam and aircraft altitude.

"GROUND EFFECT ON DOWNWASH ANGLES AND WAKE LOCATION"

NACA TR-738, 1942, NACA Langley Aero. Lab., Langley Field, VA

A theoretical study was made of the reduction in downwash and the upward displacement of the wake in the presence of the ground, and some verification of theory was obtained by means of air-flow measurements made with a ground-board and image-wing combination. Methods are given for estimating the effects and numerous examples are included to illustrate the nature of these effects and to show their order of magnitude.

Kauertz, S.

"THE CREDOS PROJECT. SAFE SEPARATION DISTANCES FOR TAKE-OFF AND DEPARTURE: EVALUATION OF MONTE CARLO BASED SAFETY ASSESSMENT RESULTS"

D3-10, November 2009.

This document contains the results of a safety assessment with regard to wake vortex encounter risk during departure using the combination of the tools WakeScene-D and VESA-D. The encounter probability and risk is assessed for several scenarios in comparison considering the effect on the encountering aircraft. Based on the relative encounter risk for different crosswinds and separations a crosswind threshold is derived which could allow a safe reduction of separations during departure.

"EXCITATION OF INSTABILITIES IN THE WAKE OF AN AIRFOIL WITH WINGLETS"

AIAA Paper No. 2006-3470, San Francisco, CA, June 2006

This paper describes experimental investigations of possibilities to destabilize the vortex wake behind an airfoil by using winglets with integrated rudders. These rudders can be deflected statically, as well as oscillated periodically around their static deflection. The oscillation is intended to excite short-wavelength instabilities inherent in the vortex system to provoke an accelerated decay of the vortices. The used model also comprises deflectable ailerons and can be equipped with a pair of trailing edge flaps to modify the vortex system. Quantitative wake investigations by Particle Image Velocimetry have been conducted up to 43 spans behind the wing model in a water towing tank. Results show a markedly earlier decay of the vortex system and abatement of induced rolling moments in the wake for certain rudder configurations in comparison to the clean airfoil configuration. However, the oscillation of the winglet rudders did not lead to a further acceleration of vortex decay compared to the statical case in the frame of the experiments conducted here.

Kauertz, S. and Neuwerth, G.

"EXCITATION OF INSTABILITIES IN THE WAKE OF AN AIRFOIL BY MEANS OF ACTIVE WINGLETS"

Aerospace Science and Technology, Vol. 10, 2006, pp. 551-562.

Strong wake vortices that develop behind every aircraft as a byproduct of lift production pose a threat where aircraft fly in close staggering such as in the vicinity of airports. One approach to alleviate these vortex wakes is the use of high lift systems or control surfaces of the wing to create an unstable vortex system. The inherent instability of this vortex system shall then lead to an accelerated decay of the vortex wake, triggered for example by a periodic motion of the control surfaces. In the work presented here a simple wing model with winglets able to produce a vortex system of up to six distinct vortices is investigated in towing tank experiments. Theoretical studies show that these vortex systems potentially have a high degree of instability. By means of active oscillation of rudders integrated into the winglets, these vortex systems are to be excited to initiate an accelerated decay of the vortices. It is shown that configurations exist which exhibit strong instabilities, that lead to a significantly lower hazard level behind the vortex generating wing, even when not actively excited. However, an additional oscillation does not seem to accelerate decay of these vortex systems in relation to the statistical reference case.

Kauertz, S., Holzaepfel, F. and Kladetzke, J.

"WAKE VORTEX ENCOUNTER RISK ASSESSMENT FOR CROSSWIND DEPARTURES"

Journal of Aircraft, Vol. 49, No. 1, January-February 2012, pp. 281-291.

In the European research project, CREDOS (Crosswind-Reduced Separations for Departure Operations), the feasibility of a concept for reduced wake turbulence separations upon departure in crosswind conditions has been investigated. The safety assessment of this concept includes risk assessment with respect to wake vortex encounters. This paper describes the methodology developed for this assessment and its application during the project. The methodology employs two simulation tools, the Wake Vortex Scenarios Simulation Package for Departures (WakeScene-D) and the Vortex Encounter Severity Assessment for Departure (VESA-D), which are extensions of existing tools related to the departure flight phase. WakeScene-D primarily determines the frequency of wake encounters, whereas VESA-D estimates the severity of these encounters. Both can be combined to quantify and compare wake encounter risk for various departure scenarios. In the risk assessment, departures with variable aircraft separations and varying crosswind conditions were investigated to determine which crosswind level is necessary to suspend wake-turbulence-related separations during departure without degrading safety. Monte Carlo simulations have been conducted comparing medium and heavy aircraft type departures with 2 min. of separation to departures with a separation of 1 min. under varying crosswind strengths. The results not only give an indication of which crosswind magnitudes could be sufficient to safely suspend wake-turbulence-related separations upon takeoff, but they also reveal significant influences, such as the departure route layout and the change of wind direction with altitude, on wake encounter risk.

Kawachi, K.

"EXTENSION OF LOCAL MOMENTUM THEORY TO HOVERING ROTOR WITH DISTORTED WAKE"

Journal of Aircraft, Vol. 19, July 1982, pp. 538-545

The local momentum theory is extended to include the effects of a rotor wake deformation in hovering flight. A comparison of this extended local momentum theory with a prescribed wake vortex theory is presented. The results indicate that the extended local momentum theory has the capability of achieving a level of accuracy like that of the prescribed wake vortex theory, using a much smaller amount of computer time. It is also shown that the analytical results obtained using either theory are in reasonable agreement with experimental data.

Kawahara, G.

"ENERGY DISSIPATION IN SPIRAL VORTEX LAYERS WRAPPED AROUND A STRAIGHT VORTEX TUBE"

Physics of Fluids, Vol. 17, May 2005, pp. 055111-1 to 055111-13

Energy dissipation in spiral layers of high azimuthal vorticity around a straight vortex tube is investigated analytically. Asymptotic expressions of local and total viscous dissipation are obtained for the spiral vortex layers. When a vortex tube, which aligns with a uniform shear flow of a shear rate S , starts with a vortex filament of circulation at an initial instant $t=0$, it wraps and stretches background vorticity lines around itself to form double spiral vortex layers of intense dissipation.

Kawanishi, H. and Lan, C. E.

"A NUMERICAL STUDY OF WAKE ROLL-UP FOR A FLAPPED TRANSPORT WING"

AIAA Paper No. 1997-2332, Atlanta, Georgia, June 1997

Results of wake roll-up from an isolated transport-type wing at a low subsonic speed calculated using the thin-layer Navier-Stokes method are presented. The computational results indicate that the vortex roll-up and its decay are faster for the flap-deployed case than for the clean configuration as indicated in experimental data. The tip vortex is stronger for the clean configuration than for the flapped case. The computed location of the trailing vortex for the clean configuration is near the mid-semispan where flow separation occurs, and more inboard than that behind a rectangular wing. On the other hand, the trailing vortex for a flapped configuration at the same or higher lift coefficient as the clean configuration tends to be more outboard, depending on the spanwise location of the partial span flap. For a flap span with the outer edge near the mid-semispan, the outboard flap vortex merges with the trailing vortex within half span length. On the other hand, if the location of the flap outer edge is more inboard, the outboard flap vortex is still distinct even at 7.5 span lengths downstream. The condition for merging appears to be the continuity of the wake vorticity distribution near the trailing edge.

Kazakov, A. V.

"STABILITY OF AN AXISYMMETRIC SWIRLED FLOW IN A SUPERSONIC COCURRENT STREAM FOR VOLUME ENERGY SUPPLY IN THE VISCOUS VORTEX CORE"

Fluid Dynamics, Vol. 40, No. 1, 2005, pp. 62-70

The results of numerical calculations of the stability of axisymmetric swirled flows in a viscous vortex embedded in a supersonic concurrent stream with a constant circulation of the azimuthal velocity component are presented. The stability characteristics of the swirled three-dimensional viscous flow in the streamwise vortex are determined based on the linearized system of Navier-Stokes equations for a viscous heat-conducting gas under the assumption that the basic undisturbed flow is locally plane-parallel. The disturbed flow stability is studied in the temporal formulation with respect to both symmetric and asymmetric three-dimensional waves traveling along the vortex axis and corresponding to both positive and negative values of the azimuthal wavenumber. It is shown that at external inviscid flow Mach numbers thermal energy supply in a small region near the vortex axis leads to considerable restructuring of the basic undisturbed flow in the vicinity of the vortex core, the growth of the adverse pressure gradient along the vortex axis, and a significant change in the small perturbation stability and behavior.

Kazakov, A. V.

"EFFECT OF VOLUME ENERGY SUPPLY ON THE STABILITY OF A SUBSONIC VORTEX FLOW"

Fluid Dynamics, Vol. 38, No. 4, 2003, pp. 552-560

Calculations of the stability of an axisymmetric vortex flow of viscous heat-conducting gas with volume energy supply are presented. The unperturbed axisymmetric vortex flow was found numerically using a quasi-cylindrical approximation of the Navier-Stokes equations under the assumption of constant peripheral-velocity circulation in the ambient co-current flow. The volume energy supply in the viscous vortex core was modeled by an additional source term in the energy equation. The stability characteristics of the viscous vortex flow in a longitudinal vortex with respect to both axisymmetric and non-axisymmetric three-dimensional waves traveling along the vortex axis and corresponding to both positive and negative values of the azimuthal wave number were found using the time-dependent formulation of the linear stability theory for compressible three-dimensional plane-parallel flows.

Kazarin, P. S. and Golubev, V. V.

"COMPARISON OF PROBABILISTIC APPROACHES FOR PREDICTING THE CONE OF UNCERTAINTY IN AIRCRAFT WAKE VORTEX EVOLUTION"

AIAA Paper 2017-4369, June 2017, Denver, CO.

The paper presents evaluation of the fast-time probabilistic wake-vortex evolution models implemented as part of the Wake Vortex Safety System (WVSS) code to be employed in the wake safety risk analyses by FAA SSMT program. The validation of obtained predictions against LIDAR data collected at Memphis and Denver airports in 1995 and 2003 is conducted to estimate the accuracy and ranges of uncertainty in the wake vortex propagation models. In particular, probabilistic wake evolution predictions based on Monte-Carlo simulations are compared against results based on P2P

and RMS approaches to examine and compare the cones of uncertainty in the wake evolution. The comparison with results obtained using several previously developed models is also presented.

Kazarin, P. S. and Golubev, V. V.

"ON EFFECTS OF GROUND SURFACE CONDITIONS ON AIRCRAFT WAKE VORTEX EVOLUTION"

AIAA Paper 2017-4368, June 2017, Denver, CO.

The paper investigates and compares decay and transport of an aircraft wake vortex in the vicinity of a solid surface, a forest canopy, and a water surface, representative of various terminal-zone environments. The analysis elucidates some critical features and differences in near-ground wake dynamics which could be important for aircraft operations during takeoff and landing. Particularly, the results of the study may provide insights for ensuring wake safety in future integration of various classes of unmanned aircraft systems (UAS) in airport operations. The reported results are based on Large Eddy Simulations (LES) conducted using an open-source OpenFOAM solver. The obtained high-fidelity findings will form the basis for reduced-order models to be integrated in the fast-analysis code under development for in-situ wake vortex evolution predictions.

Kazarin, P. S. and Golubev, V. V.

"HIGH-FIDELITY SIMULATIONS OF TERMINAL-ZONE HETEROGENEOUS TERRAIN EFFECTS ON AIRCRAFT WAKE VORTEX EVOLUTION"

AIAA Paper 2018-1279, January 2018, Kissimmee, FL.

The current work is an extension to the previous study where the wake vortex propagation in the vicinity of a solid surface, a forest canopy and a water surface was studied. The effects of different configurations of forest canopy on aircraft wake vortex transport and decay are addressed in detail in this paper. The temporal 3D LES simulations using OpenFOAM solver are performed for fully rolled-up vortices corresponding to a generic heavy aircraft. The numerical setup is validated with the experimental data from the water filled tow-tank. Different types of the forest canopy specified in terms of various shapes and physical characteristics are employed with the wake evolution results compared. The obtained predictions will be integrated in the reduced order models under development for fast-time wake vortex analysis.

"A VARIABLE-FIDELITY APPROACH TO WAKE SAFETY ANALYSIS IN THE CONTEXT OF UAS INTEGRATION IN THE NAS"

AIAA Paper 2016-3452, June 2016, Washington, DC.

The paper presents results of the wake vortex safety analysis conducted for selected unmanned aircraft systems (UAS) operating alongside commercial aircraft in the terminal zone. The approach is

developed based on a dynamic model of an aircraft entering an upstream wake vortex that allows evaluating changes in the important aerodynamic parameters following the wake vortex interaction and assessing the operational safety risks in application to variable-size UAS. The employed variable-fidelity approach integration reduced-order models of wake generation, evolution and interaction incorporating both theoretical and high-fidelity predictions. The benchmark parametric study estimates UAS responses in terms of the roll control ratios (RCR) developed by the follower aircraft depending on their position and orientation relative to the wake shed by the leader B-737 aircraft, as well as the duration of the wake-UAS interaction. The UAS dynamic reaction is examined in the context of several possible flight control scenarios that include a time-delayed maximum aileron deviation.

"VORTEX SCATTERING EFFECTS ON ACOUSTIC WAVE PROPAGATION"

AIAA Paper 2015-3267, June 2015, Dallas, TX.

In this paper, the Euler equation model is used to investigate sound wave propagation over subsonic vortices. The cases of a single vortex, a pair of counter-rotating stationary vortices, and the moving vortex pair under the mutual induction velocity are studied. The numerical scheme uses a high-order WENO scheme to accommodate the highly convective background flow at high Mach numbers. The simulation results are compared with the analytical solutions and literature data with good agreement achieved. The scattering effects of the vortices and the related scaling laws are discussed.

Keane, M., Buckton, D. and Darracq, D.

"WAKE VORTEX HAZARD DETECTION DOPPLER LIDAR"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

The performance of an airborne wake vortex detection system is investigated by simulation. The proposed detection system uses a forward looking, pulsed Doppler Lidar to interrogate the intended flight path of the aircraft. It aims to give advance warning of any hazardous wake vortices, generated by preceding aircraft, that enter the aircraft's intended airspace. Any Doppler system is only capable of resolving velocities in the direction of the emitted wave. Thus, the proposed system aims to detect hazardous wake vortices based on axial characteristics. Realistic wake vortices are simulated in a convective atmospheric boundary layer using a three-dimensional Large Eddy Simulation model. The simulation is initialized with data collected during trials made at Idaho Falls by the Federal Aviation Administration in 1990. The evolution of the vortices in characteristic atmospheric conditions is then calculated. At discrete stages in the evolution, the computed flow field is applied to the Lidar system simulator. The Lidar system simulator models the shot noise limited Lidar, the atmosphere, and the signal processing, outputting the set of line-of-sight velocities that would be measured by a Doppler Lidar interrogating the given flow field. Pattern recognition techniques are used to detect any vortices. At each stage the hazard posed by any vortex in the flow field is estimated by calculating the rolling moment that it would produce on an encountering aircraft. If this rolling moment is of the same order as the rolling-moment capability of a commercial transport aircraft, then it is classified as a hazardous vortex. This paper aims to demonstrate that all such hazardous vortices can be detected using the proposed Lidar system.

Keane, M., Buckton, D., Redfern, M., Bollig, C., Wedekind, C. and Kopp, F.

"AXIAL DETECTION OF AIRCRAFT WAKE VORTICES USING DOPPLER LIDAR"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 850-861

The real-time detection of aircraft wake vortices has become an important part of studies aimed at increased runway productivity. A processing approach is presented, which has been used to detect wake vortices from an axial point of view with a Doppler lidar system. The performance of the processing approach is investigated using simulation techniques. In addition, the effectiveness of the approach is demonstrated using data from a series of wake vortex measurement experiments carried out at Toulouse airport in March 2000. Robust axial detection of wake vortices with a Doppler lidar system has been achieved at ranges between 400 m and 2 km. Sample results for Airbus A340- and Airbus A320-generated wake vortices are presented.

Kedzie, C. R. and Griffin, K. E.

"EXPERIMENTAL MEASUREMENTS OF WAKE CHARACTERISTICS OF LOW ASPECT-RATIO DELTA AND FLAPPED-PLATE PLANFORMS"

Technical Note USAFA-TN- 83-6, March 1983, US Air Force Academy, Colorado Springs, CO.

This report documents the characteristics and location of the wakes for two generic lifting surface planforms. The geometric description locates these wakes as they develop downstream from a low

aspect-ratio delta wing and a bent-plate wing. The wakes are graphically depicted at several streamwise locations downstream of these wings with accompanying cross-velocity vector plots to assist in interpreting them. The data used to determine these wake characteristics was obtained by surveying the wings' flow field with a seven-hole pressure probe.

Keeffe, B. E.

"VORTEX ADVISORY SYSTEM SIMULATION OF CHICAGO O'HARE INTERNATIONAL AIRPORT"

FAA-RD-78-76, July 1978, FAA NAFEC, Atlantic City, NJ

This report evaluates, in simulation, the procedural implications of the Vortex Advisory System (VAS) on the Chicago O'Hare terminal air traffic control environment. It also attempts to demonstrate any cost benefits/capacity gains which may accrue using reduced VAS aircraft separation criteria on the final approach course based upon meteorological assurance of vortex dissipation. Utilizing the National Aviation Facilities Experimental Center (NAFEC) Digital Simulation Facility (DSF), a real-time simulation of the Chicago O'Hare International Airport airside operations was conducted between March 28 and June 24, 1977. There were 105 data runs of 1 hour and 20 minutes duration completed during this period. Test results indicate that (1) no procedural implications emerged which would deter the implementation of VAS at Chicago O'Hare Airport, and (2) arrival rate increases are sufficient to support previous cost/benefit analysis studies.

Keime, M., Koop, L., Ehrenfried, K. and Dillmann, A.

"A 2 D VORTEX SHEET MODEL OF THE FLAP SIDE EDGE FLOW"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

Airframe noise contributes significantly to the total sound radiated during approach. One important noise source is located at the side-edge of the extended wing-flaps. Shear layers emerge at the sharp corners of the side-edge and roll up into a vortical structure. Nonstationarity of this structure leads to pressure fluctuations at the rigid surface and thus to sound radiation into the far field. The objective of the present study is to displace or destroy the vortical structure by blowing air into the vortex, thus leading to a reduction of sound emission. The feasibility of this method of flow control has been shown experimentally. In order to further optimize the configuration of the experimental setup and to investigate the physical mechanism in detail, a two-dimensional potential flow model is developed.

Keller, J. D., McKillip Jr, R. M. and Wachspress, D. A.

"PHYSICAL MODELING OF AIRCRAFT UPSETS FOR REAL-TIME SIMULATION APPLICATIONS"

AIAA Paper No. 2008-6205, August 2008, Honolulu, HI.

Improving the understanding of flight dynamics and control response characteristics of aircraft in upset conditions has been the focus of extensive research and development in recent years. Aircraft

may experience upsets due to many factors, and without suitable corrective actions, upsets may ultimately lead to loss of control accidents. To provide models for engineering analysis and pilot training, conventional simulation approaches have historically used multi-variable aerodynamic databases (look-up tables) derived from wind tunnel and/or flight test data, which are difficult to acquire and do not always encompass the desired flight envelope. An alternative approach for modeling aerodynamic and flight dynamic characteristics of aircraft in upset conditions has been investigated based on methods that are not data-driven but that are derived from physically-based models. This paper describes a modeling approach based on nonlinear lifting line/strip theory analysis of the aerodynamic loads combined with an unsteady, freely-evolving vortex wake model for the induced velocity due to the lifting surfaces. The paper describes background work and recent developments toward a generic, physically-based model for aircraft upsets. Application of the modeling approach to unmanned aircraft is presented.

Keller, J. J.

"THE EFFECTS OF NON-UNIFORM DENSITY AND STAGNATION PRESSURE ON THE BREAKDOWN CHARACTERISTICS OF A VORTEX"

Z. angew Math Physics, Vol. 45, 1994, pp. 347-370.

This paper is concerned with the extension of the theory of vortex breakdown, that was presented in previous publications by the present author and others, to cases of non-uniform density and non-uniform stagnation pressure outside the vortex core. The effects of radial density and velocity variations play an essential role for the layout of modern low-emission burners for premixed combustion. Furthermore, these effects turn out to be important with respect to an improved understanding of the formation of zones of flow recirculation in tornado-like vortices. With the help of the extension of a variational principle for axisymmetric flow to the case of non-uniform density it is possible to discuss inviscid flows of non-uniform density and stagnation pressure in great generality. A numerical solution method is given for general axisymmetric vortex flows, including flows that undergo vortex breakdown. The influences of density and stagnation pressure variations on vortex breakdown are analyzed in detail, for the special case of a generalized Rankine vortex. It is found that a radially increasing density leads to a reduction of the swirl number at which vortex breakdown occurs, whereas a radially decreasing axial velocity component in the approach flow of a vortex breakdown bubble leads to a substantially enlarged bubble. Finally, a Richardson number criterion is proposed for the scaling of a vortex breakdown bubble in a tornado.

Keller, J. J.

"ON THE INTERPRETATION OF VORTEX BREAKDOWN"

Phys. Fluids, Vol. 7, No. 7, July 1995, pp. 1695-1702

Studying the numerous papers that have appeared in the recent past that address 'vortex breakdown' it may be difficult for a reader to avoid getting rather confused. It appears that various authors or even

schools have conflicting views on the correct interpretation of the physics of vortex breakdown. Following the investigation by Keller et al. (1985), in this paper, axisymmetric forms of vortex breakdown, as originally defined by Benjamin (1962) are addressed. It is argued that at least some of the previous investigations have been concerned with different aspects of the same phenomena and may, in fact, not disagree. One of the most fundamental questions in this context concerns the properties of the distributions of total head and circulation on the downstream side of vortex breakdown transitions. Some previous investigators have suggested that the downstream flow would exhibit properties that are similar to those of a wake. For this reason, the phenomenon of vortex breakdown is investigated for a class of distributions of total head and circulation in the domain of flow reversal that is substantially more general than in previous investigations. Finally, a variety of problems are discussed that are crucial for a more complete theory of vortex breakdown, but have not yet been solved. It is shown that for the typically small flow speeds in a domain of flow reversal produced by a vortex breakdown wave, the departures of both vortex core size and swirl number, with respect to the case of uniform total pressure in the zone of flow reversal, as discussed by Keller et al. (1985), remain surprisingly small. As a consequence, the possible appearance of large departures from a Kirchhoff-type wake must be due to viscous diffusion at low and due to shear-layer instabilities at high Reynolds numbers.

Keller, J. J.

"ON THE PRACTICAL APPLICATION OF VORTEX BREAKDOWN THEORY TO AXIALLY SYMMETRICAL AND THREE-DIMENSIONAL COMPRESSIBLE FLOWS"

Phys. Fluids, Vol. 6, No. 4, April 1994, pp. 1515-1523

A perfect-fluid theory for axially symmetrical vortex breakdown flows by Keller et al. is extended to three-dimensional compressible flows. In a first step, an approximate theory for thin vortex cores is compared to the exact theory for axially symmetrical flows of inviscid, incompressible fluids. In subsequent steps, the approximation for thin vortex cores is extended to flows of compressible fluids that are not axially symmetrical. Finally, the various types of vortex breakdown flows and the shear layer instabilities at the surface of vortex breakdown bubbles are briefly discussed.

Kelly, A. J. and Handelsman, M.

"ELECTROMAGNETIC EFFECTS OF AIRCRAFT WAKE-ACTIVE FEUILLET INTERACTION"

IEEE Trans. Aerospace and Electronic Systems, Vol. AES-10, January 1974, pp. 136-143

A mechanism by which an aircraft wake can interact strongly with the electromagnetic radiation present in an active elevated anomalous refractivity region (active Feuillet) is analyzed. The aircraft wake structure, assumed to consist of twin contrarotating vortices plus entrained irrotational gas, trailing behind the wings of typical large aircraft is shown to be capable of descending approximately 3 wing span distances and attaining a length of the order of 10 km, prior to instability-induced disruption. The parcel of air such a descending coherent wake structure can convey into an active Feuillet is

demonstrated to alter significantly the local refractive index of the duct and induce substantial radiation spillage. The general characteristics of the electromagnetic radiation produced by this interaction process (i.e., scattering by diaphanous objects) is described.

Kenig, C. E., Ponce, G. and Vega, L.

"ON THE INTERACTION OF NEARLY PARALLEL VORTEX FILAMENTS"

Comm. in Math. Phys., Vol. 243, 2003, pp. 471-483

The system for the interaction of nearly parallel vortex filaments deduced by Klein, Majda and Damodaran is considered. Local existence for the associated initial value problem with data which are small perturbations of perfect parallel filaments is proved. Assumptions on the unperturbed configurations and on the initial parameters which guarantee the existence of global regular solutions (no finite time collapse) are deduced.

"AUTOMATIC VORTEX CORE DETECTION"

IEEE Computer Graphics and Applications, July-August 1998, pp. 70-74

An eigenvector method proves effective for extracting and visualizing features such as vortex cores. Incorporated in a finite-element flow solver, the algorithm guides automatic mesh refinement.

Kerlick, G. D.

"VISUALIZATION FOR AERODYNAMIC DESIGN OF HELICOPTER ROTOR BLADES"

Proceedings of the IEEE Conference on Visualization - 'Visualization '95', October 29 - November 3, 1995, pp. 351-354.

Visualization, animation, and simulation techniques are applied to the problem of rotor design for helicopters. Periodic unsteady experimental velocity data (laser Doppler velocimetry or LDV) in two dimensions and velocity data derived from simulated vortex systems in three dimensions are compared using the same visual tools. Animations show the development of rotor wake systems and induced velocities over time. Modified particle trace integration schemes are used to calculate steady streamlines and unsteady particle paths for both kinds of data. In an extension of this work, a virtual environment system was used to view the wake vortex system and an interactive probe was used to explore the induced velocity field. Future work will enable interactive visual debugging and simulation steering.

"A FLIGHT INVESTIGATION INTO THE PERSISTENCE OF TRAILING VORTICES BEHIND LARGE AIRCRAFT"

ARC Report CP-489, September 1959, Royal Aircraft Establishment, Farnborough, England. (Also, RAE Tech. Note Aero. 2649.)

A flight investigation into the persistence of trailing vortices has been made by flying a Devon in the wake of a Lincoln. The tests were made in the clean and flaps down configurations. The results indicate that the disturbance decays rapidly after 160 seconds and 105 seconds, respectively, and produces negligible rolling moments after 190 seconds and 120 seconds, respectively. The flight results have been compared with the available theoretical work and the comparison suggests that the theory of Squire holds until the vortices start to decay rapidly.

Kevlahan, N.

"GEOMETRIC, STOCHASTIC AND ALGEBRAIC VORTICES"

In *Vortex Dominated Flows*, edited by D. Blackmore, E. Krause and C. Tung, 2005, World Scientific, New Jersey, Chapter 6, pp. 99-118.

Mathematical concepts can often be understood in one of three complementary ways: geometric, algebraic, or stochastic. In this chapter I show how vortices may be interpreted in each of these three ways. Each point of view is appropriate for certain applications, and each sheds new light on the role played by vortices in fluid dynamics. This review is necessarily brief, and makes no attempt to be exhaustive, but I hope it gives an interesting overview of vortices in all their forms.

Kevlahan, N. K.-R.

"STOCHASTIC DIFFERENTIAL EQUATION MODELS OF VORTEX MERGING AND RECONNECTION"

Physics of Fluids, Vol. 17, No. 6, June 2005, 065107-1-065107-11

We show that the stochastic differential equation (SDE) model for the merger of two identical two-dimensional vortices proposed by Agullo and Verga ['Exact two vortices solution of Navier-Stokes equation' *Phys. Rev. Lett.*, 78, 2361 (1977)] is a special case of a more general class of SDE models for N interacting vortex filaments. These toy models include vorticity diffusion via a white noise forcing of the inviscid equations, and thus extend inviscid models to include core dynamics and topology change (e.g., merger in two-dimensions and vortex reconnection in three dimensions). We demonstrate that although the $N=2$ two-dimensional model is qualitatively and quantitatively incorrect, it can be dramatically improved by accounting for self-advection. We then extend the two-dimensional SDE model to three dimensions using the semi-inviscid asymptotic approximation of Klein et al. ['Simplified equations for the interactions of nearly parallel vortex filaments,' *J. Fluid Mech.* 288, 201 (1995)] for nearly parallel vortices. This model is nonsingular and is shown to give qualitatively reasonable results until the approximation of nearly parallel vortices fails. We hope these simple toy models of vortex reconnection will eventually provide an alternative perspective on the essential physical processes involved in vortex merging and reconnection.

"A ROUTINE METHOD FOR THE CALCULATION OF AERODYNAMIC LOADS ON A WING IN THE VICINITY OF INFINITE VORTICES"

TR-133-2, May 1966, MIT Aeroelastic and Structure Laboratory, Cambridge, MA

The vortex lattice method for the calculation of loads on a wing advancing in a uniform stream was extended to the case of a wing in the vicinity of infinite vortices. The results in the report were limited to checking the convergence of the calculations.

"RESPONSE OF UNCONFINED VORTEX BREAKDOWN TO AXIAL PULSING"

Physics of Fluids, Vol. 18, 2006, pp. 038102-1-038102-4

The response of unconfined swirling jets undergoing vortex breakdown to axial pulsing is explored experimentally. In particular, the combination of particle visualization and particle image velocimetry has enabled the effect of axial pulsing on the development of shear-layer flow structures and vortex breakdown to be quantified, as a function of both pulsing frequency and amplitude. A range of Reynolds and swirl numbers is considered. A key result is that application of low-level forcing at the natural frequency intensifies the shear-layer vortices considerably and results in a substantial relative downstream shift of the mean breakdown position.

"VISUALIZATION OF TIP VORTEX/AIRFOIL INTERACTION"

Journal of Flow Visualization and Image Processing, Vol. 1, No. 1, 1993, pp. 35-41.

The effects of the vortical wake shed by a finite wing on a two-dimensional airfoil situated downstream were studied. Two forms of flow visualization were employed. First, the downstream airfoil boundary-layer behavior was studied using surface-film visualization. This consisted of smearing a mixture of propylene glycol and fluorescein onto the downstream airfoil, and viewing the resulting flow patterns under ultraviolet light. Second, the trajectory of the tip-vortex shed by the forward surface was examined using a kerosene vapor tracer. The freestream Reynolds number, based on the downstream airfoil chord length, was 150,000 for all tests. The surface-film visualization technique proved to be a very effective method for locating regions of separated flow on the airfoil. The smoke visualization provided good indication of the position of the tip-vortex relative to the two lifting surfaces. Several examples of both techniques are included in the paper.

"THE AXISYMMETRIC BOUNDARY LAYER BENEATH A RANKINE-LIKE VORTEX"

Experiments in Fluids, Vol. 22, 1997, pp. 300-311

An experimental investigation of the three-dimensional boundary layer induced by a Rankine-like vortex with its axis normal to a stationary disk is described. The velocity field through the boundary layer was measured for Reynolds number Re (based on the tangential velocity and radius at the disk edge) ranging from 10,000 to 25,000 at various radial distances by means of a 4-beam, 2-component Laser Doppler Anemometer. Our results show that the nature of the boundary layer is affected by two factors: a nonflexional instability caused by the crossflow velocity profile and a stability factor caused by the favorable pressure gradient. At lower Reynolds number, the radial pressure gradient has a very strong stabilizing effect on the boundary layer and acts to revert it to its laminar state upstream of the effusing core. At higher Re the nonflexional instability caused by the crossflow velocity dominates while the stabilizing influence of the favorable pressure gradient recedes. As such, laminar reversion likely occurs closer to the effusion core. Thus, the point of laminar reversion moves closer to the effusion core as the Reynolds number is increased.

"VORTEX BREAKDOWN IN AN UNCONFINED VORTICAL FLOW"

Experimental Thermal and Fluid Science, Vol. 14, 1997, pp. 131-148.

Flow visualization experiments were conducted on an unconfined vortex formed on a stationary impermeable base. At the low circulation range, all seven modes of vortex breakdown previously documented for a confined flow could be observed, despite the vast differences in the two sets of apparatus. The unconfined flow also revealed the existence of a conical breakdown. This occurrence has been recently observed under confined swirling flows. It is characterized by a conical breakdown envelope and occurs at the high swirl regions. At the higher circulation range, the vortex structure erupted from the base into a large-scale turbulent flow. Results are presented on a chart using parameters related to the intrinsic flow properties of the vortical flow -- circulation, extent of vortex stretching, and core size.

"LINEAR AND NONLINEAR EVOLUTION OF DISTURBANCES IN SUPERSONIC STREAMWISE VORTICES"

AFOSR-TR-97, High Technology Corp., Hampton, VA, March 1997

Evolution of disturbances in a supersonic vortex is studied by using quasi-cylindrical linear stability analysis and parabolized stability equations (PSE) formulation. Appropriate mean-flow profiles suitable for stability analysis were identified and modeled successfully. Using the quasi-cylindrical linear-stability code, the stability characteristics of cylinder axisymmetric vortices were mapped thoroughly and discussed in detail. Important trends such as viscous and compressibility effects were obtained and analyzed. The results indicate that viscosity has very little effect while increasing Mach number

significantly stabilizes the disturbance. Nonlinear evolution of helical modes as well as modal interaction is also studied by using PSE. It is found that the growth of the disturbances results in the appearance of coherent large-scale motion and significant mean flow distortion in the axial velocity and temperature fields. In the end, nonlinear effects tend to stabilize the vortex.

"STABILITY OF LONGITUDINAL VORTICES"

Potential Impacts of Advanced Aerodynamic Technology on Air Transportation System Productivity, edited by D. Bushnell, NASA TM-109154, NASA Langley Research Center, Hampton, VA, September 1994, pp. 94-95

Results of ongoing study on the stability of longitudinal vortices was given. The work was motivated by the need to destabilize and breakup the highly stable trailing line vortices generated by large commercial aircraft. Mean velocity components from a Batchelor vortex were used to perform a viscous linear stability analysis, from which two new viscous instability modes were identified, one axisymmetric and the other asymmetric. The results suggest that the key to controlling the break up and dissipation of trailing vortices was to induce at least a two-cell structure in them, and that the axisymmetric instability mode was the most likely to succeed. The desired velocity distribution might be achieved by using blowing or suction to alter the axial velocity component near the wing tip.

Khorrami, M. R.

"ON THE VISCOUS MODES OF INSTABILITY OF A TRAILING LINE VORTEX"

J. Fluid Mech., Vol. 225, April 1991, pp. 197-212

A viscous linear stability analysis of a trailing line (Batchelor) vortex is presented. Employing a staggered Chebyshev spectral collocation technique, very accurate results were obtained. The destabilizing role of viscous forces has been shown to produce two type of viscous instability modes. These viscous disturbances consist of an axisymmetric mode and an asymmetric mode. Comparison with experimental results and condensation trail observations are found to be in good qualitative agreement with the present study.

Khorrami, M. R. and Grosch, C.

"TEMPORAL STABILITY OF MULTIPLE CELL VORTICES"

AIAA Paper No. 1989-0987, Tempe, AZ, March 1989

The temporal stability of multiple cell vortices is considered. Employing a staggered Chebyshev spectral collection technique, the results are obtained very accurately and efficiently. It is shown that cell multiplicity in the vortex core has a drastic effect on the stability characteristics. While validating the spectral collocation algorithm, two new viscous modes of instability for Batchelor's vortex were

found. These two forms of instabilities include an axisymmetric, $n = 0$, as well as an asymmetric, $n = 1$, mode. Here n is the azimuthal wavenumber of the disturbance.

"STABILITY ANALYSIS FOR NOISE-SOURCE MODELING OF A PART-SPAN FLAP"

AIAA Journal, Vol. 37, No. 10, October 1999, pp. 1206-1212.

The relevant and important flow features of the local mean flowfield in the vicinity of a flap side edge are extracted from an extensive computational and experimental database. Based on the local flow features, possible mechanisms for flow-induced noise sources that are responsible for sound generation at flap side edges are conjectured. Relatively simple flow models for the dominant noise sources are proposed and developed. The models are based on the most amplified instability modes of the local shear flow. Stability analysis of the modeled flow field provides an estimate of the frequencies associated with the local flow unsteadiness. Computed frequencies show the proper trend and are in good agreement with NASA Langley Research Center's acoustic microphone array and unsteady surface-pressure measurements.

"ACTIVE CONTROL/ALLEVIATION OF TRAILING (STREAMWISE) VORTICES"

HTC-FR-1803, June 1995, High Technology Corporation, Hampton, VA

This research addressed the feasibility and development of an active control strategy to induce vortex decay in tip vortices. Destabilization and dissipation of wing tip vortices is the dominant issue for reducing wake hazard and increasing airport productivity. The wake hazard problem exists due to the longevity of trailing line vortices and their associated high rotational energy. The phase I investigation focused on an innovative technique for active excitation/energization of large-scale instability modes and inducement of bursting in tip vortices via localized external forcing. Our effort concentrated on modeling the vortex mean flow field, identifying and determining the frequencies and wavelengths of the instability waves, obtaining vortex receptivity to external forcing in the vortex initiation regime, and developing a single-frequency controller system to accomplish the external forcing. We have applied weakly nonlinear analysis to determine the mean flow modifications produced by an excited instability wave. The simulated distribution of the modified vortex circulation showed vortex disablement via bursting is readily achievable.

"REYNOLDS-AVERAGED NAVIER-STOKES COMPUTATIONS OF A FLAP-SIDE-EDGE FLOWFIELD"

AIAA Journal, Vol. 37, No. 1, January 1999, pp. 14-22

An extensive computational investigation of a generic high-lift configuration comprising a wing and a half-span flap reveals details of the mean flow field for flap deflections of 29 and 39 deg. The computational effort involves solutions of the thin-layer form of the Reynolds-averaged Navier-Stokes equations. For both flap deflections, the steady results show the presence of a dual-vortex system: a strong vortex forming on the lower portion of the flap side edge and a weaker one forming near the edge on the flap top surface. Downstream, the vortex on the flap side edge grows and eventually merges with the vortex on the flap top surface. Comparison of on- and off-surface flow quantities with our previous experimental measurements shows remarkable agreement. For the 39-deg flap deflection, the calculation also reveals the occurrence of a vortex breakdown, which is corroborated by five-hole probe velocity measurements performed in the Quiet Flow Facility at NASA Langley Research Center. The presence of the vortex breakdown significantly alters the flow field near the side edge.

"AN EXPERIMENTAL INVESTIGATION ON THE NEAR WAKE CHARACTERISTICS OF A DARRIOUS VERTICAL-AXIS WIND TURBINE"

AIAA Paper 2016-1732, January 2016, San Diego, CA.

The wake flow field ($x/D < 2.5$) measurements behind a two-bladed Darrious type VAWT were carried out by using a high-resolution PIV system, and the results obtained at two different horizontal (x - y) planes, at the equator height ($H/2$) and above the equator height ($3H/4$), for four different tip speed ratios (2, 2.5, 3 and 3.5) of the VAWT were then evaluated and compared. The wake of the VAWT is found to be significantly different to that of the HAWT's. At lower tip-speed-ratio (i.e. TSR 2) the wake tends to be very asymmetric and skewed with relatively higher amount of momentum in the wake in comparison to higher tip-speed ratios (i.e. 3 or 3.5). As tip-speed ratio increases, there is a tendency in flow stagnation in the wake and eventually flow reversal would occur at higher tip-speed-ratios. The wake dynamics (i.e., the instabilities inherent in VAWT) behind the VAWTs would lead to a much faster wake recovery in comparison to the HAWTs.

"AEROSTRUCTURAL PERSPECTIVE ON WINGLETS"

Journal of Aircraft, Vol. 54, No. 3, May-June 2017, pp. 1121-1138.

This paper presents an aero-structural perspective on the potential benefits of wings with winglets in comparison to planar wings of the same projected span. There is no consensus in the current literature on the efficiency gains possible from winglets. The present paper takes a step further toward understanding the tradeoffs in the design of wings with winglets using high-fidelity numerical optimization based on both purely aerodynamic and fully coupled aero-structural analysis. The high-fidelity analysis in both cases uses the Euler equations to model the flow along with a friction drag estimate based on the surface area. Three configurations are considered: winglet-up, winglet-down, and planar. The results show that downward winglets produce a greater drag reduction than upward

winglets for two reasons. First, the downward winglet moves the tip vortex further away from the wing from a purely aerodynamic standpoint. Second, the winglet-down configuration has a higher projected span at the deflected state due to the structural deflections. This indicates that fully coupled high-fidelity aero-structural optimization is required to quantify the benefits of winglets properly. The winglet-down configuration can reduce the total drag by up to 2 percent at the same weight as the optimal planar counterpart.

"SPATIAL SIMULATION OF CONTRAIL FORMATION IN NEAR-FIELD OF COMMERCIAL AIRCRAFT"

Journal of Aircraft, Vol. 52, No. 6, November-December 2015, pp. 1927-1938.

During this study, three-dimensional numerical simulations of contrails generated by commercial aircraft in cruise conditions were performed. The objective was to study the early development of contrails in the near field of an aircraft, including engine core and bypass flows. Computational fluid dynamics simulations, based on the three-dimensional Reynolds-averaged Navier-Stokes approach, were carried out on a realistic aircraft geometry. A microphysical model was implemented in the computational fluid dynamics code to simulate particle growth using a Eulerian approach. Results showed that the mixing process in the bulk plume were in good agreement with the literature. Then, the early growth of a contrail in the near wake of the aircraft was investigated for two ambient relative-humidity conditions. This parameter played a significant role in contrail local properties. Increased relative humidity led to an increase in the fraction of particles under the supersaturated condition and condensation rate. This resulted in a higher mean particle radius and, consequently, in a higher optical depth, making contrails more distinct. Particle-size distribution shifted toward larger particles due to an increase in available vapor and got narrower as the relative humidity increased because more particles were in favorable conditions for ice growing.

Kiang, R. L.

"SUB-SCALE MODELING OF AIRCRAFT TRAILING VORTICES"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 81-95

A pilot study of trailing vortices using a sub-scale model is described. The essential feature of the laboratory facility is to have a vortex-generating wing moving along a pair of elevated rails so that the vortices shed by the wing remain relatively fixed with respect to ground-based instrumentation and can be observed and measured throughout their entire life-span. The vortices are rendered visible by smoke traces and by drifting soap bubbles. Hot-wire anemometer probes are used to study the turbulence nature of the vortices. Geometrically similar wings of different sizes running at various speeds and angles of attack have been tested. A scaling study is also described based on existing theories that predict the decay rate of a turbulent line vortex. None of the theories examined is capable of correlating the results of the sub-scale experiments.

"AIRPORT CAPACITY PREDICTION WITH EXPLICIT CONSIDERATION OF WEATHER FORECAST UNCERTAINTY"

Journal of Air Transportation, Vol. 24, No. 1, January 2016, pp. 18-28.

This paper describes a stochastic analytical model for predicting airport capacity with a look-ahead horizon suitable for strategic traffic flow management. The model extends previous research on airport capacity estimation by explicitly integrating the impact of terminal weather and its uncertainty. Different types of weather forecast inputs are explored, including deterministic forecasts, deterministic forecasts with forecast error models, and ensemble forecasts, to produce distributions of predicted arrival and departure capacity for each runway configuration at an airport. The paper introduces a mathematical capacity prediction model and weather data sources supported by a proof-of-concept prototype implementation, including results of validation studies at Hartsfield-Jackson Atlanta International Airport. These results are compared with standard airport benchmark capacities and actual observed throughputs. Results show that our analytical airport capacity model accurately predicts maximum available airport capacity for Hartsfield-Jackson Atlanta International Airport for different weather conditions. The validation studies reveal a limited impact of forecast uncertainty representation on the accuracy of airport capacity predictions.

Kida, S.

"DESCRIPTION AND DYNAMICS OF VORTICAL STRUCTURES OF TURBULENCE"

Lecture Notes in Physics, Vol. 567, 2001, pp. 3-16

The vortical structure of turbulence is analyzed in terms of the low-pressure vortex, the central axis of which is given by loci of pressure minimum and the core is defined as concave regions of pressure. Since the position and direction of vortex axes are specified, we can analyze the vorticity field by decomposing the axial and cross-axial components. It is found that the fundamental vortical structure - the elementary vortex - is a tubular vortex core with strong axial vorticity accompanied with spirally wrapped vortex layer of cross-axial vorticity. These surrounding layers can contribute more than the tubular cores to energy dissipation because of their wider spatial extent.

Kida, S. and Miura, H.

"IDENTIFICATION AND ANALYSIS OF VORTICAL STRUCTURES"

European Journal of Mechanics, B/Fluids, Vol. 17, No. 4, 1998, pp. 471-488.

Various identification and visualization methods of vortical structures, especially of slender vortices, are critically reviewed with a special attention to their objectivity. The sectional-swirl-and-pressure-minimum scheme is presented as a new identification method and applied to homogeneous turbulence. Since the physical quantities associated with an individual vortex can be analyzed separately, this new scheme enables us to investigate quantitatively various physical characteristics

related to vortices, such as the variations of the core shape, the circulation and the vorticity vector along a vortex and the temporal evolution of arbitrarily selected vortices.

Kida, S. and Takaoka, M.

"VORTEX RECONNECTION"

Annual Review Fluid Mechanics, 1994, Vol. 26, pp. 169-189

Understanding the dynamics and the mutual interaction among various types of vortical motions, including vortex reconnection, is a key ingredient in clarifying and controlling fluid motions. Thanks to the rapid development of supercomputers, the direct numerical study of vortex reconnection has become possible in the past few years. Complete data of field quantities, such as velocity, vorticity, and concentration of a passive scalar, at any time and at any position can be stored in the computer memory. There have been many numerical simulations published so far with various motivations ranging from fundamental physics to engineering application. But for understanding the fundamental mechanism of vortex interaction, which is our main concern here, it is better to investigate the simplest situation possible that still retains some essential mechanism. In this review we describe the current understanding of vortex (vorticity or scalar) reconnection and the related phenomena from a fundamental point of view.

Kida, S., Kawahara, G., Tanaka, M. and Yanase, S.

"VORTICITY DYNAMICS AROUND A STRAIGHT VORTEX TUBE IN A SIMPLE SHEAR FLOW"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany, pp. 173-182.

The mechanism of wrap, tilt and stretch of vorticity lines around a strong thin straight tubular vortex in a simple shear flow is investigated analytically. An asymptotic expression of the vorticity field around a vortex which starts with a filament is derived at large vortex Reynolds numbers and at short times of evolution. An oblique vortex, which inclines from the streamwise direction both to the vertical and the spanwise, wraps and stretches the simple shear vorticity to form double spiral layers of high azimuthal vorticity of alternating sign in adjacent spirals. These spirals induce axial shear flows of the same spiral shape and sign which in turn tilt the simple shear vorticity toward the axial direction. Vorticity lines wind helically around the vortex, which results in conversion of the simple shear vorticity to the axial direction. The effects of system rotation on this interaction are also discussed.

Kidd, R. M.

"WAKE TURBULENCE - THE INVISIBLE KILLER"

CATCA Journal, Vol. 5, Fall 1973, pp. 4-7

A number of hazardous takeoff situations and some accidents caused by wake vortices (wing tip vortices) from a preceding aircraft on a congested runway are described. Details are given on a wake vortex accident of June 8, 1966, resulting in a collision of an XB-70 and an F-104 over the Mojave Desert in California, and on the crash of a DC-9 behind a DC-10 at Fort Worth on May 30, 1972. Recommendations made by the ALPA air safety team after the crash are listed.

Kier, T. M.

"AN INTEGRATED LOADS ANALYSIS MODEL FOR WAKE VORTEX ENCOUNTERS"

International Forum on Aeroelasticity and Structural Dynamics (IFASD 2013), Paper 30C, June 2013, Bristol, UK.

When a plane crosses the wake generated by a preceding aircraft, large dynamical loads in the order of the design loads may be induced. Loads analysis models for such wake vortex encounters need to consider aspects important for maneuver, as well as gust type responses. If the angle between the path and the trailing vortices is small, the encounter is maneuver like due to large induced roll motion. When the vortices are crossed almost perpendicularly, a gust type response is to be expected, where unsteady aerodynamic effects are significant. Previously a modeling approach of an integrated loads analysis model suitable for wake vortex encounters was presented. This contribution will further investigate the requirements for such flight loads models for wake vortex encounters. One important aspect is, that the bandwidth of the excitation due to gust type wake vortex encounters is considerably larger compared to classical design gusts. Hence, the convergence behavior for high reduced frequencies of the doublet lattice models needs to be examined in more detail. A rational function approximation (REA) is required to make the unsteady aerodynamics amendable for nonlinear time domain simulations. Previously, a 'physical' RFA could significantly improve the results for incompressible flow at high reduced frequencies by explicit approximation of the added mass term. The 'physical' RFA scheme is now extended to the compressible regime. The results are compared to the solution of the Poisson's equation and a velocity potential method for unsteady motion of airfoils in compressible flow. Further, the (time domain) integral loads analysis model is compared to a frequency domain approach. Induced velocities due to a pre-described trajectory for a wake crossing are determined. A subsequent Fourier transformation yields the excitation spectrum for the frequency domain calculations. Various encounter angles with wake vortices are computed and compared to time domain simulations, where the trajectory is determined as a nonlinear response during the simulation. Results show that in some encounter scenarios these nonlinearities can become crucial.

Kikumoto, H., Ooka, R., Sugawara, H. and Lim, J.

"OBSERVATIONAL STUDY OF POWER-LAW APPROXIMATION OF WIND PROFILES WITHIN AN URBAN BOUNDARY LAYER FOR VARIOUS WIND CONDITIONS"

Journal of Wind Engineering and Industrial Aerodynamics, Vol. 164, 2017, pp. 13-21.

This paper investigates the accuracy and limitations of wind profile modeling using the power-law (PL), especially for low-speed conditions in which air and thermal pollution can prevail. A Doppler lidar system and ultrasonic anemometer were installed to measure wind profiles and turbulence statistics in the urban boundary layer of Tokyo, Japan over seven months. The wind speeds at a height of 67.5 m (u) at average intervals of 10 min were < 6 m/s for 80 percent of the observation period. For low wind speeds, the difference in wind direction with height is significant, making it difficult to determine the prevailing wind direction. The PL could be used to model the wind profiles for high wind speeds ($u > 6$ m/s), whereby the power-law index (PLI) converges to 0.25. Although the PL model can be used for an ensemble-averaged profile composed of all profiles from the observed period, the accuracy of the PL decreases for profiles with low speeds and short average time intervals. The PLI on average decreases to -0.21 for low wind speeds and shows diurnal changes with small PLIs during the daytime. This research quantitatively discusses the application limits of the PL for wind profiles under low-speed conditions.

"A COMPARISON OF GROUND-BASED LIDAR AND MET MAST WIND MEASUREMENTS FOR WIND RESOURCE ASSESSMENT OVER VARIOUS TERRAIN CONDITIONS"

Journal of Wind Engineering and Industrial Aerodynamics, Vol. 158, 2016, pp. 109-121.

In order to assess reliability of measurements from LiDAR (Light Detection and Ranging), a measurement campaign was led using ground-based LiDAR of WINDCUBE V2 and meteorological masts at three measurement sites: Sumang, Gangjeong, and Susan, on Jeju Island, Korea. Each site had a different topographical complexity, which was evaluated by using a Ruggedness Index (RIX). Wind data was collected for 11-14 days from four heights on each site's met mast. Data filtering was done to ensure data comparability between LiDAR and wind sensors. Analyses of LiDAR error, standard deviation, turbulence intensity and LiDAR error rate were conducted on data coming from each site. Also, the CFD analysis was performed at Sumang with the highest RIX. As a result, the concurrent wind measurement slopes were all close to one based on linear regression analysis. The coefficient of determination was almost all more than 0.9 for all heights at each site. LiDAR error rates for the measurement sites ranged from approximately between 2% and 6%. The result of the CFD analysis showed that the depression was formed between two parasitic cones, between which the measurement point of Sumang was located, which led to greater positive LiDAR error.

"IMPROVED METHOD FOR ROTOR WAKE CAPTURING"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 794-803

An accurate simulation of rotor aerodynamics has been a challenging problem for the computational fluid dynamics community, largely because numerical diffusion in the typically coarse grids away from the blades seriously degrades the prediction of the returning wakes. A numerical scheme is proposed

to improve the reconstruction stage of a MUSCL approach in the framework of a finite volume formulation. A fourth-order upwind scheme, based on the interpolation of the local characteristic variables in the reconstruction stage, is applied instead of the conventional third-order upwind-biased scheme. Different slope limiters are applied to different characteristic fields to reduce the numerical dissipation of entropy and shear waves. We have implemented the proposed scheme into the TURNS code. Numerical results for a hover case show a significant improvement in the wake capturing capability over the baseline TURNS code.

Kim, H., Williams, M. H. and Lyrintzis, A. S.

"AN IMPROVED METHOD FOR ROTOR WAKE CAPTURING"

AIAA Paper No. 2001-2669, Anaheim, CA, June 2001

Accurate simulation of rotor aerodynamics has been a challenging problem for the computational fluid dynamics (CFD) community, largely because numerical diffusion in the typically coarse grids away from the blades seriously degrades the prediction of the returning wakes. In this paper, we propose a numerical scheme to improve the reconstruction stage of a MUSCL (Monotone Upstream-centered Scheme for Conservation Law) finite volume formulation. A fourth-order upwind scheme, based on the interpolation of the local characteristic variables in the reconstruction stage is applied instead of the conventional third-order upwind biased scheme. Different slope limiters are applied to different characteristic fields to reduce the numerical dissipation of entropy and shear waves. We have implemented the proposed scheme into the TURNS (Transonic Unsteady Rotor Navier-Stokes) code. Numerical results for a hover case show a significant improvement in the wake capturing capability over the baseline TURNS code.

Kim, H.-J., Lee, S. and Fujisawa, N.

"COMPUTATION OF UNSTEADY FLOW AND AERODYNAMIC NOISE OF NACA0018 AIRFOIL USING LARGE-EDDY SIMULATION"

International Journal of Heat and Fluid Flow, B/Fluids, Vol. 27, Issue 2, April 2006, pp. 229-242

The flow field around a symmetrical NACA airfoil in the uniform flow under generation of noise was numerically studied. The numerical simulation was carried out by a large-eddy simulation that employs a deductive dynamic model as the sub-grid scale model. The results at small angle of attack indicate that the discrete frequency noise is generated when the separated laminar flow reattaches near the trailing edge of pressure side and the strong instability thereafter affects positive vortices shed near the trailing edge. The quasi-periodic behavior of negative vortex formation on the suction side is affected by the strength and the periodicity of positive vortices near the trailing edge. The computation using aero-acoustic analogy indicates the primary discrete peak at the Strouhal frequency by the vortex shedding from the trailing edge, which is in a close agreement with the experiment.

Kim, J. M. and Komerath, N. M.

"SUMMARY OF THE INTERACTION OF A ROTOR WAKE WITH A CIRCULAR CYLINDER"

AIAA Journal, Vol. 33, No. 3, March 1995, pp. 470-478.

To compute the aerodynamics of a rotorcraft in low-speed flight, the interaction of the strong vortices in the rotor wake with the airframe must be modeled. Using a hemisphere cylinder airframe and a 2-bladed rotor for reference, the various phenomena encountered during such interactions are summarized, combining previous results on various configurations with recent experimental results. Differences between the interaction at the front and aft positions of the wake are discussed. The pre-collision phase conforms to expectations from potential flow, and includes distortion of the vortex trajectory determined by the sense of rotation of the vortex. The collision phase involves complex boundary layer interactions. The axial velocity in the vortex core causes substantial asymmetry, and influences the surface pressure distribution on the airframe side under the advancing rotor blade, where the axial flow stagnates. The post-interaction vortex is much weaker, but still contains some swirl energy. Where flow separation occurs due to airframe shapes, the interaction is not modified significantly, because the vortex dominates the interaction with separated shear layers for parameter values of practical interest. Areas of remaining uncertainty are discussed.

"APPLICATION OF AVIATION TURBULENCE INFORMATION TO AIR-TRAFFIC MANAGEMENT (ATM)"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 24, 2016, Springer International Publishing Switzerland, pp. 481-500.

Unexpected turbulence, especially in the upper troposphere and lower stratosphere where cabin crews and passengers in cruising aircraft are likely to be unbuckled, causes in-flight injuries, structural damage, and flight delays. Therefore, turbulence information can be used to improve safety while pursuing efficiency in the air-traffic management (ATM). In this chapter, an optimal flight path that minimizes both total flight time (e.g., fuel consumption) and potential encounters of turbulence from departure to arrival airports is derived by combining simple modeling of aircraft flight trajectories with wind and turbulence predictions. In addition, probabilistic ensemble turbulence forecasts, evaluated against in situ eddy dissipation rate turbulence observations from commercial aircraft, are applied to suggest an optimal strategic and tactical ATM route planning for given weather and turbulence conditions in the USA. The variations of long-haul transoceanic flight routes and their turbulence potentials are also investigated using global reanalysis data to understand how the upper-level large-scale flow patterns can affect the long-term ATM planning through the changes of winds and turbulence conditions.

"DILATATION AND VORTEX STRETCHING EFFECTS ON TURBULENCE IN ONE-DIMENSIONAL/AXISYMMETRIC FLOW"

AIAA Journal, Vol. 40, No. 12, December 2002, pp. 2476-2482.

A theoretical analysis is carried out to predict the amplification of turbulence in flows experiencing one-dimensional and axisymmetric dilatations. When three representative vortices are tracked, the variations of vortex radius and vorticity are calculated, and then the amplification of turbulence is obtained from them. When a vortex is tracked, conservation laws of mass and angular momentum of the vortex are used. For a one dimensionally compressed flow, the present analysis slightly underestimates the amplification of velocity fluctuations and turbulent kinetic energy, relative to that of rapid distortion theory in the solenoidal limit. For an axisymmetrically distorted flow, the amplification of velocity fluctuations and turbulent kinetic energy and the anisotropy depend not only on the density ratio, but also on the ratio of streamwise mean velocities, which represents streamwise vortex contraction/stretching. The amplification predicted by the present analysis is in excellent agreement with that by the rapid distortion theory. In both flows, the amplification of turbulence is dictated by the mean density ratio, whereas the anisotropy is primarily dictated by the flow boundary. However, streamwise vortex stretching/contraction alters the amplification slightly and the anisotropy significantly in the axisymmetric flow.

"APPLICATION OF CONTINUOUS VORTICITY PANELS TO GENERAL UNSTEADY INCOMPRESSIBLE TWO-DIMENSIONAL LIFTING FLOWS"

J. Aircraft, Vol. 23, No. 6, June 1986, pp. 464-471

Continuous vorticity panels are used to model general unsteady inviscid, incompressible, two-dimensional lifting flows. The geometry of the airfoil is approximated by a series of short straight segments having endpoints that lie on the actual surface. A piecewise linear, continuous distribution of vorticity over the approximated surface is used to generate the disturbance flow. The no-penetration condition is imposed at the midpoint of each segment and at discrete times. The wake is simulated by a system of discrete vortex cores (point vortices), which move at the local particle velocity. At each time step a new core is placed at the trailing edge, and the condition of constant circulation around wing and wake is imposed. Because the system is overdetermined, an optimization scheme is used to obtain simultaneously the unknown values of the surface velocity at the endpoints of the segments and the unknown value of the circulation around the core at the trailing edge. Comparisons are made with known exact solutions and wind tunnel data for one- and two-component airfoils in steady flow, and with other computed results and one experiment for unsteady flow. The present approach provides an attractive alternative to those developed earlier, being easy to formulate, easy to use, and very accurate.

"LONG TIME COMPUTATION OF TWO-DIMENSIONAL VORTEX SHEET BY POINT VORTEX METHOD"

Journal of the Physical Society of Japan, Vol. 72, No. 8, August 2003, pp. 1968-1976.

Two-dimensional vortex sheet suffers an unstable deformation from the Kelvin-Helmholtz instability and a curvature singularity which develops in a finite time. In this paper, long time computations of the two-dimensional vortex sheet are performed by a robust and efficient numerical method with high accuracy. To handle the rapid and non-uniform stretching of the interface, we adopt the adaptive point insertion and redistribution procedures. Computational results show highly refined structures of a complex and chaotic pattern for the vortex sheet up to very long time.

"PREDICTION OF TIP-VORTEX FLOW PAST A FINITE WING"

AIAA Paper No. 2005-0058, Reno, NV, January 2005

Turbulent flow past a finite wing is computed to assess the fidelity of modern computational fluid dynamics (CFD) in predicting the tip-vortex flow. Efficacy of a feature-adaptive local mesh adaption is demonstrated to resolve the steep gradients in the flow-field near the tip-vortex. The impact of turbulence modeling is evaluated using several popular eddy-viscosity models and a Reynolds-stress transport model. The results indicate that the combination of a computational mesh with adequate resolution, high-order spatial discretization scheme and advanced turbulence models can predict the tip-vortex flow with commendable accuracy.

"WINGTIP VORTEX SIMULATION BY USING NONEQUILIBRIUM EDDY VISCOSITY MODEL"

Journal of Aircraft, ol. 47, No. 6, Nov.-Dec. 2010, pp. 2184-2187.

This study investigates the performance of the nonequilibrium eddy viscosity model, proposed by Yoshizawa et al., for the simulation of the wingtip vortex. Results predicted by using the standard k-e model, the two-component-limit (TCL) second-moment closure model, and the nonequilibrium model were compared with the experimental data of Chow et al. Through the comparison, we found that the nonequilibrium model performed as good as or only slightly inferior to the TCL model. We thus conclude that the nonequilibrium eddy viscosity model is indeed a very good model for practical wingtip vortex simulation, considering the fact that the TCL model is a Reynolds stress transport model, which is not as easy as two-equation turbulence models for practical application.

Kimura, Y.

"MOTION OF THREE-DIMENSIONAL VORTEX FILAMENT AND PARTICLE TRANSPORT"

In IUTAM Symposium on Elementary Vortices and Coherent Structures: Significance in Turbulence Dynamics, edited by S. Kida, Springer, The Netherlands, 2006, pp. 275-282.

Motions of fluid particles advected by a 3D vortex filament are studied. As extensions of a circular vortex ring, which provides a basis of fluid transport by vortex, two types of motions, elliptic vortex ring

and vortex soliton are considered. For an elliptic vortex ring, it is verified that the local induction equation (LIE) describes its motion properly if the aspect ratio is close to 1. Using the solution of LIE, particle motions are simulated for two different induction constants corresponding to a thin and a fat vortex for the circular vortex ring case, respectively. Intrinsic difficulty for calculating the finite transported volume by an elliptic vortex ring is suggested. For a vortex soliton, it is demonstrated that particle motions are confined in a torus near the kink of a soliton for a wide range of parameters that characterize the shape and the strength of the vortex soliton.

"VORTEX MOTION, SOUND RADIATION, AND COMPLEX TIME SINGULARITIES"

Physics of Fluids, Vol.A2, No. 2, Feb. 2009, pp. 214-219.

The equations of motion for interacting point vortices can be embedded in a system of ordinary differential equations with polynomial couplings and thus subjected to the 'Painleve test' for integrability. The arrays of singularities produced by this analysis confirm well known results on integrability and chaos in few-vortex systems, and are shown by further numerical experiments to predict qualitative features of the low Mach number sound radiation from the vortex system. The correspondence between singularity distribution, vortex trajectory pattern, time series of far-field pressure, and sound spectrum are illustrated and discussed based on a parametric numerical survey of some simple three- and four-vector motions. The results suggest a physical interpretation of the Painleve singularities.

"RECENT DEVELOPMENTS IN BACKGROUND ORIENTED SCHLIEREN METHODS FOR ROTOR BLADE TIP VORTEX MEASUREMENTS"

13th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, June 2006

Compressible blade tip vortices (BTV) of rotary wings have been subject of numerous investigations and their importance for the understanding of the helicopter flow field has clearly been drawn. Due to its great impact on the dynamics of the flow field, the investigation of the BTV is directly linked to issues of flow control and aeroacoustic optimization. However, despite of the velocity field data of the BTV, additional density information for vortex modeling is desirable. In this work we briefly describe the set-up of an airborne background oriented optical stereoscopic schlieren (BOSS) system for helicopter flight tests as well as preliminary experimental results of background oriented optical tomography (BOOT) of a 0.4 Mach scaled rotor model investigation. The tomographic approach enabled us computing an estimate of the tip vortex density field. This method is demonstrated to yield reasonable scales of the vortex core diameter. The advantages and applicability of the filtered back-projection method for rotor investigations will be discussed.

Kindler, K., Goldhahn, E., Leopold, F. and Raffel, M.

"RECENT DEVELOPMENTS IN BACKGROUND ORIENTED SCHLIEREN METHODS FOR ROTOR BLADE TIP VORTEX MEASUREMENTS"

Experiments in Fluids, Vol. 43, 2007, pp. 233-240

The compressible blade tip vortex of rotary wings has been the subject of numerous investigations and its importance for the understanding of the helicopter flow field has been clearly emphasized. Due to its great impact on the dynamics of the flow field, the investigation of the tip vortex is directly linked to issues of flow control and aero-acoustic optimization. However, among velocity field data, additional core density information on the blade tip vortex is desirable with a view to vortex modelling. In this work we describe an airborne background oriented Schlieren system for full-scale helicopter flight tests as well as the first results of the tomographic reconstruction of the compressible vortex core. We report the measurements of both a 0.4 Mach-scaled rotor model of the MBB BO 105 and the corresponding full-scale helicopter in hover flight condition. The tomographic reconstruction of the data allows us to estimate the density and the radius for the viscous core.

"TOWARDS IN-FLIGHT MEASUREMENTS OF HELICOPTER BLADE TIP VORTICES"

Advanced In-Flight Measurement Techniques, Research Topics in Aerospace, edited by F. Boden et al, 2013, Springer-Verlag Berlin Heidelberg, pp. 171-185.

In the framework of the AIM project the near field of the blade tip vortex of a full-scale helicopter in simulated hover flight was investigated by combining three-component Particle Image Velocimetry and Background Oriented Schlieren measurements. The velocity field measurements in the range of wake ages of 1 degree to 30 degrees in azimuth provided a reference for a quantitative analysis of the Schlieren results yielding vortex core density estimates. Ongoing vortex roll-up was observed at 1 degree while considerable aperiodicity was persistent thereafter. The vortex parameters for greater than 1 degree were consistent with the Scully vortex model. However, the challenges of full-scale, outdoor testing, especially the limited spatial resolution and aperiodicity effects, yielded a higher level of measurement uncertainty as compared to sub-scale experiments.

Kindler, K., Mulleners, K., Richard, H., van der Wall, B. G. and Raffel, M.

"APERIODICITY IN THE NEAR FIELD OF FULL-SCALE ROTOR BLADE TIP VORTICES"

Experimental Fluids, Vol. 50, 2011, pp. 1601-1610.

Blade tip vortices are the dominant vortical structures of the helicopter flow field. The inherent complexity of the vortex dynamics has led to an increasing interest in full-scale in situ experiments, where the near field, closely behind the blade, is of particular interest, since measures of vortex control mostly target this initial stage of development. To examine the near field, three-component particle image velocimetry (PIV) measurements of blade tip vortices of a full-scale helicopter in simulated hover

flight in ground effect were conducted. A feasible and robust evaluation procedure was developed to minimize the shortcomings of full-scale PIV applications, such as a moderate spatial resolution and an elevated measurement noise level. At vortex ages ranging from rotor azimuth 1 to 30 degrees, a pronounced aperiodicity and asymmetry of the vortex were observed in sections perpendicular to the vortex axes. At a rotor azimuth of 1 degree, a preferential orientation of the vortex was observed. For increasing wake age, vortex wandering increased while the asymmetry of the vortex cores decreased. The high level of aperiodicity and core asymmetry must be taken into account when considering phase-averaged vortex characteristics in the near wake region.

King, R. M. and Gopalaranthnam, A.

"IDEAL AERODYNAMICS OF GROUND EFFECT AND FORMATION FLIGHT"

J. of Aircraft, Vol. 42, No. 5, September-October 2005, pp. 1188-1199

The theoretical induced-drag benefits are presented for ideally loaded wings flying in formation and ground effect. An optimum-downwash approach using a vortex-lattice implementation was used to study formations of wings loaded optimally for minimum induced drag with roll trim. An exact approach was also developed to examine the drag of elliptically loaded wings in formation. The exact approach allows for decomposition of the benefits by considering the mutual-interference contributions from different pairs of wings in a formation. The results show that elliptically loaded wing formations have nearly the same drag as optimally loaded wing formations. For a formation of planar wings, in or out of ground effect, the optimum lateral separation corresponds to a 10% span overlap of wing tips. At this optimum lateral separation, a formation of 25 elliptically loaded wings flying out of ground effect experiences an 81% drag reduction compared to 25 wings flying in isolation. For large formations, in or out of ground effect, multiple local optima are seen for the lateral separation. Large formations experience small additional benefits caused by ground effect even at relatively large ground clearances of four wing spans. The shape of vee formations, for equipartition of drag benefits, is found to be nearly independent of flight in or out of ground effect.

"NATURE OF LOCALLY STEADY ROTOR WAKES"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 750-758

The regions over which steady and unsteady rotor wake patterns exist have been examined numerically for one- and two-bladed rotors. A lifting-line theory is used to model each rotor blade, and a time-stepping vortex method is used to calculate the tip-vortex motion. Tip-vortex geometries for a rotor in hover and vertical climb have been computed. The velocities within the first few turns of the wake have been obtained, and the results indicate a periodic nature of the wake in both time and space. Temporal aperiodicity is observed beyond the first few turns of the tip vortex for hovering rotors, whereas for rotors in sufficient climb the entire wake is steady relative to the blades and both spatially and temporally periodic. Both Euler and Adams-Moulton schemes have been tested for

accuracy. The numerical results are shown to be independent of both time step and spatial grid below clearly defined values. Rotor thrust calculations have been performed and the effect of the lower wake on rotor thrust determined. The computed thrust values show some variation because the lower wake remains unsteady. The results for the wake geometry are analyzed and compared to previous predictions and two distinct sets of experimental results.

Kini, S., Godavarty, V. and Conlisk, A. T.

"COMPARISON OF TWO DISTINCT MODELS OF ROTOR WAKES WITH EXPERIMENT"

AIAA Paper No. 2002-0158, Reno, NV, January 2002

Rotor blades are often modeled using either the lifting-line or the lifting-surface approach. Classical lifting-line theory treats the case of a high aspect ratio blade where the blade is modeled by a single bound vortex line. The lifting-line approach will thus be expected to be accurate for large aspect ratio wings and rotor blades. In the lifting-surface approach the blade is modeled by a thin lifting surface to more realistically resolve the chordwise flow close to the blade surface and its effect on the formation of the tip-vortex and consequently the entire wake. The objective of the present work is to compare results from two distinct vortex-wake models. The Wake Model with Lifting-Line has a robust model for the wake. The Lifting-Surface Model with Wake Effects has a robust model for the lifting-surface with additional terms in the governing equations representing a simplified model for the wake. Bound and tip-vortex strengths, tip-vortex trajectories, and velocity profiles very close to the blade are evaluated using these models. It is observed that the results obtained from these models are comparable. To establish the validity of the models the results are also compared with experimental data.

"EVALUATION OF EFFECTIVENESS OF VARIOUS DEVICES FOR ATTENUATION OF TRAILING VORTICES BASED ON MODEL TESTS IN A LARGE TOWING BASIN"

NASA CP-2202, December 1973, Hydronautics Inc., Laurel, MD

The effectiveness of various candidate aircraft-wing devices for attenuation of trailing vortices generated by large aircraft is evaluated on basis of results of tests conducted with a 0.03-scale model of a Boeing 747 transport aircraft using a unique technique developed at the Hydronautics Ship Model Basin. Emphasis is on the effects produced by these devices in the far field where the unaltered vortex wakes could still be hazardous to small following aircraft.

Kirkpatrick, D. L. I.

"EXPERIMENTAL INVESTIGATION OF THE BREAKDOWN OF A VORTEX IN A TUBE"

ARC Paper CP-821, 1965, Royal Aircraft Establishment, Bedford, England

The distribution of the total pressure and the angle of swirl across a vortex in a tube were measured using a pitot probe upstream of breakdown. The static pressure distribution along the length of the tube containing the breakdown was also measured. It was found that the total pressure fell sharply in the vortex core towards a very low value on the axis, and that the swirl-angle distribution was similar to that of an exponential vortex. The static pressure distribution along the wall of the tube was found to include a positive pressure gradient upstream and a negative pressure gradient downstream of the breakdown's position. When breakdown did not occur these pressure gradients were not present. From the total pressure and swirl-angle distributions across the vortex, the static and dynamic pressure distributions and the axial and circumferential velocity distributions were calculated. These results will be used as boundary conditions for numerical solution of the equations of motion of the vortex.

"ESTIMATION OF MOMENTS OF INERTIA OF AIRPLANES FROM DESIGN DATA"

NACA TN-575, July 1936, Langley Aeronautical Lab., Langley Field, VA.

A method of determining the moments of inertia of an airplane from design data pertaining to the weights and locations of the component parts is described. The computations required to ascertain the center-of-gravity position are incorporated with the calculations of moments of inertia. A complete set of data and calculations for a modern airplane is given to illustrate the procedure. From a comparison between calculated values and measured values it is believed that the moments of inertia can be estimated within 10 percent by use of this method.

Kirschbaum, H. W.

"ESTIMATION OF MOMENTS OF INERTIA OF AIRPLANES FROM DESIGN DATA"

Technical Note No. 575, July 1936, Langley Memorial Aeronautical Laboratory, Hampton, VA.

A method of determining the moments of inertia of an airplane from design data pertaining to the weights and locations of the component parts is described. The computations required to ascertain the center-of-gravity position are incorporated with the calculations of moments of inertia. A complete set of data and calculations for a modern airplane is given to illustrate the procedure. From a comparison between calculated values and measured values it is believed that the moments of inertia can be estimated within 10 percent by use of this method.

"HAZARDS DUE TO HELICOPTER WAKES"

College of Aeronautics Report No. 9311, Dec. 1993, Cranfield University, Bedford, UK

The local velocities induced in the wake of a helicopter can be a serious hazard to light aircraft operating nearby. A theoretical model is developed which makes it possible to estimate the rolling

moment induced on a light aircraft entering the wake of a helicopter. The model shows good agreement with the limited amount of flight test data available. An annotated bibliography of the literature available on helicopter wakes is presented to identify specific areas in which further research is required.

"A STUDY OF BLADE-VORTEX INTERACTION AEROACOUSTICS UTILIZING AN INDEPENDENTLY GENERATED VORTEX"

Aerodynamics and Aeroacoustics of Rotorcraft, AGARD-CP-552, August 1995, pp. 20-1 to 20-19.

This paper presents results from an experimental study of rotor blade-vortex interaction (BVI) aerodynamics and acoustics. The experiment utilized an externally generated vortex interacting with a two-bladed rotor operating at zero thrust to minimize the influence of the rotor's own wake. The rotor blades were instrumented with a total of 60 absolute pressure transducers at three spanwise and ten chordwise stations on both the upper and lower surfaces. Acoustic data were obtained with fixed near-field microphones as well as a movable array of far-field microphones. The test was carried out in the acoustically treated test section of the NASA Ames 80- by 120-Foot Wind Tunnel. Several parameters which influence BVI, such as vortex-rotor separation distance, vortex strength, and vortex sense (swirl direction), as well as rotor tip Mach number and advance ratio, were varied. Simultaneous measurements were obtained of blade surface pressure distributions, near-field acoustics, and far-field acoustics during the vortex-blade encounters.

"EXPERIMENTAL INVESTIGATION OF SLENDER STREAMWISE VORTICES AND OBLIQUE SHOCK-VORTEX INTERACTION"

AIAA Paper No. 2005-4652, Toronto, Canada, June 2005

Velocity measurements of a slender streamwise vortex and vortex breakdown caused by the interaction of the vortex with an oblique shock (oblique shock-vortex interaction, OSVI) are presented. The circumferential and axial velocity profiles of the supersonic wing tip vortex are measured at two freestream Mach numbers and three locations downstream of the vortex generator for four vortex strengths using a two-component Laser Doppler Velocimetry (LDV) system. The velocity distribution in the interaction region of the vortex and the shock are investigated by Particle Image Velocimetry (PIV) at freestream Mach numbers. In order to obtain information about the global structure of the flow field and unsteady flow phenomena, the flow is visualized using the schlieren technique in conjunction with a high-speed digital video camera. The LDV measurements show the axial Mach number distribution of the vortex to possess a distinct wake-like profile, while the tangential Mach number profile has the shape of an asymmetric Burgers vortex. The experiments also reveal the decay in the swirl ratio of the vortex as it travels downstream. Furthermore, flow visualizations evidence the strong time-dependent

behavior of the flow structure and the existence of a locally normal shock in the vicinity of the vortex core.

Klaas, M., Thomer, O. and Schroder, W.

"EXPERIMENTAL AND COMPUTATIONAL INVESTIGATION OF OBLIQUE SHOCK-VORTEX INTERACTION"

AIAA Paper No. 2002-3305, St. Louis, MO, June 2002

Experimental and numerical results of vortex breakdown caused by the interaction of slender vortices and oblique shocks (oblique shock-vortex interaction, OSVI) are presented. Wind tunnel experiments are conducted at freestream Mach numbers of 2.0 and 2.9. To obtain information about the global structure of the flow field and unsteady flow phenomena, the flow is visualized using a color-schlieren method along with a digital video camera. For a more detailed analysis of the shock-vortex interaction the differential interferometry is applied. The numerical investigation is based on solutions of the Euler and Navier-Stokes equations for unsteady three-dimensional supersonic flow. The experimental and numerical results show the strong time-dependent behavior of the flow structure and evidence the necessity of a locally normal shock in the vicinity of the vortex core to cause vortex breakdown.

Klar, J.-U. and Breitsamter, C.

"UNSTEADY AERODYNAMIC LOADS ON A HIGH-AGILITY AIRCRAFT DUE TO WAKE VORTEX ENCOUNTER"

Journal of Aircraft, Vol. 51, No. 5, September-October 2014, pp. 1511-1521.

The presented investigation focuses on the determination of unsteady aerodynamic loads for different kinds of wake vortex encounters. The wake-generating aircraft is a delta-canard configuration, whereas for the penetration, just a delta wing is considered. Based on extensive experimental and numerical investigations of the wake vortex system of a preceding aircraft, the wake-induced angle of attack on an encountering aircraft is determined. Therefore, the induced flow field of the wake-generating aircraft is transformed into the coordinate system of the penetrating aircraft. Because the unsteadiness results on the one hand from the velocity fluctuations inside the wake, and on the other hand from the relative movement of the two aircraft, the wake problem is split into a discrete and a continuous wake problem. Both problems lead to an unsteady distribution of the angle of attack, which is variable in the chord and spanwise directions. The resulting lift and pitching moment distribution is calculated by an alternative approach in the unsteady lifting surface method. For the discrete wake problem, the resulting loads depend on the heading and bank angle of the penetrating aircraft relative to the vortex axes. In general, negative lift, rolling, and pitching moments can be observed. Their magnitude varies with the encounter maneuver. The continuous wake problem refers to the unsteady loads due to velocity fluctuations inside the wake on an aircraft following the wake-generating aircraft. Thereby, high-frequency forces and moments act upon the following aircraft.

Klar, J.-U., Breitsamter, C. and Adams, N.

"EXPERIMENTAL AND NUMERICAL INVESTIGATIONS OF THE WAKE VORTEX SYSTEM OF A DELTA-CANARD-CONFIGURATION"

ICAS 2010, Paper 2010-10.2.4, Sept. 2010, Nice, France.

High-agility aircraft may encounter the wake of a preceding aircraft. The associated loads are influenced by the actual maneuver, the unsteady angle of attack due to the wake encounter and the aircraft structure's dynamic behavior. Experimental and numerical investigations of the wake vortex system of a delta-canard-configuration are presented.

Klar, J.-U., Breitsamter, C., Hickel, S. and Adames, N.

"INTEGRATED EXPERIMENTAL-NUMERICAL ANALYSIS OF HIGH-AGILITY AIRCRAFT WAKE VORTEX EVOLUTION"

Journal of Aircraft, Vol. 48, No. 6, November-December 2011, pp. 2050-2058.

The presented investigation includes a combined experimental-numerical approach to quantify the wake vortex system of a high-agility aircraft from the near field up to the far field. Detailed near-field data are obtained by low-speed wind-tunnel tests on a delta-canard configuration of 1:15 scale. The measurements are performed at several angles of attack applying advanced hot-wire anemometry. For a wake distance of up to 16 wing spans, mean and turbulent velocity fields are measured. The upstream data are used to initialize implicit large-eddy simulations aimed to compute the velocity fields of the wake vortex system over a wake distance of up to 50 spans. Here, a validation case is shown comparing measured and calculated wake data over a distance from 4 to 16 spans, with the implicit large-eddy simulations initialized by the measured quantities at a position of 2 wing spans. Compared with the experimental data, the numerical results show the expected lateral and vertical movement of the wake vortex system due to the interaction of the single vortices. The distributions of axial vorticity, crossflow velocities, and turbulence intensities match well with the experimental data. In addition, the dissipation process can be observed, resulting in a reduction of circulation. In the context of this study, the measured and computed velocity fields will be used to determine unsteady aerodynamic loads acting on a fighter aircraft encountering the wake. This is of great importance as wake induction may result in critical structural dynamic loads.

Kleb, B. and Wood, B.

"CFD: A CASTLE IN THE SAND?"

AIAA Paper No. 2004-2627, June 2004, Portland, OR.

The computational simulation community is not routinely publishing independently verifiable tests to accompany new models or algorithms. A survey reveals that only 22 percent of new models published are accompanied by tests suitable for independently verifying the new model. As the community develops larger codes with increased functionality, and hence increased complexity in terms of the number of building block components and their interactions, it becomes prohibitively expensive for

each development group to derive the appropriate tests for each component. Therefore, the computational simulation community is building its collective castle on a very shaky foundation of components with unpublished and unrepeatable verification tests. The computational simulation community needs to begin publishing component-level verification tests before the tide of complexity undermines its foundation.

Klein, M. A., Lentz, W. K. and Komerath, N. M.

"REDUCTION OF FLUCTUATIONS OVER SWEEPED WINGS USING MINI-FENCES"

AIAA Paper No. 1997-0548, January 1997, Reno, NV.

Passive and active surface devices are used to modify the narrow-band velocity fluctuations over a 59.3-degree delta wing at high angles of attack. Previous work has traced these fluctuations to counter-rotating structures in the shear layer below the post-burst vortex. Small vertical fences placed near the point of origin of the fluctuations attenuate the peak spectral energy by as much as 78 percent. The lift and drag are shown to be unaffected. Fences placed at other locations and orientations show various levels of suppression and amplification. The most effective fence height, position, and orientation for attenuation at 25 deg. angle of attack are identified. An active fence and a ramp modulated at the fluctuation frequency show attenuation corresponding to the effective duty cycle of deployment in a given range of shear layer. It is seen that the fences must extend well beyond the surface boundary layer to be effective, but extending into the central region of the flow is ineffective, further proving that the fluctuations originate in the outer shear layer of the vortex, not in the core.

Klein, R. and Majda, A. J.

"AN ASYMPTOTIC THEORY FOR THE NONLINEAR INSTABILITY OF ANTIPARALLEL PAIRS OF VORTEX FILAMENTS"

Phys. Fluids A, Vol. 5, No. 2, February 1993, pp. 369-379

Simplified asymptotic equations describing the nonlinear dynamics of perturbed pairs of parallel vortex filaments are derived and analyzed here. The derivations are general enough to allow for vortices of unequal strength, but emphasis here is on the antiparallel vortex pair. The simplified asymptotic equations account for both the internal effects of self-induction and self-stretching for each filament and the external effects of mutual induction that lead to a nontrivial coupling of the perturbations of the two filaments. When these nonlinear equations are linearized at the unperturbed filament pair, the linearized stability theory of Crow is recovered in a systematic fashion. The asymptotic equations are derived in a novel singular limit at high Reynolds numbers through assumptions like the authors' recent theories for the dynamics of a single perturbed vortex filament. Through the Hasimoto transform, these equations become two coupled perturbed nonlinear Schrodinger equations for a pair of filament functions. A series of numerical solutions of the asymptotic equations exhibits several new phenomena in the nonlinear instability of pairs of antiparallel vortex filaments.

Klein, R. and Ting, L.

"VORTEX FILAMENT WITH AXIAL CORE STRUCTURE VARIATION"

Applied Mathematics Letters, Vol. 5, Issue 4, July 1992, pp. 99-103.

Using the methods of matched asymptotics with the slenderness ratio ϵ as the expansion parameter, we derive the governing equations for the velocity of the centerline of a slender viscous vortex filament and the evolution of its vortical core structure. In the core, both the circumferential and axial velocity components relative to the centerline of the filament can be $O(1/\epsilon)$ and have axial variations in addition to the rapidly decaying radial variations.

Klein, R., Majda, A. J. and Damodaran, K.

"SIMPLIFIED EQUATIONS FOR THE INTERACTION OF NEARLY PARALLEL VORTEX FILAMENTS"

J. Fluid Mech., Vol. 288, April 1995, pp. 201-248

New simplified asymptotic equations for the interaction of nearly parallel vortex filaments are derived and analyzed here. The simplified equations retain the important physical effects of linearized local self-induction and nonlinear potential vortex interaction among different vortices but neglect other non-local effects of self-stretching and mutual induction. These equations are derived systematically in a suitable distinguished asymptotic limit from the Navier-Stokes equations. The general Hamiltonian formalism and conserved quantities for the simplified equations are developed. Strong evidence is presented that for any filament pair with a negative circulation ratio, there is finite-time collapse in a self-similar fashion independent of the perturbation but with a structure depending on the circulation ratio. On the other hand, strong evidence is presented that no finite-time collapse is possible for perturbations of a filament pair with a positive circulation ratio.

"HIGH-LIFT AIRFOIL INTERACTING WITH A VORTICAL DISTURBANCE: WIND-TUNNEL MEASUREMENTS"

AIAA Journal, Vol. 53, No. 6, June 2015, pp. 1681-1692.

This paper describes experimental investigations on the effect of large-scale disturbances interacting with the flow around a two-element airfoil. Quasi two-dimensional transversal vortices are created in a closed wind-tunnel test section shortly after the nozzle. Moving along the test section, these vortices interact with a two-element airfoil in high-lift configuration. Various measurement techniques are used to identify and characterize these complex interactions. The techniques are phase-locked particle image velocimetry, time-resolving five-hole probe, time-resolving static pressure measurements, and time-averaged measurements of the static pressure distribution of the high-lift airfoil. The vortex generation and evolution along the empty wind-tunnel test section is discussed before considering the vortex-airfoil interactions. As a result, the influence of the induced vortices on the time-resolving static

pressure along the airfoil surface and the interaction with the airfoil flap flow is described. The findings are linked to flow field images and the induced flow effects (the circulatory effect and the local velocity effect) are discussed.

"INVISCID ANALYSIS OF EXTENDED-FORMATION FLIGHT"

AIAA Journal, Vol. 51, No. 7, July 2013, pp. 1703-1715.

Flying airplanes in extended formations, with separation distances of tens of wingspans, significantly improves safety while maintaining most of the fuel savings achieved in close formations. The present study investigates the impact of roll trim and compressibility at a fixed lift coefficient on the benefits of extended-formation flight. A Euler solver with adjoint-based mesh refinement combined with a wake propagation model is used to analyze a two-body echelon formation at a separation distance of 30 spans. Two geometries are examined: a simple wing and a wing-body geometry. Energy savings, quantified by both formation-drag fraction and span efficiency factor, are investigated at subsonic and transonic speeds for a matrix of vortex locations. The results show that, at fixed lift and trimmed for roll, the optimal location of vortex impingement is about 10 percent inboard of the trailing airplane's wing tip. Interestingly, the improvement in drag fraction is relatively robust in the vicinity of the optimal position. Over 90 percent of energy benefits can be obtained with a 5 percent variation in vertical and 10 percent variation in spanwise positions. Control surface deflections required to achieve roll trim reduce the benefits of formation flight by 3-5 percent at subsonic speeds and 9-11 percent at transonic speeds. Overall, simulations show peak induced drag saving for the trail aircraft are 54 percent in subsonic flow and 35 percent in transonic flow while accounting for trim.

"ON THE LOGARITHMIC MEAN PROFILE"

Journal of Fluid Mechanics, Vol. 638, 2009, pp. 73-93.

Elements of the first-principles-based theory are clarified and their veracity tested relative to the properties of the logarithmic mean velocity profile. While the approach employed broadly reveals the mathematical structure admitted by the time averaged Navier-Stokes equations, results are primarily provided for fully developed pressure driven flow in a two-dimensional channel. The theory demonstrates that the appropriately simplified mean differential statement of Newton's second law formally admits a hierarchy of scaling layers, each having a distinct characteristic length. The theory also specifies that these characteristic lengths asymptotically scale with distance from the wall over a well-defined range of wall-normal positions, y . Numerical simulation data are shown to support these analytical findings in every measure explored. The mean velocity profile is shown to exhibit logarithmic dependence (exact or approximate) self-similarity from layer to layer within the hierarchy. The condition of pure self-similarity corresponds to a constant leading coefficient in the logarithmic mean velocity equation. The theory predicts and clarifies why logarithmic behavior is better approximated as

the Reynolds number gets large. An exact equation for the leading coefficient (von Karman coefficient κ) is tested against direct numerical simulation data. Two methods for precisely estimating the leading coefficient over any selected range of y are presented. These methods reveal that the differences between the theory and simulation are essentially within the uncertainty level of the simulation. The von Karman coefficient physically exists owing to an approximate self-similarity in the flux of turbulent force across an internal layer hierarchy. Mathematically, this self-similarity relates to the slope and curvature of the mean vorticity profile. The theory addresses how why and under what conditions logarithmic dependence is approximated relative to the specific mechanisms contained within the mean statement of dynamics.

Kliment, L. K.

"DYNAMICS OF LONGITUDINAL WAKE VORTICES"

PhD Thesis, July 2009, Wichita State Univ., Wichita, Kansas.

In the present study, the mid-field vortex wake is investigated. For the most part, the results focus on the motion of a pair of co-rotating vortices prior to merger, both in and out of ground effect. However, in order to verify the experimental and computational methods, results for single vortices, counter-rotating pairs, and complex wakes are also presented. A method is presented which allows measurement of the time dependent motion of vortex filaments. This optical method interferes minimally with the wake and allows recording of vortex location and time-dependent motion. From the position and time information recorded, extraction of the amplitudes of motion, core motion, spiraling behavior, vortex strengths, and the principal planes of motion is possible. First, a single vortex is studied to establish a basis for comparison. The dye remains in the core and the motion of a single vortex is shown to exhibit a growth in amplitude with increasing downstream distance and strength. The core motion is shown to be minimal, remaining smaller than one core diameter. In addition, when the single vortex is forced to oscillate at a given frequency, the dye remains in the core, even though the amplitudes of motion are large. The forcing frequency is identified easily against the background noise. Two four-vortex cases are then presented. The first case consists of filaments that spiral while in the second they scatter. These results are consistent with those shown in literature and show that the experimental method can be used for analyzing complex wakes. Pairs of unforced, co-rotating filaments are studied outside of ground effect. The constant rate of spiraling is shown to increase as the vortex strength increases and vortex span decreases. Vortex span either remains constant or decreases with downstream distance depending on the vortex separation distance. The motion of the center of spiraling is shown to be minimal, similar to the motion of the vortex core in the single-vortex cases. Ground effect is then considered for counter-rotating vortices, because there is a wealth of information on this topic in the literature. When counter-rotating vortices are near a ground plane, a lateral drift as well as a rebounding behavior is present.

Kliment, L. K. and Rokhsaz, K.

"EXPERIMENTAL INVESTIGATION OF THE FORCED RESPONSE OF A PAIR OF CO-ROTATING VORTEX FILAMENTS"

AIAA Paper No. 2004-2434, Portland, OR, June-July 2004.

The interactions of pairs of co-rotating vortex filaments have been investigated in a water tunnel. The time history of the motion of each filament has been recorded at several downstream locations to analyze its spatial and temporal behavior. The vortices have been excited over a range of frequencies using a shaker. The filaments have been shown to move along preferred directions, suggesting their tendency to form planar waves. The amplitudes of these waves have been shown to grow, implying unstable interaction between the vortices. The angles of the planes containing the motion have been presented and compared with analytical prediction. The flow is shown to contain all the essential features predicted by two analytical models.

Kliment, L. K. and Rokhsaz, K.

"EXPERIMENTAL INVESTIGATION OF PAIRS OF VORTEX FILAMENTS IN GROUND EFFECT"

J. Aircraft, Vol. 45, No. 2, March-April 2008, pp. 622-629

The motion of corotating filaments in ground effect is investigated using a water tunnel. The vortices are generated using two flat blades and the ground is modeled with a splitter plate. The time history of the vortex motion is recorded at several downstream locations. Data are shown for two ground-plane positions and compared with the vortex behavior in the freestream. The experimental data are also compared with a potential-flow model. Results show that the vortices undergo a rebound as the result of ground effect. The vortices also undergo a lateral motion due to potential-flow effects. A leapfrogging behavior is present due to the differences in the lateral motions caused by the ground proximities of the spiraling vortices. In addition, the filaments form planar waves and move along preferred directions.

Kliment, L. K. and Rokhsaz, K.

"PRELIMINARY INVESTIGATION OF A COMPLEX AIRCRAFT WAKE VORTEX CONFIGURATION"

AIAA Paper No. 2003-3600, Orlando, FL, June 2003

The interactions between two sets of co-rotating vortex filaments are investigated experimentally. The experiments are carried out in a water tunnel. Two specific cases are addressed; one in which the filaments on each side spiral around one another, and a second case in which the filaments on each side scatter. In the spiraling case, a simple method is introduced to determine the vortex strengths from the experimental data. Also, in this case, it is demonstrated that the mutual induction between the vortices leads to oscillations of the filaments with a preferred direction of motion that rotates at the same rate as the orbiting rate. The experimental data shown indicates that in the scattering case, the filaments close to each other exhibit a Crow-type of motion, while those farther apart retain the

characteristics of isolated filaments. These results are in complete agreement with those obtained earlier concerning the behavior of single and co-rotating vortices.

Kliment, L. K. and Rokhsaz, K.

"INFLUENCE OF TERRAIN ROUGHNESS ON TRAILING VORTICES IN GROUND EFFECT"

AIAA Paper No. 2007-4365, Miami, FL, June 2007

The spatial and temporal behaviors of counter-rotating vortex filaments in ground effect have been investigated experimentally in a water tunnel over a range of thirteen span lengths. The vortices have been generated using two flat blades and the ground has been modeled with a splitter plate. Streamwise ridges of varying height and spacing have been added to the ground plane and their effects on vortex trajectories and vortex meandering have been studied. Three sets of data are presented that include different vortex strengths and vortex spans, in addition to variations in the ground roughness. In comparison with the results for a smooth ground plane, vortex trajectories, their preferred direction of motion, and the rate of growth of their amplitudes of motion have been shown to be insensitive to terrain roughness.

Kliment, L. K. and Rokhsaz, K.

"EFFECT OF GROUND ROUGHNESS ON AIRCRAFT TRAILING VORTICES"

Proceedings of 3rd Annual GRASP Symposium, Wichita State University, 2007, pp. 185-186.

Experiments were performed in a water tunnel to study the effect of terrain roughness on the spatial and temporal behavior of trailing vortices. Without ground roughness, the spatial behavior was consistent with data in the current literature. The ground roughness had negligible effect on the position of the vortices and their temporal behavior. These results were based on one combination of vortex span and ground roughness. Other combinations may lead to different results.

Kliment, L. K., Miller, T. S. and Rokhsaz, K.

"DYNAMICS OF COROTATING VORTEX FILAMENTS PART 2: EXPERIMENTAL RESULTS"

Journal of Aircraft, Vol. 44, No. 1, January-February 2007, pp. 100-105

The interactions of pairs of corotating vortex filaments have been investigated experimentally in a water tunnel. The time history of the motion of each filament has been recorded at several downstream locations to analyze its spatial and temporal behavior. Two sets of data are presented in which the vortices have been excited over a range of frequencies using a shaker. The excitation frequency and its multiples have been shown to be present in the downstream flow. At each downstream position, the filaments have been shown to move along preferred directions, suggesting their tendency to form planar waves, inclined relative to the line connecting them. The amplitudes of these waves have been shown to grow, implying unstable interaction between the vortices. The angles

of the planes containing the motion have been presented and compared with the predictions of two analytical models. The scatter in the data prevented quantitative comparison with the analytical predictions. However, the flow is shown to contain all of the essential features predicted by two analytical models.

Klinge, F., Kirmse, T. and Kompenhans, J.

"INVESTIGATION OF THE DENSITY AND VELOCITY DISTRIBUTION OF A WING TIP VORTEX BY MEANS OF STEREOSCOPIC BACKGROUND ORIENTED SCHLIEREN METHOD (BOS) AND STEREOSCOPIC PARTICLE IMAGE VELOCIMETRY (PIV)"

The Calouste Gulbenkian Foundation, 12th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, July 2004

A wind tunnel wing tip vortex test combining the techniques of Background Oriented Schlieren (BOS) and Particle Image Velocimetry (PIV) is described. The combined techniques provide simultaneous density and velocity measurements of the vortex field.

Klinge, F., Kirmse, T. and Kompenhans, J.

"APPLICATION OF QUANTITATIVE BACKGROUND ORIENTED SCHLIEREN (BOS): INVESTIGATION OF A WING TIP VORTEX IN A TRANSONIC WIND TUNNEL"

Proceedings of PSFVIP-4, Chamonix, France, June 2003, pp. 1-11

Background Oriented Schlieren (BOS) measurements have been performed in combination with Particle Image Velocimetry (PIV) measurements in order to derive quantitative flow velocity and density data of a wing tip vortex generated by an airfoil model of a modern large transportation aircraft in the transonic wind tunnel (TWG) of the German-Dutch wind tunnel (DNW) in Gottingen. The model has a span of 0.6m and a wing area of 0.1m squared. The test was performed in the 1 x 1m transonic test section of the TWG with different flow Mach numbers ($Ma = 0.5 / 0.6 / 0.7$). The measurement technique BOS is still under development, nevertheless local quantitative density measurements in 2D flows are already possible. This test was performed to prove the applicability of BOS to 3D axis symmetrical flows in real wind tunnel experiments as well as the applicability of three component PIV measurements in transonic flows. The measurement system (BOS and PIV) consists of 4 digital cameras and a double pulsed Nd:YAG laser with 2x320mJ. This paper focuses on the theoretical as well as on the technical aspects of the BOS recording and evaluation methods especially for 3D axis symmetrical flows.

"DEVELOPMENT OF STEREOSCOPIC BACKGROUND ORIENTED SCHLIEREN METHOD (BOS) AND LASER LIGHT SHEET TECHNIQUE (ILS) FOR STUDY OF REYNOLDS NUMBER EFFECTS ON WING TIP VORTEX POSITIONS UNDER CRYOGENIC CONDITIONS"

13 International Symposium on Applied Laser Techniques to Fluid Mechanics, Lisbon, Portugal, June 2006

Wake vortex turbulence induced by large transport aircrafts is problematic for airports capacity because of their hazardous impact on following aircraft. Safety rules defining minimum distances between landing and taking off aircrafts are based on the strength and temporal duration of dissipation of the vortex turbulence. The wing tip vortex position is of major interest because interactions with vortices generated from e.g. the elevator of the airplane are desired to accelerate their decay. Experimental data are needed to enable quick and accurate vortex modelling. These data are coming up to now mostly from wind tunnels which cannot simulate the 'real' Reynolds and Mach number. Thereby it is usually assumed that this mismatch does not affect the results. Klinge et al showed that wing tip vortices can be localized quantitatively with high accuracy during wind tunnel tests by means of stereoscopic BOS and additional software tools. The objective of this experiment was to find out, whether the Reynolds number has a significant impact on the vortex position of a wing tip vortex.

Kloosterman, M. H. M.

"DEVELOPMENT OF THE NEAR WAKE BEHIND A HORIZONTAL AXIS WIND TURBINE, INCLUDING THE DEVELOPMENT OF A FREE WAKE LIFTING LINE CODE"

MS Thesis, June 2009, Delft University of Technology, Delft, The Netherlands.

A lot of research has been carried out in the past on wind turbine wake aerodynamics. Models exist for both the near field and the far field. The near wake is governed by a typical vortex structure that gradually decays due to viscous and turbulent mixing effects, forming the less structured far wake region. The formation of the far field from the rotor region and near wake is not completely understood yet. In this thesis an attempt is made to develop a simple model that tries to capture the decay of the vortex wake within the first two diameters downstream of the rotor. A free wake lifting line vortex model has been developed. Viscous effects have been added to the vortex code in the form of vortex core models and a simple model that describes the turbulent decay of circulation as a function of ambient turbulence intensity. Furthermore, models for simulating wind shear and the presence of the nacelle have been implemented. A thorough validation study of the model has been carried out by means of hot-film and Particle Image Velocimetry (PIV) measurements. Close to the rotor the model compares well with the measured induced velocities measured with a hot-film. PIV measurements show that the model captures the position of the tip vortex quite well within the first diameter downstream. The measured velocity field can however not be reproduced correctly by the code. No measurements were available that can validate the turbulent decay of the vortex wake; instead, suggestions are made for an experiment in the Open Jet Facility of Delft University of Technology. The new model is only valid in the region of the wake where the vortex structure of the wake is still intact which is typically between one or two diameters downstream. Further downstream the outputs from the model may be used as an input for a Reynolds Averaged Navier-Stokes model that describes the far wake of the rotor.

"NUMERICAL STUDY OF SOUND EMISSION BY 2D REGULAR AND CHAOTIC VORTEX CONFIGURATIONS"

Journal of Computational Physics, Vol. 116, 1995, pp. 226-246

The far-field noise generated by a system of three Gaussian vortices lying over a flat boundary is numerically investigated using a two-dimensional vortex element method. The method is based on the discretization of the vorticity field into a finite number of smoothed vortex elements of spherical overlapping cores. The elements are convected in a Lagrangian reference along particle trajectories using the local velocity vector, given in terms of a desingularized Biot-Savart law. The initial structure of the vortex system is triangular; a one-dimensional family of initial configurations is constructed by keeping one side of the triangle fixed and vertical, and varying the abscissa of the centroid of the remaining vortex. The inviscid dynamics of this vortex configuration are first investigated using non-deformable vortices. Depending on the aspect ratio of the initial system, regular or chaotic motion occurs. Due to wall-related symmetries, the far-field sound always exhibits a time independent quadrupolar directivity with maxima parallel and perpendicular to the wall. When regular motion prevails, the noise spectrum is dominated by discrete frequencies which correspond to the fundamental system frequency and its super harmonics. For chaotic motion, a broadband spectrum is obtained; computed sound levels are substantially higher than in non-chaotic systems. A more sophisticated analysis is then performed which accounts for vortex core dynamics. Results show that the vortex cores are susceptible to inviscid instability which lead to violent vorticity reorganization within the core. This phenomenon has little effect on the large-scale features of the motion of the system or on low frequency sound emission. However, it leads to the generation of a high-frequency noise band in the acoustic pressure spectrum. The latter is observed in both regular and chaotic system simulations.

Knox, C. E.

"AN INVESTIGATION OF AIR TRAFFIC CONTROL PROCEDURES AND PILOT TECHNIQUES IN A HIGH DENSITY TERMINAL AREA"

Ph.D. Thesis, 1974, Kansas University, Lawrence, KS

An investigation was conducted to determine if increases in runway capacity could be achieved through the modification of various air traffic control procedures and pilot techniques. Modified procedures and techniques were to be specified such that equipment not already necessary for IFR and/or VFR flight in a high density, semi-positive controlled airspace would not be required. A summary of pertinent pilot and air traffic controller constraints and airspace structure around the high-density terminal area and a review of wake vortex characteristics and avoidance procedures was included in this investigation. Kinematic equations of motion and aircraft performance equations were developed for take-off, landing, and in-flight maneuvering computations.

"AUTOMATED TURBULENCE FORECASTING STRATEGIES"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 12, 2016, Springer International Publishing Switzerland, pp. 243-260.

Forecasting aviation turbulence remains a challenge in the twenty-first century because of the small temporal and spatial scales of the phenomenon and the multiplicity of causes of the turbulence. In this chapter we discuss both the theoretically derived methods and the empirical techniques used to forecast aviation turbulence. The focus is mainly on clear-air turbulence (CAT), but forecasting techniques for low-level, convectively induced, and mountain wave turbulence (MWT) are also surveyed. We conclude with a brief glimpse into the future of aviation turbulence forecasting.

"DETAILED MEASUREMENTS IN THE WAKE OF A 2MW WIND TURBINE"

European Wind Energy Association 2012 Conference, April 2012, Copenhagen, Denmark.

Detailed, high-resolution measurements with a UAV upstream and in the wake of a full-scale wind turbine located in complex terrain are reported. The wake centerline velocity deficit measurements made with UAV are compared to wind tunnel measurements with a subscale wind turbine in a non-uniform velocity profile and simulated thermal stratification and surface roughness. The comparison shows good agreement. Upstream velocity profiles measured with the UAV are also compared to measurements made with a LIDAR profiler. Comparison of total velocity profiles showed good agreement whereas the horizontal speed shows discrepancy due to the uniform flow assumption that is used in LIDAR profiler measurements. Comparison of the predicted velocity field from the recently developed ETH Zurich Wake Model and wake measurements made with the UAV are also shown. There is overall good agreement between the model and the UAV measurements.

"DEVELOPMENT OF AN OPERATIONAL WAKE VORTEX SENSOR BASED ON PULSED COHERENT LIDAR"

9th Conference on Coherent Laser Radar, Paper Th3, Linkoping, Sweden, June 1997

An overview is given of NASA Langley's development of pulsed lidar for a operational wake vortex sensor. Data is presented from aircraft landings at JFK International Airport and Norfolk International Airport. The lidar system, including several generations of lasers, is presented. Future field deployments and project goals are discussed.

"HIGH-ENERGY 2 MICRON DOPPLER LIDAR FOR WIND MEASUREMENTS"

Optical Engineering, Vol. 46, No. 11, November 2007, pp. 116201-1 - 116201-14.

A coherent Doppler lidar at 2 micron wavelength has been built with higher output energy (100 mJ) than previously available. The laser transmitter is based on diode-pumped Ho:Tm:LuLiF, a recently developed laser material that allows more efficient energy extraction. Single-frequency operation is achieved by a ramp-and-fire injection seeding technique. An advanced photodetector architecture is used incorporating photodiodes in a dual-balanced configuration. A digital signal processing system has been built, allowing real-time display of wind and aerosol backscatter data products. The high pulse energy and receiver efficiency provides for measurement of wind fields to ranges not seen before with 2- micron lidars, and example wind measurements were made to show this capability.

Koch, G. J., Murray, J., Lytle, C. and Nguyen, C.

"A 1000 HZ PULSED SOLID-STATE RAMAN LASER FOR COHERENT LIDAR MEASUREMENT OF WAKE VORTICES"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 292-298.

A coherent lidar based on a Raman shifted Nd laser is under development with parameters optimized for wake vortex detection. Specifications for the laser are a wavelength of 1.56 microns, pulse repetition frequency of 1000 Hz, pulse width of 1000 ns, and pulse energy of 10 mJ. Range and resolution capabilities are discussed as well as preliminary designs for the laser, receiver, and signal processor.

Koch, G., Staton, L. and Nguyen, C.

"DESIGN CONSIDERATIONS FOR AN OPERATIONAL WAKE VORTEX LIDAR SENSOR AT 2-MICRON WAVELENGTHS"

Optical Society of America, Technical Digest Series, Vol. 19, No. TuD4-1, 1995, pp. 190-192

The lidar is envisioned to be a coherent Doppler system located in the terminal area. Since the lidar will be operating in an environment where people may be exposed to the beam, unconditional eye safety is a further constraint. Because of this eye safety requirement and in consideration of recent advances in solid-state laser development, our baseline lidar design is for a 2-micron based coherent lidar. Extensive system studies are underway to set the specifications for the lidar, such as pulse width, pulse energy, pulse repetition frequency, waveform modulation, and scanning requirements.

Koch, M. E. and Buchholz, A.

"QUANTITATIVE ANALYSIS OF AIRCRAFT HEIGHT ON FINAL APPROACH"

IEEE/AIAA 30th Digital Avionic Systems Conference, Paper 1A4, October 2011, Seattle, WA.

Wake turbulence encounters are a significant risk to pilots, and rules and guidance exist to ensure the safety of all aircraft operating in the National Airspace System. In poor weather and in airspace serviced by surveillance and Air Traffic Control (ATC). ATC is responsible for separating aircraft from one another, and a conservative set of standards, including consideration of lead aircraft wake category, ensures the safety of all aircraft without requiring any input from the pilots. In good weather, when separation responsibility has been delegated to flight crews, pilots can use the situation awareness provided by direct visual contact to decrease separation between aircraft, increasing capacity to the nation's airports. One way pilots avoid wake encounters during decreased-separation situations is by adjusting their trajectory with respect to the airplane they are following on final approach. Previous efforts have obtained qualitative feedback from pilots on their wake avoidance strategies. This paper examines actual track data from multiple sources to determine how aircraft behave in real operations for approaches to single runways as well as closely spaced parallel runways. Results confirm that pilots of smaller aircraft, generally those below about 100,000 pounds (lbs) maximum takeoff weight (MTOW), ride higher than the leading aircraft in visual conditions, whereas those over the 100,000 lbs MTOW tend not to modify their approach trajectory. Sensitivity to various parameters such as lead aircraft type, weather, distance between aircraft, and airport are examined in detail.

Kocks, S., Bode, S., Feuerle, T., Paetzold, C., Schoenhals, S. and Hecker, P.

"AN INTEGRATED WAKE VORTEX VISUALIZATION CONCEPT FOR EXISTING COCKPIT DISPLAY SYSTEMS"

Paper EN-022, Second ENRI International Workshop on ATM/CNS, EIWAC 2010, November 2010, Tokyo, Japan.

Major hub airports often operate at their capacity limit and will become more and more the bottlenecks of the air transport network. Among other factors, conservative wake vortex separations during approach and takeoff have a significant impact on an airport's operation efficiency. One possibility to increase capacity is the delegation of separation responsibility from the air traffic controller to the flight crew. However, to guarantee safe operations the pilots must obtain full situational awareness of their environment including potentially hazardous vortex traffic. This paper introduces a concept for the graphical provision of wake vortex hazard areas in existing cockpit displays.

The chosen approach has been realized and integrated into an Airbus A320 cockpit simulator at the Institute of Flight Guidance of the Technische Universitaet Braunschweig. An overview of the institute's simulation environment is given, followed by a presentation of the chosen visualization concept. Results of first evaluations with pilots of commercial and general aviation are summarized. Finally, future work and further developments are addressed.

Kocster, S., Cook, R. and Barbcc, B.

"WINDMILL INTERACTION WITH A VORTEX WAKE"

ASE 463 Q, University of Texas at Austin, Austin, TX, 2003

The purpose of this study is to analyze the effects of descending vortices from high-speed, low altitude, large aircraft on a ground-based windmill. In particular, the goal is to demonstrate a basis for determining the capacity, or lack thereof, of such vortices to damage the windmills. The approach is to model this situation in a laboratory setting by simulating a vortex, translating it through a windmill model outfitted with strain gages, recording bending strains, conducting digital photography of the windmill's motion, and drawing conclusions based on the analysis of all gathered data. Several methods of actual vortex generation were examined and found to be inadequate, although vortex scaling parameters and velocity profiles were computed. Therefore, it was decided to simulate the key features of the vortex with two opposing airflows generated by ducted centrifugal fans. A standard American Style windmill model was purchased from The American Wind Power Center and has been instrumented with strain gages, and two 435 CFM centrifugal fans have been purchased from the Dayton Company. Designs for the fan ducts and the experimental setup have been completed. The next engineering team will be able to proceed by setting up a data acquisition system, building the experimental apparatus, conducting tests, and recording and analyzing data.

Kocurek, J. D. and Tangler, J. L.

"A PRESCRIBED WAKE LIFTING SURFACE HOVER PERFORMANCE ANALYSIS"

Journal of the American Helicopter Society, Vol. 22, No. 4, Issue 1, 1977, pp. 24-35.

The application of lifting surface theory to the calculation of rotor hover performance and the development of an improved prescribed wake representation resulting from schlieren flow visualization studies of model rotor wakes are described. Qualitative comparisons between lifting line and lifting surface methods show the tendency of the lifting line to react excessively when a vortex passes close to a blade. The flow visualization studies reveal wake sensitivity to thrust coefficient, number of blades, and twist not identified in previous investigations. The need to include a recirculation mechanism in the analytical model to provide inflow in addition to that available from the prescribed wake structure is established. A possible source of the recirculation is demonstrated to be the result of vortex interaction and wake expansion immediately below the well-defined near wake.

Kodis, R. D.

"WAKE VORTEX SENSORS"

FAA Symposium on Turbulence, Federal Aviation Administration, Washington, DC, March 1971, p. 28

The results obtained to date on the Transportation Systems Center task to identify remote sensing techniques to detect, locate, and measure wake vortices near the ground is presented. A simple bistatic radar that detects pulses of acoustic radiation deflected by a vortex is described and experimental data shown. Sensors that use electromagnetic signals scattered by particulate matter in wake vortices are indicated to be feasible but would probably prove less acceptable at airports due to their cost, potential hazard, and difficult maintenance.

Kodis, R. D.

"THE DETECTION OF AIRCRAFT WAKE VORTICES"

Conference Proceedings on Flight in Turbulence, AGARD, Number 140, 1973, pp. 11-1 to 11-9

The trailing vortices deposited in the wakes of heavy jet aircraft constitute a serious hazard for encountering aircraft. In the terminal area this hazard leads to longer separation standards and reduced runway capacity. To shorten the required separations without compromising safety it is necessary to be able to detect the presence and the motion of vortices in regions where they constitute a threat. This paper reviews sensing techniques that have been developed and tested for this purpose. In particular, the characteristics of acoustic and wind pressure sensors developed by the U.S. Transportation Systems Center for the Federal Aviation Administration will be described in detail.

Kodis, R. D.

"REMOTE SENSING TECHNIQUES FOR OBSERVING WAKE VORTICES NEAR THE GROUND"

AIAA Paper No. 1975-0320, Washington, DC, 1975

The advent of heavy jet aircraft has made it necessary to develop remote sensors capable of detecting and tracking wake vortices for the purposes of data collection and traffic control. Active sensors now being evaluated include acoustic and optical radars. Passive wind sensors that respond to the velocity field of a nearby vortex have also proved their usefulness. The full complement of such sensors which have been engineered and installed at the Kennedy International Airport (JFK) are described. Typical data are presented and the performance characteristics and limitations of each sensor technique are discussed. Possible application to air traffic operations is indicated.

Kodis, R. D.

"WAKE VORTEX SENSING"

Proceedings of the 18th International Aerospace Instrumentation Symposium, Instrument Society of America, Vol. 18, 1972, pp. 281-283

Experimental studies and tests are reported on two wake vortex sensing techniques designed to sense the presence and track the motions of low altitude aircraft wake vortices endangering operations around terminal areas. The techniques studied are based on acoustic pulse deflection and velocity field measurements.

Koenig, R.

"AIRCRAFT RESPONSE AND PILOT BEHAVIOUR DURING A WAKE VORTEX ENCOUNTER PERPENDICULAR TO THE VORTEX AXIS"

AGARD, Flight in Adverse Environmental Conditions, September 1989

Vortex systems can be hazardous to trailing aircraft which encounter them in flight. The greatest hazard occurs in areas where aircraft from a wide range of classes operate and where the flight paths are close to the ground. Upwash velocities induced by the wake vortices can be equivalent to the design gust velocities. Furthermore, different types of hazardous effects exist when encountering the vortex system, such as imposed rolling and pitching moments, a loss of rate of climb, a loss of altitude and structural loads. Aircraft response and pilot behavior during takeoff are described when a wake vortex is encountered perpendicular to the vortex axis. The aircraft response is calculated by nonlinear digital simulation with a mathematical model of a wake vortex system close to the ground. This real-time vortex model is also used in the Boeing B-737 simulator of Deutsche Lufthansa to examine the pilot behavior. Close to the ground, the wake vortex system induces additional horizontal velocities. There exists a critical flight path where very large g-loads are induced by vertical and horizontal vortex velocities and normal vertical acceleration shortly after takeoff. Often the pilot will attempt to counteract these g-loads, but this produces only a small effect.

Kohl, R. E.

"MODEL EXPERIMENTS TO EVALUATE VORTEX DISSIPATION DEVICES PROPOSED FOR INSTALLATION ON OR NEAR AIRCRAFT RUNWAYS"

NASA CR-132365, August 1973, Hydronautics Inc., Laurel, MD

The effectiveness of various vortex dissipation devices proposed for installation on or near aircraft runways is evaluated on basis of results of experiments conducted with a 0.03-scale model of a Boeing 747 transport aircraft in conjunction with a simulated runway. The test variables included type of vortex dissipation device, mode of operation of the powered devices, and altitude, lift coefficient, and speed of the generating aircraft. A total of fifteen devices was investigated. The evaluation is based on time sequence photographs taken in the vertical and horizontal planes during each run.

"THE EXPERIMENTAL DETERMINATION OF THE MOMENT OF INERTIA OF A MODEL AIRPLANE"

Honors Research Projects, 585, Fall 2017, The University of Akron, Akron, OH.

This paper describes an experimental setup that can be used to measure the moment of inertia for a model airplane, and it validates the setup by measuring the moment of inertia on a wooden block.

Kokurin, M. and Rokhsaz, K.

"SEMI-ANALYTICAL VISCOUS TRAILING VORTEX-GROUND INTERACTION AND COMPARISON WITH AVOSS MODEL"

AIAA Paper 2017-3036, June 2017, Denver, CO.

A two-dimensional, physics-based model was created and used to analyze the motion of a wake vortex pair with and without the presence of crosswind. The model is used to compute boundary layer separation on the ground plane. Thwaites' and Head's methods are used for boundary layer calculations along with Michels criterion for transition. The results are compared favorably with those from the AVOSS model.

Kolar, V.

"VORTEX IDENTIFICATION: NEW REQUIREMENTS AND LIMITATIONS"

International Journal of Heat and Fluid Flow, Vol. 28, 2007, pp. 638-652

Firstly, a brief survey dealing with popular vortex-identification methods is presented. The most widely used local criteria (applied point by point) - sharing a basis in the velocity-gradient tensor are treated more thoroughly to recall their underlying ideas and physical aspects. Many recent papers have pointed out various applicability limitations of these popular schemes and formulated (explicitly or implicitly) new general requirements, for example: validity for compressible flows and variable-density flows, determination of the local intensity of swirling motion, vortex-axis identification, non-local properties, ability to provide the same results in different rotating frames, etc. Other quite natural requirements are pointed out and added to those already mentioned. Secondly, the vortex-identification outcome of the proposed triple decomposition of the relative motion near a point is presented. The triple decomposition of motion based on the extraction of a so-called 'effective' pure shearing motion - has been motivated by the fact that vorticity cannot distinguish between pure shearing motions and the actual swirling motion of a vortex. This decomposition technique results in two additive vorticity parts (and, analogously, in two additive strain-rate parts) of distinct nature, namely the shear component and the residual one. The residual vorticity represents a direct measure of the actual swirling motion of a vortex. The new kinematic vortex-identification method is discussed on the background of previous methods and general vortex-identification requirements (illustrative examples are included).

Kolar, V. and Sistek, J.

"COROTATIONAL AND COMPRESSIBILITY ASPECTS LEADING TO A MODIFICATION OF THE VORTEX-IDENTIFICATION Q-CRITERION"

AIAA Journal, Vol. 53, No. 8, August 2015, pp. 2406-2410.

The 3-D modification of the vortex-identification Q-criterion, labeled (Q sub M)-criterion, has been proposed. It is based on the corotational and compressibility arguments, and in this regard, it represents a one-way extension from 2-D to 3-D concept. The (Q sub M)-criterion has been successfully applied to different flow situations: it closely reproduces the results of some widely used methods in regions of low external shear and performs better in regions of strong shearing similarly as the average-corotation method. The popular schemes Q and λ^2 tend to interpret the high shear zones of flat plate near wakes behind sharp edges in a biased manner as vortices. These schemes also produce much noisier outcome for the transonic flow past a turbine cascade. Similarity of results between the (Q sub M)-criterion and the average-corotation scheme is understandable due to the common corotational background. Finally, while the average corotation is a vectorial quantity and, therefore, more informative, an appealing aspect of the proposed (Q sub M)-criterion is its ease of evaluation.

"AVERAGE COROTATION OF LINE SEGMENTS NEAR A POINT AND VORTEX IDENTIFICATION"

AIAA Journal, Vol. 51, No. 11, November 2013, pp. 2678-2694.

An easy-to-interpret kinematic quantity measuring the average corotation of material line segments near a point is introduced and applied to vortex identification. At a given point, the vector of average corotation of line segments is defined as the average of the instantaneous local rigid-body rotation over 'all planar cross sections' passing through the examined point. The vortex-identification method based on average corotation is a one-parameter, region-type local method sensitive to the axial stretching rate as well as to the inner configuration of the velocity gradient tensor. The method is derived from a well-defined interpretation of the local flow kinematics to determine the 'plane of swirling' and is also applicable to compressible and variable-density flows. Practical application to direct numerical simulation datasets includes a hairpin vortex of boundary-layer transition, the reconnection process of two Burgers vortices, a flow around an inclined flat plate, and a flow around a revolving insect wing. The results agree well with some popular local methods and perform better in regions of strong shearing.

"VORTEX-FLOW MANIPULATION ON A GENERIC DELTA-WING CONFIGURATION"

Journal of Aircraft, Vol. 51, No. 5, September-October 2014, pp. 1380-1390.

The manipulation of characteristic vortex-flow instabilities, which occur in the flow around delta wings, is of great interest for increasing the performance of such configurations. This work presents experimental results of vortex-flow manipulation on a generic delta-wing configuration using pulsed blowing slot actuators along the leading edge. The frequencies of the examined blowing cases are chosen on the basis of unsteady characteristics that occur in the shear-layer roll-up during vortex formation and vortex breakdown. The results of hot-wire measurements substantiate the receptivity of the shear layer for the pulsed excitation until into the vortex core. The flow field response to this periodic forcing is shown by the displacement of the vortex bursting location in a chordwise direction, thus satisfying the aim of enhancing the aerodynamic performance.

Kollmann, W.

"ACCURATE NUMERICAL SIMULATIONS OF VORTEX FLOWS. I: VORTEX BREAKDOWN"

Computers and Fluids, Vol. 41, 2011, pp. 103-109.

Vortex breakdown in uniform axial flow is investigated numerically by solving the Navier-Stokes equations using a hybrid spectral finite difference method. Two Reynolds numbers and a high swirl number are considered with the lower Re-number resulting in axisymmetric flow, that possesses an asymptotic state, and a higher Re-number, that leads to unsteady flow and a moderate spectral range. The structural properties of the vorticity field are analyzed in terms of vorticity lines and surfaces. A recirculation bubble and a wake emerge that undergo significant fluctuations.

Kollmann, W.

"ACCURATE NUMERICAL SIMULATIONS OF VORTEX FLOWS. II: INTERACTION OF SWIRLING VORTEX RINGS"

Computers and Fluids, Vol. 41, 2011, pp. 110-118.

An accurate numerical method is applied to the investigation of the flow generated by two co-rotating vortex rings with axial flow in opposite direction at the Reynolds number $Re = 2000$. The rings are shown to generate a strong wake with significant axial vorticity due to the stretching induced by the rings. The rings merge and form a single ring with complex internal structure.

"NUMERICAL SIMULATION OF THE WAKE OF AN AIRLINER"

Journal of Aircraft, Vol. 55, No. 4, July-August 2018, pp. 1689-1699.

Large-eddy simulation of the wake past a realistic model airliner at cruise is presented. The near wake is resolved in a rectangular domain that extends through a distance of 3.33 times the wing span downstream from the wing tips. Dynamical properties of the trailing vortices and the jets are analyzed. The Moore-Saffman model is found consistent with the tangential velocity profiles obtained from the

numerical simulation. Recommendations are made for the future far-wake modeling using the near-wake data as the initial condition.

Kolomenskiy, D., Paoli, R. and Boussuge, J.-F.

"HYBRID RANS-LES SIMULATION OF WINGTIP VORTEX DYNAMICS"

Proceedings of the ASME 2014 4th Joint US-European Fluids Engineering Division Summer Meeting (FEDSM2014), August 2014, Chicago, IL.

This paper presents a feasibility study of a hybrid RANS-LES approach to numerical simulation of aircraft wing-tip vortices. A NACA 0012 wing is considered for which earlier published experimental and numerical data are available. Mesh sensitivity tests of our RANS solver and comparisons between two different turbulence models indicate that the RANS approach adequately describes the flow upstream from the trailing edge, but overestimates the rate of decay of the wing-tip vortex. A hybrid RANS-LES method is presented that results in a better agreement with the wind tunnel experiment, hence this approach is suggested for numerical simulation of the wake of an airliner.

Kolos-Lakatos, T.

"A SYSTEM LEVEL STUDY OF NEW WAKE TURBULENCE SEPARATION CONCEPTS AND THEIR IMPACT ON AIRPORT CAPACITY"

PhD Thesis, June 2017, Massachusetts Institute of Technology, Cambridge MA.

The air transportation industry continues to grow worldwide, but demand is often limited by available airspace and airport capacity. This thesis focuses on evaluating new air traffic procedures: specifically, new, and emerging wake turbulence separation rules that could potentially increase runway capacity based on today's knowledge of wake vortex turbulence and technological capabilities. While legacy wake separation rules establish aircraft-classes based on weight of aircraft, these new separation rules can define separation standards by considering other aircraft parameters and dynamic wind conditions. A fast-time runway system model is developed for studying these wake separation rules, using Monte-Carlo simulations, to provide accurate and realistic runway capacity estimates based on the randomness of arrival and departure operations. A total of nine new proposed wake separation rules are analyzed in detail, which include both distance-based and time-based methods, as well as static and dynamic concepts. Seven of the busiest and most delayed U.S. airports are selected as case studies for the illustration of runway capacity benefits enabled by these new wake separation rules: Boston (BOS), New York J.F. Kennedy (JFK), New York LaGuardia (LGA), Newark (EWR), San Francisco (SFO), Los Angeles (LAX), and Chicago O'Hare (ORD). For a detailed capacity analysis, the new wake separation rules are tested under the most constraining runway configurations at each of these airports. The results indicate that increasing the number of aircraft wake categories can increase runway capacity, but the added benefits become smaller with each new category added. A five-or six-category wake separation system can capture most of the runway capacity that can be achieved with a static pair-wise system. Additionally, shifting wake category boundaries between airports as a function of local fleet mix

can provide additional runway capacity benefits, meaning that airport specific wake separation rules can increase capacity over a universal separation rule system. Among the new wake separation rules, the results indicate that reducing wake separations further from current minimum separations (separation values of 2NM or less) can shift the operational bottleneck from the approach path to the runway, as runway occupancy time becomes the limiting factor for inter-arrival separations. The findings from the time-based separation rule demonstrate that switching from distance-based separations to time-based separations in strong headwind conditions can recover significant lost capacity. Time-based separation rules can be of great value to increase operational reliability and capacity predictability at airports in all weather conditions. Moreover, the results also indicate that a reduction in minimum separations enabled by dynamic wind and aircraft information can offer marginal runway capacity benefits over the capacity enabled by static pair-wise wake separations, as more and more aircraft pairs become limited by runway occupancy time. Therefore, a joint effort is needed for reducing both wake separations and runway occupancy to accommodate future air traffic demand.

Kolos-Lakatos, T.

"THE INFLUENCE OF RUNWAY OCCUPANCY TIME AND WAKE VORTEX SEPARATION REQUIREMENTS ON RUNWAY THROUGHPUT"

MS Thesis, May 2013, MIT, Cambridge, MA.

Air traffic growth in the U.S. has led to runway capacity constraints in the air transportation network. There has been limited new construction of runways due to land availability. One approach to increase capacity of existing runways is to reduce inter-arrival separations during the final approach phase of flight. This study evaluates two major elements influencing runway capacity; runway occupancy and wake vortex separation, and under what conditions each becomes a constraint to runway capacity. A detailed analysis of runway occupancy time measurements and wake vortex separation measurements is performed for Boston, Philadelphia, New York La Guardia, and Newark airports based on Airport Surface Detection Equipment Model-X (ASDE-X) aircraft surveillance data. The findings of this study indicate that runway occupancy does not necessarily scale with aircraft size. Small aircraft often occupy the runway as often as large aircraft, which limits the potential for reduced separations behind small aircraft. The results also indicate that high-speed runway exits can make a significant difference in runway occupancy. Runways equipped with high-speed exits have lower runway occupancy times than runways equipped with standard 90-degree exits. Comparison of runway occupancy times in Visual Meteorological Conditions (VMC) and Instrument Meteorological Conditions (IMC) suggest no significant difference between the two weather conditions. Wake vortex separation measurements show that aircraft pairs with small lead aircraft receive longer separation buffers than other aircraft pairs, and airports with more runways implement longer separation buffers. The comparison of landing time intervals and runway occupancy illustrates that wake vortex separation requirements limit runway capacity when heavy or Boeing 757 is the lead aircraft. Lastly, this study evaluates the runway capacity benefits of reduced wake separation requirements for the aircraft re-categorization (RECAT) program. The results estimate an 8.2-8.3% increase in runway capacity at Philadelphia and at Newark, a 7.8%

increase at Boston, and a 5.1% increase at La Guardia. The magnitude of benefits strongly depends on how the local traffic mix looks like.

"THE STATUS OF WAKE VORTEX RESEARCH IN JAPAN"

13th CLRC Proceedings, Oct. 2005, Tokyo, Japan, pp. 140-143

Electronic Navigation Research Institute (ENRI) has been researching wake vortex at the aim of effective flight operation since FY2002. We first detected wake vortices generated by medium commercial aircraft (B767) using wind profile LIDAR in FY2002. Based on the result, we newly made LIDAR for the wake vortex observation and has started observation last winter. The LIDAR is set up at our branch site adjacent to Sendai Airport. At the airport 100 commercial aircraft take off/land a day. Most of them belong to category M. This time, we report the activity status of wake vortex research in Japan, and show some observation results of the wake vortices generated by the commercial aircraft.

Komerath, N.

"EXPERIMENTAL RESULTS ON ROTOR WAKES"

ARO Rotorcraft Wake Prediction Basic Research Workshop, March 2009, Georgia Institute of Technology, Atlanta, GA.

The wake of a rotor is at once an extremely complex flow field, and one where the dominant phenomena are amenable to simple description. While the Landgreb-Gray deconstruction of the hover wake structure into tip vortices and helical vortex sheets, done in the early 1960s, still holds mostly true, several other details and implications have been proven. The transition from the near wake to far wake is known to occur through deterministic vortex-pairing rather than through chaotic processes, even at high Reynolds number. Similarly, mysterious 'jitter' phenomena have mostly been shown to be adequately explained through predictable vortex interactions. Through these advances, shown both experimentally and through analysis and computation, it has become possible to calculate rotor wakes to long ages, far beyond the current reach of first-principles finite-difference CFD. Meanwhile, the ancient disconnect between the correct wake geometry as calculated from blade loading, and the correct thrust as calculated using the wake geometry, has been attributed to a basic flaw in the application of lifting-line analysis to rotor wakes. Patient application of accurate non-intrusive measurement techniques in facilities where vortex-wall interactions are minimized, have enabled clean measurements of vortex core structure in axial and in edgewise flight, to large wake ages. This has enabled a new look at the data in the literature. The traditional assumption that all the vorticity outboard of the bound circulation peak will roll into the tip vortex, has been debunked by experiments, and by correlation of data from a broad range of experiments done in several organizations over the years. It is seen that a large part of this vorticity gets convected into the edge of the inboard vortex sheet. The extent to which this occurs depends on the details of the blade tip shape, demanding high-resolution numerical techniques to capture in predictive analysis.

Komerath, N. and Smith, M. J.

"ROTORCRAFT WAKE MODELING: PAST, PRESENT AND FUTURE"

Proceedings of the European Rotorcraft Forum, Sept. 2009, Hamburg, Germany.

Rotorcraft wake modeling is still a major concern in rotorcraft design and analysis as it influences the aerodynamic, aero-acoustic, and aeroelastic behavior of the vehicle. This paper presents a comprehensive overview of rotorcraft wake modeling, in the last decade, from the experimental, theoretical and computational viewpoints. Present capabilities are discussed and trends for future development are explored based on a recent Army Research Office sponsored Workshop in Wake Modeling held in March 2009 at the Georgia Institute of Technology, in which experts from all over the globe discussed status and limitations, as well as future needs and trends in wake modeling. This paper summarizes this workshop and juxtaposes it with current research on-going in wake experimentation and numerical modeling. Advances in computational fluid dynamics have improved near- and mid-wake modeling capabilities, but hybrid methods that employ vortex element, vorticity transport or vorticity

confinement methods will be necessary for long-age (far-wake) modeling in the near-term. A new hover experiment with high-accuracy measurements that tie the blade loading, rotor performance and wake characteristics is needed for the numerical model correlation and development.

Komerath, N. M. and Tung, C., editors

"PROCEEDINGS OF THE ARO ROTORCRAFT WAKE PREDICTION BASIC RESEARCH WORKSHOP"

Proceedings of the ARO Rotorcraft Wake Prediction Basic Research Workshop, March 2009, Georgia Institute of Technology, Atlanta, GA.

The structure and dynamics of the wakes from rotor blades continue to pose first-order uncertainties in the prediction of hover payload and forward flight speed of rotorcraft. The structure of the rotor wake continues to pose challenges in prediction and measurement. There have been advances in the theory, computational approaches, visualization, and measurement capabilities in this field in the past decade, but these have been slow to be translated into first-principles based prediction capability for vehicle design and analysis.

Komerath, N. M., Smith, M. J. and Tung, C.

"A REVIEW OF ROTOR WAKE PHYSICS AND MODELING"

Journal of the American Helicopter Society, Vol. 56, No. 2, Issue 1, April 2011, pp. 22006-1 to 22006-19.

This paper presents an overview of developments in rotorcraft wake modeling, particularly in the past decade, from the experimental, theoretical, and computational viewpoints. Current understanding of wake physics and limitations in wake modeling are summarized and juxtaposed with trends experimental and numerical research. Advances in flow imaging and velocimetry have provided evidence that supports simplified models of rotor wake behavior. Persistence of tip vortices to long ages, deterministic rollup phenomena leading to the transition to the far wake, and entrainment of a part of the nascent tip vortex vorticity into the counterrotating inboard wake have been shown through experiments. Advances in computational fluid dynamics have improved near- and far-wake wake modeling capabilities. Hybrid methods that employ vortex element, vorticity transport, or vorticity confinement methods will be necessary for long-age (far-wake) modeling soon. A new hover experiment with high-accuracy measurements that tie the blade loading, rotor performance, and wake characteristics is one suggestion to facilitate numerical model correlation and development.

Komerath, N. M., Thompson, T. L., Kwon, O. J. and Gray, R. B.

"VELOCITY FIELD OF A LIFTING ROTOR BLADE IN HOVER"

J. Aircraft, Vol. 25, No. 3, March 1988, pp. 250-257

Detailed measurements have been made using a laser velocimeter in the close vicinity of a lifting, single-bladed model rotor blade in simulated hover conditions to validate codes for predicting

rotorcraft aerodynamics. Data acquired at a rotor tip speed of 32 m/s and a tip Reynolds number of $2.7 \times 100,000$ are compared with predictions made using a thick-bladed panel code coupled to a prescribed wake calculation. Rotor inflow measurements are seen to agree closely with panel code results, even when examined with high chordwise resolution. Agreement is less definite in the near wake, where strong tip vortex effects are felt, and the vortex core model becomes important. Tip vortex formation is clearly visible from the data. Deviations from periodicity are insignificant in the close vicinity of the blade. Particle spin-out effects are seen to be pronounced in the vortex core when using conventional seeding materials but to be greatly reduced using incense seeding. The precise measurement of vortex core velocity profiles is seen to be within reach.

Komerath, N., Wong, O. and Ganesh, B.

"ON THE FORMATION AND DECAY OF ROTOR BLADE TIP VORTICES"

AIAA Paper No. 2004-2431, Portland, OR, June 2004

Models for the rate of decay of rotor tip vortices, based on near-wake data and computations, disagree with the observed persistence of rotor tip vortices for many revolutions. A correlation of data from the literature shows that the measured tip vortex strength is only 40% of the strength expected from the peak of the blade bound circulation, for blades with sharply-cut straight-edged tips, over a wide range of tip Mach and Reynolds numbers. Explanations of this drop in the near wake through turbulence models, are seen to be both counter-intuitive and in conflict with measurements of turbulent fluctuations. Using flow visualization and velocimetry in the wake of a 2-bladed rotor in low-speed forward flight, explanations are shown for these mysteries. Shear layer development at the blade tip, and the twist distribution of the blade have a strong influence on the fraction of the blade tip vorticity lost into the inboard counter-rotating wake. The observations of elliptic core shape and of multiple local extrema of axial velocity deficit, are shown to be features of the shear-layer separation and rollup processes. Blade-to-blade differences in vortex evolution from the same rotor are traced to surface texture differences at the blade tip. Results in the literature reporting 90 to 100% tip circulation recovery for such blades, are seen to be in cases where the induced velocity due to the tip vortex could not be distinguished from that due to the inboard sheet.

"PARTICLE IMAGE VELOCIMETRY: STATUS OF DEVELOPMENT AND EXAMPLES OF APPLICATION IN INDUSTRIAL TEST FACILITIES"

Proceedings 3rd ONERA-DLR Aerospace Symposium, Paris, France, June 2001, pp. S4-1/1-12

For the past few years particle image velocimetry (PIV) has been increasingly used for aerodynamic research and development. This is mainly due to the unique feature of the PIV technique, which allows the recording of a complete velocity field in a plane of the flow within a few microseconds. Thus, PIV provides information about unsteady flow fields, which is difficult to obtain with other experimental techniques. The short acquisition time and fast availability of data reduce the operational time, and

hence cost, in large scale test facilities. Technical progress made in the last years allowed the PIV teams of the European research establishments on aeronautics to develop reliable, modular PIV systems for use in industrial wind tunnels. Development, and application of PIV as well as information exchange about PIV with industrial end-users have been considerably supported by EC. This paper will summarize the state-of-the-art of PIV by describing the basic features of a PIV system for application in wind tunnels and will present some results of recent PIV applications within EC funded projects such as EUROPIV 1 and 2, PivNet, APIAN, WAVENC, EUROWAKE, C-Wake, EUROLIFT, and HELIFLOW. Most of these results have been obtained by joint teams of different EREA members, European aeronautical industry, and wind tunnels.

"AIRCRAFT WAKE VORTEX INVESTIGATIONS BY MEANS OF PARTICLE IMAGE VELOCIMETRY - MEASUREMENT TECHNIQUE AND ANALYSIS METHODS"

Proceedings of 3rd Int'l. Workshop on PIV'99, University of California, Santa Barbara, CA, 1999, pp. 255-260

The investigation of wake vortices is a traditional subject of aerodynamics. A continuous interest arises from general safety aspects of aircraft whereas in the past years the need to reduce the safety distance between following aircraft stimulated new investigations. This paper summarizes experimental aspects of work carried out in this field employing modern optical techniques for the measurement of instantaneous flow velocity fields. It will be shown that the use of a modern mobile Particle Image Velocimetry (PIV) system in combination with advanced evaluation and post processing techniques allows much faster progress in such a complex field of high technological (and economical) interest.

Kompenhans, J., Dieterle, L., Vollmers, H., Stuff, R., Schneider, G., Raffel, M., Dewhirst, T., Kahler, C., Pengel, K., Monnier, J.-C., Gilliot, A. and Coton, P.

"QUALITATIVE AND QUANTITATIVE VISUALIZATION OF WAKE VORTICES IN INDUSTRIAL TEST FACILITIES"

Proceedings of 9th International Symposium on Flow Visualization, Edinburgh, Scotland, August 2000, pp. 437-1 - 437-10.

The investigation of wake vortices is a traditional subject of aerodynamics. A continuous interest arises from general safety aspects of aircraft, which became even more important after the recent announcement of aircraft manufacturers in Europe and the US to bring larger airplanes into operation during the next few years. A number of national and international projects have been performed in Europe in the past years comprising experimental as well as theoretical investigations of the wake vortex problem. The objective of this paper is to show that the use of a modern mobile particle image velocimetry (PIV) system in combination with advanced evaluation and post processing techniques

allows to improve the insight into the complex flow field of wake vortices as compared to traditional methods such as smoke visualization and five-hole probes.

Kong, J.

"SAFETY EVALUATION OF A380 WAKE TURBULENCE SEPARATION"

Applied Mechanics and Materials, Vols. 278-280, 2013, pp. 31-34.

CAAC (Civil Aviation Administration of China) set a standard on A380 wake turbulence separation right after China Southern Airlines brought in Airbus A380 in 2001. This paper considers from the possibility of the latter aircraft wake turbulence influencing the preceding one, which means the wake turbulence risk, makes safety evaluation on the wake turbulence separation standard of the preceding aircraft as A380, and the latter one as heavy type, medium type and light type, based on the safety target level that ICAO (International Civil Aviation Organization) authorized. Each type chooses a typical aircraft to calculate the possibility of influenced by the preceding wake turbulence corresponding with the standard under calm wind. The final result shows that the A380 wake turbulence separation standard setting by CAAC is safe.

Konig, R.

"AIRCRAFT RESPONSE AND PILOT BEHAVIOR DURING A WAKE VORTEX ENCOUNTER PERPENDICULAR TO THE VORTEX AXIS"

AGARD, Flight in Adverse Environmental Conditions, September 1989.

Vortex systems can be hazardous to trailing aircraft which encounter them in flight. The greatest hazard occurs in areas where aircraft from a wide range of classes operate and where the flight paths are close to the ground. Upwash velocities induced by the wake vortices can be equivalent to the design gust velocities. Furthermore, different types of hazardous effects exist when encountering the vortex system, such as imposed rolling and pitching moments, a loss of rate of climb, a loss of altitude and structural loads. Aircraft response and pilot behavior during takeoff are described when a wake vortex is encountered perpendicular to the vortex axis. The aircraft response is calculated by nonlinear digital simulation with a mathematical model of a wake vortex system close to the ground. This real-time vortex model is also used in the Boeing B-737 simulator of Deutsche Lufthansa in order to examine the pilot behavior. Close to the ground, the wake vortex system induces additional horizontal velocities. There exists a critical flight path where very large g-loads are induced by vertical and horizontal vortex velocities and normal vertical acceleration shortly after takeoff. Often the pilot will attempt to counteract these g-loads, but this produces only a small effect.

Konopka, J.

"WIND PROFILES AND THEIR IMPACT ON WAKE TURBULENCE SEPARATION - FIRST RESULTS FROM THE WAKE VORTEX WARNING SYSTEM AT FRANKFURT AIRPORT"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

The Wake Vortex Warning System, WVWS, at Frankfurt Airport in particular the so-called glide-path extension is now technically completed. The glide-path extension shall enable a reduction of the wake turbulence separation using predictions of the wake vortices' motion between the two closely spaced parallel final approach paths for runways 25L and 25R in the entire height range up to 5000 ft above ground level. The glide-path extension of the WVWS comprises a Wind-Temperature-Radar with a Radio Acoustic Sounding System for high-resolution measurements of wind and temperature profiles in real time. Every two minutes the actual wind profile is measured and fed into a wind forecast algorithm which produces estimates of the wind up to 20 minutes ahead. This information is then used to determine whether wake transport between the two neighboring glide-paths can be excluded with high confidence. The installation is now running on a routine basis since May 2004 without any modification to the separation standards yet. The data collected under operational conditions so far allows for a first assessment of the potential capacity increase when such a crosswind-based system is used for approaches to closely spaced parallel runways. In the presentation the impact of different factors on the estimated benefit in terms of capacity will be discussed. These influencing factors include for example the wind profile itself, the runway geometry and the performance of aircraft on the glide-slope. The paramount system requirements regarding data availability and accuracy are confronted with the experience gathered so far. It turns out that the meteorology deteriorates the benefits for two reasons: Firstly, the state of the atmosphere does not always allow for safe reduction of the wake turbulence separation and secondly the performance of remote sensing systems like wind-profilers, sodars or lidars, etc. are crucially dependent on the ambient conditions.

Konopka, J.

"INCREASING CAPACITY BY WAKE TURBULENCE AVOIDANCE SYSTEMS AT FRANKFURT/MAIN AIRPORT"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Frankfurt/Main is among the 10 largest airports in the world. It accommodates a traffic volume of 460,000 movements per year (2000) including a 30% fraction of heavy type aircraft like Airbus 340s or Boeing 747s. The runway system consists of two closely spaced parallel runways (25/07) plus a third runway (18) that is exclusively used for departures. One of the most stringent capacity-limiting factors are wake turbulence separation requirements due to leading heavy aircraft. German Air Navigation Services (DFS) together with Frankfurt Airport (FRAPORT) is developing systems and novel procedures that allow for safe reduction of wake turbulence separation minima for landing traffic on different but close spaced runways even in IMC conditions. This paper gives an overview on the concept of the Wake Vortex Warning System (WVWS), its components, and how the system will be incorporated in a real Air Traffic Control environment. While current ICAO provisions rely on wake decay, the novel procedure will ensure wake turbulence safety because the wake of the leading (heavy type) aircraft will be transported away from the flight corridor of the trailing (medium type) aircraft. This shall be accomplished by accurate measurement of the prevailing meteorological conditions and subsequent forecast of the wake vortices' motion between the two glideslopes. Currently the WVWS covers a

safety box of 80 m height, however as a next step a wind-temperature radar will supplement the system and provide necessary data to extend the prognosis along the entire final approach path. Another alternative is presently tested in field trials: In the High Approach Landing System/Dual Threshold Operation (HALS/DTOP) project, FRAPORT and DFS have built an additional threshold (26L) on an existing runway (25L). The new threshold is displaced by 1500 m and thus ensures that aircraft approaching 26L will always stay 80 m above leading aircraft on 25R. Due to this 80 m shift the aircraft's flight corridor will be clear of wake turbulence.

"EDDF-2 DATA COLLECTION CAMPAIGN REPORT"

CREDOS Report D2-4, May 2008, DFS Deutsche Flugsicherung GmbH, Langen, Germany.

Operational surveillance and meteorological data have been collected at Frankfurt airport. The EDDF-2 data collection campaign lasted for more than one year to characterize the true operating conditions at a location where wake turbulence separation minima limit air traffic capacity. For six months also wake vortex data of departing aircraft have been collected and correlated to the other data. This report describes how the EDDF-2 data collection campaign was organized, summarizes its characteristic features of and provides information about its overall performance. Results of statistical analyses of various subsets of the data are given.

"THE WAKE VORTEX WARNING SYSTEM AT FRANKFORT AIRPORT"

24th Digital Avionics Systems Conference, Vol. 1, Nov. 2005, pp. 3.A.6-1-3.A.6-14

The Wake Vortex Warning System, WVWS, at Frankfurt Airport, in particular the so-called glide-path extension is now technically completed. The system shall enable a reduction of the wake turbulence separation using predictions of the wake vortices' motion between the two closely spaced parallel final approach paths for runways 25L and 25R up to 5000 ft above ground level. The glide-path extension of the WVWS comprises a wind-temperature radar with a radio acoustic sounding system, WTR/RASS for real-time measurements of wind and temperature profiles. Every two minutes the wind profile is measured and fed into a wind forecast algorithm which produces estimates of the wind up to 20 minutes ahead. This information is used to determine whether wake transport between the two neighboring glide paths can be excluded with high confidence. The installation is now running on a routine basis since May 2004 without any modification to the separation standards yet. The data collected under operational conditions so far allows for a first assessment of the potential capacity increase when such a crosswind-based system is used for approaches to closely spaced parallel runways. The impact of different factors on the estimated benefit in terms of capacity will be discussed. These influencing factors include for example the wing profile itself, the runway geometry, and the performance of the aircraft on the glide slope. The paramount system requirements regarding data availability and accuracy are confronted with the experience gathered so far. It turns out that the

meteorology deteriorates the benefits for two reasons: Firstly, the state of the atmosphere does not always allow for safe reduction of the wake turbulence separation and secondly the performance of remote sensing systems like wind profilers, sodars or lidars etc. are crucially dependent on the ambient conditions.

"THE CREDOS PROJECT: EDDF 6-MONTH WAKE AND WEATHER DATASET RWY25L/R [EDDF-2]"

D1-2, November 2009.

A long-term measurement campaign of vortices from departing aircraft has been conducted at Frankfurt airport between January and June 2007. Meteorological as well as aircraft trajectory data have been collected in parallel. Data from the various sensors have been fused and correlated to characterize the vortices in an operational and meteorological context. More than 10,000 cases mostly including heavy aircraft taking off runway 25R have been collected. The data is delivered on a separate data carrier. This document describes the different formats of the collected data, summarizes the definitions, and gives additional guidance for further analyses.

"NEAR GROUND LATERAL TRANSPORT/DECAY OF VORTICES AS OBSERVED FROM WINDLINE DATA AT FRANKFURT AND ITS IMPLICATIONS"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

The Frankfurt windline is used to track vortices under routine operations at Frankfurt/Main Airport. Ten state-of-the-art ultrasonic anemometers are installed between the closely spaced parallel approach paths to runways 25L and 25R approximately 0.5 NM before the thresholds. The device is part of the Wake Vortex Warning System and is operating on a 24-hours a day, 365 days a year basis. Although the

system has not been designed for this purpose and therefore has some limitations, it allows for wake vortex behavior analyses to an extent that cannot be achieved with data dedicated short-term measurement campaigns. Major advantages of the Frankfurt Windline data are: a high statistical significance, even if the data is sorted by aircraft types; a large fraction of heavy aircraft; and measurement under all weather conditions. In the presentation the influence of the ambient meteorological conditions on wake transport and decay is examined: The vortex transport distances are well correlated with the ambient crosswind, but a clear relationship between the lifetime of wake vortices and any of the available atmospheric variables could not be determined. Nevertheless, the data suggests that wake vortex lifetimes near the ground increase with aircraft size in such a way that is not in agreement with the widely used scaling with normalized time.

"THE GERMAN WAKE VORTEX PROJECT FOR FRANKFURT AIRPORT PARALLEL RUNWAY SYSTEM 25"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Quebec, Canada, December 1997, pp. 27-32

DFS has designed a Wake Vortex Warning System for Frankfurt/Main Airport. The system is safe and operational but faces acceptance problems from the side of the users. This paper outlines the basic principles and the present status of the German WVWS project. It includes a cost/benefit analysis, identifies the present problems, and gives an outlook on how the still existing problems may be brought to a solution.

"TOWING TANK INVESTIGATIONS ON 2- AND 4-VORTEX SYSTEMS IN GROUND EFFECT USING PIV"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

The spatial-temporal flow evolution of 2- and 4-vortex systems in ground proximity was investigated performing flow velocity field measurements in a tow tank. The F13 model consisting of one or two rectangular wings is used as vortex generator and is towed along an adjustable ground plate at specific heights of $h/b = 0.5, 0.25$ and 0.125 with respect to the trailing edge of the main wing. Three different vortex configurations were investigated; i.e. a 2-vortex system and two 4-vortex systems consisting of two co- and counter-rotating vortex pairs with a span width ratio of 0.3 and circulation ratios of plus and minus 0.3 . A Stereo Particle Image Velocimetry setup is employed to determine the flow velocity fields in a cross plane. The flow fields are analyzed with respect to flow separation at the ground, the generation of secondary vortices and the spatial-temporal development of the vortex trajectories and their circulation strengths.

Konrath, R. and von Carmer, C. F.

"VALIDATION EXPERIMENT WITH 4-VORTEX WAKE IN LARGE TOW TANK"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

Stereo PIV measurements on a 2- and 4-vortex system have been performed in a large tow tank of SVA at Potsdam. The aim was to provide experimental data for validation of numerical simulations of 4-vortex systems with respect to medium- and long-wave instabilities. Such instabilities could be an efficient way to promote a decay of the wing tip vortices. The experiments had to be performed within a large facility to preclude flow disturbances caused by end- and wall-effects. The considered 4-vortex system consists of two counter-rotating vortex pairs with a span width ratio of 0.3 and a circulation ratio of -0.3. For comparisons also the corresponding 2-vortex system is measured. Using DLR's generic wing model F-13 of 0.3 m span width as vortex generator the large tow tank of SVA at Potsdam allows measurements at very far distances which can be expressed by the dimensionless vortex age parameter of 8. A submersible Stereo PIV system was attached to a vertical traversing system to determine cross-sectional velocity fields of the descending wake vortex system. Specific time dependent triggering sequences account for the occurring high ranges of flow velocity magnitudes. The port as well as the starboard side vortices are measured simultaneously using a large observation area. The measurement's setup is described and first results will be discussed qualitatively.

Konrath, R., Agocs, J., Otter, D., Roosenboom, E. W. M., Wolf, Th. and Quest, J.

"FLOW FIELD MEASUREMENTS BY PIV AT HIGH REYNOLDS NUMBERS"

AIAA Paper 2013-0869, January 2013, Grapevine, TX.

Stereo PIV measurements have been applied to the wake flow on a high-lift aircraft configuration in the cryogenic pressurized transonic wind tunnel ETW at realistic Mach and Reynolds numbers. A cryo-PIV system, developed specially for the ETW to enable flow field measurements at gas temperatures down to 110 K and gas pressures of up to 450 kPa, has been adapted to a large measurement field extending over the complete span width of the half wing model. The specific seeding technique using ice particles and the optical systems are described as well as the automation the PIV measurements linked with the wind tunnel control system. First results of the vortical wing wake flow obtained at a Reynolds number of 17 million will be presented.

Konrath, R., Pallek, D., Mattner, H. and v. Carmer, C. F.

"ANALYSIS OF FLOW FIELD MEASUREMENTS OBTAINED IN A LARGE TOW TANK REGARDING THE DECAY OF WAKE VORTICES IN THE FAR-FIELD FOR TWO- AND FOUR-VORTEX SYSTEMS"

AIAA Paper 2009-0342, Jan. 2009, Orlando, FL

Stereo PIV measurements on a 2- and 4-vortex system have been performed in a large tow tank of SVA in Potsdam. The considered 4-vortex system consists of two counter-rotating vortex pairs generated by wings of a span width ratio of 0.3 and a circulation ratio of -0.3. As reference the

corresponding 2-vortex system is also considered. A submersible Stereo PIV system attached to a vertical traversing system was employed. Cross-plane velocity fields are obtained of the descending wake vortex system to access the vortex dynamics well into the wake far field (x/b greater than 500 and non-dimensional time greater than 11). The spatio-temporal evolution of the vortex systems is analyzed with respect to the vortex trajectories, circulations and core radii as well as the total kinetic energy contained in the measured flow field.

"A VORTEX-LATTICE METHOD FOR GENERAL, UNSTEADY AERODYNAMICS"

J. Aircraft, Vol. 22, No. 1, January 1985, pp. 43-4.

A general method of calculating unsteady, incompressible, inviscid, three-dimensional flows around arbitrary planforms has been developed. The method is an extension of the vortex-lattice technique. It is not limited by aspect ratio, camber, or angle of attack, as long as vortex breakdown does not occur above the surface of the wing and separation occurs only along sharp edges. As the wing performs arbitrary maneuvers, the position of the wake and the distribution of circulation on the wing and in the wake are obtained as functions of time. One desirable feature of the present method is its ability to treat steady lifting flows very efficiently. Several examples of steady and unsteady flows are presented. These include rectangular wings, with and without flaps, delta, and cropped delta wings.

Kontis, K.

"EXPERIMENTAL STUDIES ON THE INTERACTION OF JETS WITH THE VORTEX WAKE OF SLENDER BODIES"

Journal of Visualization, Vol. 8, No. 2, 2005, pp. 109-116.

An experimental study has been conducted to examine the low-speed aerodynamic characteristics of a pair of circular jets behavior in the vortex wake of a blunted cone cylinder-body combination with and without a 70-degree leading edge sweep delta wing. The induced flow field was examined via two-dimensional hot-wire anemometry surveys. Comparisons were made between the induced wake with and without the circular jets. The flow field over the models was visualized using smoke and oil visualization. The jet pair was found to undergo severe distortion within a very short distance from the nozzle exits. The shape of the jets was shown to change considerably when placed in the wake flow field of the models, which caused the jet pair to spread and become entrained within the vortices and wake created by the models.

"VORTICAL PATTERNS IN THE WAKE OF AN OSCILLATING AIRFOIL"

AIAA Journal, Vol. 27, No. 9, September 1989, pp. 1200-1205

The vortical flow patterns in the wake of a NACA 0012 airfoil pitching at small amplitudes are studied in a low-speed water channel. It is shown that a great deal of control can be exercised on the structure of the wake by the control of the frequency, amplitude, and the shape of the oscillation waveform. An important observation in this study is the existence of an axial flow in the cores of the wake vortices. Estimates of the magnitude of the axial flow suggest a linear dependence on the oscillation frequency and amplitude.

"LONG-WAVE INSTABILITY OF A VORTEX RING"

Fluid Dynamics, Vol. 30, No. 6, 1995, pp. 864-869.

The instability of barrel-shaped vibrations of a vortex ring in an ideal fluid is investigated. These vibrations, stable for a vortex ring with a piecewise-uniform vorticity profile, appear to be unstable for a vortex ring with a smooth vorticity profile. The instability growth rate is found on the basis of the energy balance equation determining the energy transport from perturbations with negative energy in the critical layer to perturbations with positive energy in the rest of the flow. The curvature of the vortex ring, by virtue of which the perturbations with energies of different signs appear to be connected, plays a prominent role in the mechanism under consideration.

Kopiev, V. F. and Chernyshev, S. A.

"OCTUPOLE RADIATION OF LOCALIZED VORTEX"

AIAA Paper No. 2005-2955, Monterey, CA, May 2005

For a weakly compressible inviscid fluid (with the Mach number $M \ll 1$), we consider the problem of obtaining the maximum possible number of terms of the asymptotic expansion of a sound field in powers of the Mach number for the aerodynamic sound generated by localized vortices. Using Crow's approach and the matching procedure of Van Dyke, quadrupole and octupole terms are obtained in the asymptotic expansion. It is shown that higher moments of the sound field cannot be obtained in such a procedure because of the divergence of the respective integrals in the inner expansion. We discuss the possibility of representing the sound field in terms of expressions for the quadrupole and octupole moments of an incompressible flow with a retarded argument. The theory of vortex ring eigen-oscillations and the formulas for quadrupole and octupole sound obtained previously by the authors based on matching asymptotic expansions are used for predictions of non-axisymmetric octupole radiation generated by eigen-oscillations of the vortex ring. The result obtained previously for axisymmetric case is elaborated for 3D problem. The calculation of octupole term has shown that for thin vortex rings this component depends on the ratio of two small parameters and may appear to be large.

Kopiev, V. F. and Chernyshev, S. A.

"VORTEX RING EIGEN-OSCILLATIONS AS A SOURCE OF SOUND"

J. Fluid Mech., Vol. 341, 1997, pp. 19-57

Two coupled problems are investigated: a complete description of long-wave vortex ring oscillations in an ideal incompressible fluid, and an examination of sound radiation by these oscillations in a weakly compressible fluid. The first part of the paper relates to the problem of eigen-oscillations of a thin vortex ring in an ideal incompressible fluid. The solution of the problem is obtained in the form of an asymptotic expansion in the small parameter μ . The complete set of three-dimensional eigen-oscillations and axisymmetric modes (two-dimensional oscillations) is obtained. It is shown that, unlike the vortex column oscillations which have the form of simple angular harmonics, most of eigen-oscillations of a thin vortex ring have a more complex form which is a combination of two harmonics in the leading approximation. This leads to dramatic changes in the efficiency of sound radiation produced by modes of the vortex ring in comparison with the corresponding modes of the vortex column. In the second part of the paper the solution obtained is used to investigate the process of sound radiation by vortex perturbations in a weakly compressible fluid. The vortex ring eigen-oscillations are classified according to their sound radiation efficiency. It is shown that the modes with the dimensionless frequency about $1/2$ radiate sound most efficiently. They are two isolated modes, two infinite families of Bessel modes and a set of axisymmetric modes.

Koplin, K.

"WAKE VORTICES - A EUROPEAN REGULATORY VIEW"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 3-1 to 3-10

The activities of the 26-member Joint Aviation Authorities (JAA) are described along with JAA's relationship with other European organizations concerned with civil aviation regulations. Wake vortex hazards are worrisome in Europe and must be considered in planning for air traffic growth, but JAA does not consider this an urgent safety problem at present.

Kopp, F.

"THE INFRARED DOPPLER LIDAR: AN IMPORTANT TOOL FOR EXPERIMENTAL INVESTIGATION OF AIRCRAFT WAKE VORTICES"

Optical Society of America, Technical Digest, Vol. 12, 1991, pp. 306-308

The DLR laser Doppler anemometer represents an important contribution to the German wake-vortex program. Especially vortex transport and decay within the area of ground influence have been investigated at Frankfurt Airport.

Kopp, F.

"PROPERTIES OF AIRCRAFT WAKE VORTICES MEASURED BY GROUND-BASED CONTINUOUS-WAVE DOPPLER LIDAR"

Society of Photo-Optical Instrumentation Engineers (SPIE) Proceedings, Vol. 3707, 1999, pp. 204-209

The DLR ground-based cw Doppler lidar has been developed for wind and turbulence measurements in the atmospheric boundary layer. Moreover, it is used for experimental investigations of aircraft wake vortices. This paper presents measurements of wake vortices generated by military-type fixed-wing as well as rotor-wing aircraft. The experimental data are analyzed regarding the structure and circulation of wake vortices and their temporal development. The influence of flight parameters is measured during several consecutive fly-bys. Small variations in the velocity profiles are observed which are overlain by the signatures of the variable wind and turbulence field, a problem which can only be solved by statistical treatment. The influence of the aircraft design is demonstrated by comparison of the vortex signatures generated by two B707-type aircraft with pronounced differences in aircraft design.

Kopp, F.

"DOPPLER LIDAR INVESTIGATION OF WAKE VORTEX TRANSPORT BETWEEN CLOSELY SPACED PARALLEL RUNWAYS"

AIAA Journal, Vol. 32, No. 4, April 1994, pp. 805-810

The paper demonstrates the potential of the Doppler lidar technique for the investigation of aircraft wake vortices. During several extended field experiments at the Frankfurt/Main Airport, the DLR laser Doppler anemometer has measured the vortex properties of a large variety of landing aircraft. These data are used to increase the understanding of the behavior of wake vortices with special emphasis on the horizontal vortex transport in ground effect. In particular, the results of the vortex transport considerations are the basis for air traffic control to enhance the efficiency of closely spaced parallel runway systems with respect to wake vortices.

Kopp, F.

"MORE INSIGHT INTO AIRCRAFT WAKE VORTICES BY MEANS OF GROUND-BASED CW DOPPLER LIDAR"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

Aircraft wake vortices are presenting a potential hazard to other aircraft following closely behind. This is not only a safety problem but also a capacity problem at major airports. Several approaches are under investigation: A reduction of the presently binding separation distances can be achieved by long-range airfield systems or forward-looking onboard sensors for wake vortex detection and warning. In the design phase of new aircraft types, mechanical features for vortex alleviation can be considered. Supposition for these approaches is the precise knowledge of the vortex properties and their temporal behavior. At DLR, a cw Doppler Lidar has been developed for boundary layer wind measurements. This system is also used for the investigation of vortex properties, like velocity distribution, circulation,

transport in ground influence and decay. During several field experiments, the signatures of a large variety of aircraft types have been acquired covering the bandwidth from small business to large commercial aircraft. Experimental data will be presented, including data of scarcely investigated vortices like those being generated by fighter-type aircraft and by helicopters. The relationship to aircraft parameters and to the atmospheric environment will be considered.

Kopp, F.

"EXPERIMENTAL INVESTIGATION OF WAKE VORTEX STRUCTURE AND PROPAGATION USING THE DLR LASER DOPPLER ANEMOMETER"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 46-1 - 46-8

Extensive experiences in the USA and Germany have proved that the infrared Doppler Lidar is the most effective and flexible remote sensing method for wake-vortex detection, measurement, and tracking. Therefore, the DLR Laser Doppler Anemometer has been incorporated into the German Wake Vortex Program. This program is concentrated on the highly frequented Frankfurt Airport where additional capacity limitations are caused by the separation of 1700 ft between the two parallel runways. This separation is often too small for operating both runways independently with respect to wake vortices. Therefore, the main objectives are the determination of the strength and propagation of the vortices of 'new generation' aircraft, such as B757, B767, and A320, and the identification of atmospheric conditions where vortex-independent operation of the parallel runways is possible.

Kopp, F.

"WAKE-VORTEX CHARACTERISTICS OF MILITARY-TYPE AIRCRAFT MEASURED AT AIRPORT OBERPFAFFENHOFEN USING THE DLR LASER DOPPLER ANEMOMETER"

Aerospace Science and Tech., Vol. 3, No. 4, June 1999, pp. 191-199

Experimental investigations of wake vortices generated by military-type aircraft, including fixed-wing and rotary-wing aircraft, were made using the DLR ground-based CW Doppler lidar. Attention was given in the measurements to the vortex roll-up phase. The experimental data analyzed dealt with vortex structure, circulation, and temporal development. Vortex signatures measured during consecutive aircraft flybys were used to investigate the influence of flight parameters, especially the aircraft mass. Small variations in the velocity profiles could be observed, but the differences in flight parameters from flyby to flyby were not large enough to produce systematic variations of the vortex signatures. In practice, the vortex signatures are always overlayed by the signatures of the variable surrounding wind and turbulence field. This problem can be solved on a statistical basis by measuring many cases under the same conditions. The influence of aircraft design was demonstrated by comparing the vortex signatures of two B707-type aircraft showing pronounced design differences, namely a standard B707 and an AWACS E3A, which is a B707 bearing a radome on top of the fuselage. The velocity profiles and, therefore, the circulation profiles of both aircraft show different shapes.

Kopp, F.

"LONG-RANGE DETECTION OF AIRCRAFT WAKE VORTICES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

For flight safety and airport capacity, it is of growing importance to detect wake vortices and atmospheric hazards, like wind shear, downdraft, and clear-air turbulence, well before a possible encounter of the aircraft. This can be achieved either by a forward-looking sensor being installed in the aircraft or by a ground-based sensor covering the approach area of highly-frequented airports. The most promising candidate for such sensors is the Doppler lidar in pulsed version. A pulsed Doppler lidar system has been developed and tested in the frame of the EC Project MFLAME (Multifunction Laser Atmospheric Measuring Equipment). It is based on the laser transceiver unit MAG-1 from CLR Photonics with special features necessary for wake-vortex detection: the pulse repetition rate of 500 Hz allows to cover the field-of-view of 12 x 13 degrees within a few seconds with sufficient spatial resolution and the pulse length of 500 ns provides a range resolution well adapted to the size of the phenomenon. Following the transceiver, the laser beam is twenty-times expanded by an off-axis telescope and then deflected into the sensing area by a scanning device. This device is the combination of two separate units: a fast vertical scanner consisting of two counter-rotating prisms and an oscillating plane mirror providing the horizontal scan. In this way, one complete image is covered within 5 s by a sinusoidal scan pattern with 75 vertical lines. The detector signals from the atmospheric return and the pulse-monitor reference are digitized with 500 MHz sampling rate and stored by the data acquisition and quick-look unit. Links to the scanner device enable the localization of each line-of-sight within the field-of-view. To demonstrate the feasibility of the pulsed lidar for wake-vortex detection, ground tests have been carried out at the airport Toulouse-Blagnac in February and March 2000. There, the lidar system was installed below the glide slope of runway 33L approximately 800 m in front of the threshold. The detection of vortices generated by a large variety of aircraft has been successfully demonstrated up to ranges of more than 2 km.

Kopp, F. and Krichbaumer, W. A.

"EXPERIMENTAL AND THEORETICAL DOPPLER-LIDAR SIGNATURES OF AIRCRAFT WAKE VORTICES"

13th International Laser Radar Conf., NASA Langley, August 1986.

The DFVLR laser Doppler anemometer is a CO₂ continuous wave homodyne system designed for boundary layer wind measurements. During the last three years, it was mainly used in the wake-vortex program at Frankfurt airport for determination of vortex strength, transport, and lifetime. The strategy for that special type of measurement was previously reported in detail along with single experimental results. Therefore, herein is given a short summary of the data concerning questions of air traffic control. In addition to the experimental activities a computer model describing wake-vortex behavior was installed. It allows the comparison of the measured data with the hydrodynamically predicted

quantities. On the other hand, it leads to an improved procedure for future wake-vortex measurements.

Kopp, F., Rahm, S. and Smalikho, I.

"CHARACTERIZATION OF AIRCRAFT WAKE VORTICES BY 2-MICRON PULSED DOPPLER LIDAR"

Journal of Atmospheric and Oceanic Technology, Vol. 21, 2004, pp. 194-206

The 2-micron pulsed Doppler lidar, already successfully used for wind and turbulence measurements, has been modified for long-range wake-vortex characterization. In particular, a four-stage data processing algorithm has been developed to achieve precise profiles of tangential velocities from which the vortex parameters such as trajectories, core separation, tilt angle, and circulation can be derived. The main advantage of the pulsed lidar is its long-range capability of more than 1 km. This allows for observations over long periods from the moment of wake generation to a progressed state of vortex decay. With the field experiment at Tarbes airfield the potential of the 2-micron pulsed Doppler lidar for full-scale wake-vortex characterization has been demonstrated. Two examples showing the parameters of wake vortices generated by large transport aircraft (LTA)-type aircraft will be presented.

Kopp, F., Rahm, S., Smalikho, I., Dolfi, A., Cariou, J.-P., Harris, M. and Young, R. I.

"COMPARISON OF WAKE-VORTEX PARAMETERS MEASURED BY PULSED AND CONTINUOUS-WAVE LIDARS"

Journal of Aircraft, Vol. 42, No. 4, July-August 2005, pp. 916-923

Field trials carried out at Tarbes airfield in the summer of 2002 offered the unique opportunity to compare the results of simultaneous wake-vortex measurements by the pulsed Doppler lidar from DLR, German Aerospace Research Center, and the continuous wave (CW) Doppler lidars from ONERA and QinetiQ. The discrepancies in vortex core position obtained from the data of the pulsed lidar and the CW lidars are 9 m for the vertical and 13 m for the horizontal coordinates. The accuracies of the vortex circulation measurements with the DLR and ONERA lidars are almost the same and equal 13 m squared/s. This accuracy and the long-range capability of the pulsed lidar allows precise measurements over long periods from the moment of wake generation to a progressed state of vortex decay. Moreover, the influence of different atmospheric turbulence conditions and aircraft configurations on the wake-vortex circulation can be analyzed. This has been demonstrated out of ground effect under conditions of weak to moderate levels of turbulence.

Kopp, F., Smalikho, I., Rahm, S., Dolfi, A., Cariou, J.-P., Harris, M., Young, R. I., Weekes, K. and Gordon, N.

"CHARACTERIZATION OF AIRCRAFT WAKE VORTICES BY MULTIPLE-LIDAR TRIANGULATION"

AIAA Journal, Vol. 41, No. 6, June 2003, pp. 1081-1088

Three continuous-wave lidar systems have been deployed to measure simultaneously the airflow associated with wake vortices generated by a medium-size full-scale test aircraft. The lidar systems were positioned to permit investigation of fundamental aspects of vortex behavior. Two lidars were located 27 m apart, along a line parallel to the glide slope. This allowed a consistency check via comparison of the two sets of results and gave an indication of axial variations in vortex location and character. The third lidar was positioned 80 m away along a line perpendicular to the glide slope. This permitted accurate location of the vortex cores by triangulation methods via a tracking algorithm based on an extended Kalman filter, typically to an accuracy of better than plus/minus 4.0 m. The mean value of core separation for a vortex age of 2 s agrees to within 5% of that predicted for this aircraft using the approximation of elliptically distributed lift. Calculation of vortex circulation requires accurate information on vortex range in conjunction with tangent velocity profiles: The trajectories thus determined are an essential input, and, hence, this method will reduce the uncertainty in the values of circulation in comparison to studies involving only a single lidar.

"THRUST MODELS BASED ON OPERATIONAL FLIGHT DATA USED IN PARAMETER ESTIMATION FOR SAFETY ANALYSES"

31st Congress of the International Council of the Aeronautical Sciences (ICAS 2018), September 2018, Belo Horizonte, Brazil.

Based on available operational flight data of a Boeing 737-300 with CFM56-3 engines, four different thrust models are developed in MATLAB. The model development is supported by the software GasTurb which can compute operating lines for engine components based on a design point. The results are used for the generation of lookup tables. The computed thrust is then utilized in parameter estimation for the landing phase from touchdown to a calibrated airspeed of 50 kts. Here, zero drag coefficients, spoiler drag coefficients and a braking coefficient are estimated for about 1500 flights using the Output Error Method combined with the Gauss-Newton algorithm.

"FORMATION FLIGHT OF LOW-ASPECT-RATIO WINGS AT LOW REYNOLDS NUMBER"

Journal of Aircraft, Vol. 54, No. 3, May-June 2017, pp. 1025-1034.

This paper examines the application of formation flight to micro air vehicles regarding possible power savings. Results of an experimental investigation on echelon formations using low-aspect-ratio ($AR = 2$) flat plate rectangular wings at low Reynolds number ($Re = 35,000$) are presented. One, two, and three-wing configurations are tested in a low-speed wind tunnel. To quantify the power savings by lift enhancement and drag reduction, the aerodynamic loads acting on each wing are measured using specific balances while the trailing wings of the formation are being traversed laterally and vertically in fine steps. In addition, the flow fields of the wing wakes are measured using particle image

velocimetry. The force and flow field measurements show that the optimal positions for lift enhancement appear at slightly spanwise overlapping between the leading and trailing wings.

Korner, H.

"HERMANN SCHLICHTING'S WORK AND WAKE IN AIRPLANE-AERODYNAMICS"

Notes on Numerical Fluid Dynamics and Multidisciplinary Design, Vol. 102, 2009, pp. 18-38.

This paper gives a survey of the work of Hermann Schlichting in the field of airplane-aerodynamics. It includes his scientific work as well as his commitment in building up test facilities. It furthermore describes his role in the reconstruction of aerodynamics research after the war, when he became one of the key persons. Under his leadership the reconstruction of wind tunnels and the establishment of new priority fields in research took place. Subsequently, he introduced this new orientation of German aerodynamics research to the international community.

"MULTI-MODEL ENSEMBLE WAKE VORTEX PREDICTION"

Aircraft Engineering and Aerospace Technology, Vol. 88, Issue 2, 2016, pp. 331-340

Purpose Wake vortices that are generated by an aircraft due to lift constitute a potential danger to the following aircraft. To predict and avoid dangerous situations, wake vortex transport and decay models have been developed. Being based on different model physics, they can complement each other with their individual strengths. This paper investigates the skill of a Multi-Model Ensemble (MME) approach to improve prediction performance. Therefore, this paper aims to use wake vortex models developed by NASA (APA3.2, APA3.4, TDP2.1) and by DLR (P2P). Furthermore, this paper analyzes the possibility to use the ensemble spread to compute uncertainty envelopes.

Korner, S. and Holzaepfel, F.

"MULTI-MODEL ENSEMBLE WAKE VORTEX PREDICTION -- FURTHER DEVELOPMENT AND PROBABILISTIC ASSESSMENT"

AIAA Paper 2016-3438, June 2016, Washington, DC.

This paper investigates the capability of the Multi-Model Ensemble approach to improve both the deterministic and probabilistic forecast of wake vortex behavior. Therefore, the models D2P, APA 3.2, APA 3.4 and TDP 2.1 were provided within the framework of a NASA-DLR cooperation. In a previous study the Bayesian Model Averaging (BMA) approach, that computes the ensemble forecast as a weighted sum of PDDs, turned out to be promising. For this reason, the focus of this paper lies on the further development and assessment of this method. While the previously presented approaches did not consider that the error increases temporally, the new approach considers the growing

uncertainties. For training and evaluation wake vortex campaigns accomplished by NASA (DFW97, MEM95) and DLR (WakeMUC, WakeFRA, WakeOP) are employed.

Korner, S., Ahmad, N. N., Holzaepfel, F. and VanValkenburg, R. L.

"MULTI-MODEL ENSEMBLE WAKE VORTEX PREDICTION"

AIAA Paper 2015-3173, June 2015, Dallas, TX.

Several multi-model ensemble methods are investigated for predicting wake vortex transport and decay. This study is a joint effort between National Aeronautics and Space Administration and Deutsches Zentrum für Luft- und Raumfahrt to develop a multi-model ensemble capability using their wake models. An overview of different multi-model ensemble methods and their feasibility for wake applications is presented. The methods include Reliability Ensemble Averaging, Bayesian Model Averaging, and Monte Carlo Simulations. The methodologies are evaluated using data from wake vortex field experiments.

Korner, S., Ahmad, N. N., Holzaepfel, F. and VanValkenburg, R. L.

"MULTIMODAL ENSEMBLE METHODS FOR PREDICTION OF WAKE-VORTEX TRANSPORT AND DECAY"

Journal of Aircraft, Vol. 54, No. 5, September-October 2017, pp. 1849-1859.

Several multi-model ensemble methods are selected and further developed to improve the deterministic and probabilistic skills of individual wake-vortex transport and decay models. The different multi-model ensemble methods are introduced, and their suitability for wake applications is demonstrated. The selected methods include direct ensemble averaging, Bayesian model averaging, and Monte Carlo simulation. The different methodologies are evaluated employing data from wake-vortex field measurement campaigns conducted in the United States and Germany.

"PERFORMANCE OF ONBOARD WAKE-VORTEX PREDICTION SYSTEMS EMPLOYING VARIOUS METEOROLOGICAL DATA SOURCES"

WMO Aeronautical Meteorological Scientific Conference 2017, November 2017, Toulouse, France.

Wake vortices, generated by aircraft enroute, naturally descend towards lower flight levels. Due to the minimum vertical spacing the possibility for an aircraft at lower flight level to encounter wake turbulence seems small at first glance. However, 73 wake-turbulence incidents have been reported at upper flight levels between 2009 and 2012. Furthermore, in January a Challenger business jet experienced a severe wake encounter with several passengers injured and the aircraft being forced to perform an emergency landing. To reduce the risk of wake vortex encounters in-flight onboard wake

vortex forecasts can predict the position and strength of vortices generated by nearby aircraft. In this work the accuracy of wake-vortex predictions of DLR's wake encounter avoidance and advisory system (WEAA) is analyzed by means of data gathered from a flight test campaign in April 2014. The system is based on airborne data exchange between aircraft and allows pilots to avoid potentially dangerous wake-vortex encounters. As the vortex evolution is strongly controlled by atmospheric parameters, the acquisition of meteorological data is crucial for WEAA. The accuracy of the wake-vortex predictions is investigated, employing first the current automatic dependent surveillance (ADS-B) standard, which is then extended by additional meteorological data transmitted via telemetry, or data from numerical weather predictions (NWP).

Kornev, N. and Abbas, N.

"NUMERICAL SIMULATION OF THE TIP VORTEX BEHIND A WING OSCILLATED WITH A SMALL AMPLITUDE"

Journal of Aircraft, Vol. 54, No. 2, March-April 2017, pp. 828-835.

The aim of the present study is the validation of unsteady wing-wake simulations using different CFD models. Numerical URANS simulations reproduce increase of the maximum tangential velocities, streamwise vorticity, and vortex strength during pitch-down, compared with these during pitch-up. The level of difference between pitch-down and pitch-up values increases slightly with the frequency and angle of attack. Because the relaminarization is not modeled and the separations are not observed at small AOA, the reason for this difference is due to common delay effects, which are well known in aerodynamics and caused by formation of unsteady vortices. Overall, the agreement between URANS and measurements can be considered as satisfactory. The discrepancy between numerical results and measurements is due to four reasons: insufficient resolution of the vortex core, application of imperfect turbulence models, small number of simulated oscillation cycles, and measurement uncertainty. A strong discrepancy is observed in the range of small AOA in the pitch-up phase. It can be explained by the relaminarization leading to a significant change of the flow, which cannot be captured by turbulence models used in this note. This effect requires additional investigation in the future.

"A WAY TO SPLIT THE NAVIER-STOKES EQUATIONS IN THE CONTEXT OF THE VORTEX METHOD"

Communications in Numerical Methods in Engineering, Vol. 14, Issue 4, April 1998, pp. 313-319

A numerical scheme has been obtained rigorously from the initial-boundary value problem for the Navier-Stokes (NS) equations in the context of the vortex method. The technique is based on a transformation of the NS equation into a parabolic equation which has an exact solution. The numerical scheme is derived by expanding the exact solution in Taylor series in powers of a small time-interval. Numerical implementation is developed with use of vortex particles to represent the vortex flow domain. The method is used to solve practical engineering problems. The technique can also incorporate turbulence modelling.

Kornev, N. V. and Reichert, G.

"THREE-DIMENSIONAL INSTABILITY OF A PAIR OF TRAILING VORTICES NEAR THE GROUND"

AIAA Journal, Vol. 35, No. 10, October 1997, pp. 1667-1669

A linear analysis of inviscid fluid is presented, indicating that trailing vortices undergo a growing sinusoidal instability in close vicinity to the ground and encounter it. However, in reality, the approaching vortices generate the boundary layer along the ground that separates and causes the primary vortices to follow a complicated trajectory.

Kornev, N., Treshkov, V. and Reichert, G.

"DYNAMICS OF THE TRAILING VORTICES NEAR THE GROUND"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany, pp. 425-434.

The first part of the paper is devoted to the trailing vortices dynamics in the near vortex wake of a lifting surface near the ground. The problem has been extensively investigated because of its historical importance in the ekranoplan application. In this paper we describe some specific features of the trailing vortices behavior near the ground. The second part of the paper focuses on the trailing vortices behavior in the far vortex wake. An important aspect of the present paper is the theoretical study of the three-dimensional Crow instability near the ground. Both the cases of inviscid and viscous flow have been considered. The developed analytical model in inviscid flow predicts three types of the vortex instability near the ground, depending on the dimensionless height of flight. The possible scenario of the vortex trailing instability and decay in ground effect has been proposed as a result of the theoretical analysis.

"PROBABILISTIC WAKE VORTEX INDUCED ACCIDENT RISK ASSESSMENT"

Third USA/Europe Air Traffic Management R&D Seminar, June 2000, Naples, Italy

New Air Traffic Management (ATM) concepts for departure and landing on busy airports might have a major impact on capacity if the wake vortex induced risks are better understood. The present wake vortex separation standards for the use of a single runway are often limiting capacity too much. To give ATM concept developers feedback with respect to the safety of new ATM concepts, a novel probabilistic methodology is under development for the assessment of wake vortex induced accident risks. The results of the safety assessment give insight in critical ATM design issues and thereby well-founded advice can be given on improvement of the design of the ATM concept. The probabilistic wake vortex induced accident risk assessment is based on recent progress in wake vortex research. Commonly accepted models for wake vortex evolution and wake encounter have been adapted and

integrated in the stochastic modelling and analysis setting of the TOPAZ (Traffic Organization and Perturbation AnalyZer) methodology. This paper outlines this probabilistic wake vortex induced accident risk assessment methodology and illustrates its initial application to the case of multiple aircraft landing on a single runway.

"VISCOUS FLUID SIMULATION WITH THE VORTEX ELEMENT METHOD"

31st Congress of the International Council of the Aeronautical Sciences (ICAS 2018), September 2018, Belo Horizonte, Brazil.

Vortex methods have shown their effectiveness for several kinds of incompressible fluid dynamics problems, where the viscosity effects can be neglected. However, simulation of viscous flows via vortex methods meets difficulties because of the viscosity term in the vorticity evolution equation that needs to be resolved. In this paper we give a general overview of several viscosity models that we apply to the Vortex Element Method based on fragmentations. We consider three different approaches: Particle Strength Exchange, Diffusion-Velocity Method, and a hybrid scheme to approximate the viscosity term. Finally, we show two simple simulation examples of the diffusion of rectilinear vortex and vortex ring in viscous fluid.

Koumoutsakos, P.

"INVISCID AXISYMMETRIZATION OF AN ELLIPTICAL VORTEX"

Journal of Computational Physics, Vol. 138, 1997, pp. 821-857

The inviscid evolution of elliptical, nonuniform vorticity distributions is studied computationally using a high resolution Lagrangian (vortex) method with minimal numerical dissipation. The simulations reveal that the vortices evolve, through a process of filamentation, to a configuration consisting of a vortex surrounded by weak filamentary structures. The shape of the final configuration depends on the profile of the initial vorticity distribution. For the same ellipticity, relatively smooth profiles evolve to axisymmetric vortical structures, whereas sharper initial vorticity distributions result in robust non-axisymmetric configurations. A systematic convergence study is conducted to establish the accuracy of the method for long time inviscid simulations. To further assess the issue of axisymmetrization, we compare our results with related numerical and experimental studies.

Koumoutsakos, P., Leonard, A. and Pepin, F.

"BOUNDARY CONDITIONS FOR VISCOUS VORTEX METHODS"

Journal of Computational Physics, Vol. 113, 1994, pp. 52-61

This paper presents a Neumann-type vorticity boundary condition for the vorticity formulation of the Navier-Stokes equations. The vorticity creation process at the boundary, due to the no-slip condition, is

expressed in terms of a vorticity flux. The scheme is incorporated then into a Lagrangian vortex blob method that uses a particle strength exchange algorithm for viscous diffusion. The no-slip condition is not enforced by the generation of new vortices at the boundary but instead by modifying the strength of the vortices in the vicinity of the boundary.

Koziol, Jr., J. S.

"AN ASSESSMENT OF CURRENT METEOROLOGICAL DATA SYSTEMS AT LARGE AIRPORTS FOR WAKE VORTEX AVOIDANCE SYSTEMS"

PM-P-8, September 1974, DOT Transportation System Center, Cambridge, MA

The objective of this assessment was to determine to what extent current airport meteorological data systems can provide a basis for the formulation and implementation of a wake vortex prediction model. This involved an investigation of meteorological data systems at ten high-traffic density airports, weather forecasting services, and prediction model requirements.

"DISTINCTIVE FEATURES OF THE TURBULENT FLOW IN A TRAILING VORTEX"

Fluid Dynamics, Vol. 39, No. 1, 2004, pp. 69-75

An analysis of the applicability of the well-known one-equation turbulence model of Spalart and Allmaras, which makes allowance for rotation and streamline curvature effects, to the description of the two-dimensional turbulent vortex flow downstream of the trailing edge of an aircraft wing and the three-dimensional interaction of the trailing vortex with the exhaust jets, is performed. A modification of the turbulence model is proposed and the results of numerical calculations are compared with the available experimental data.

Kraft, Jr., C. C.

"FLIGHT MEASUREMENTS OF THE TRAILING VORTICES OF AN AIRPLANE"

NACA TN-3377, March 1955, Langley Aeronautical Lab., Langley Field, VA

The disturbance created by the trailing vortices of an airplane can have a detrimental effect on the flight of another airplane passing through the wake. An attempt has been made to measure the velocity distribution and persistence of the trailing vortices of a propeller-driven fighter-type aircraft. This airplane was equipped with a smoke-generating device to mark the vortices. A jet airplane having a high-frequency angle-of-attack vane and a sensitive total-pressure instrument was used to fly through the vortices.

Kranepuhl, R., Shkarayev, S. and Planchenault, P.

"WINGTIP VORTEX MODIFICATIONS USING ALTERNATING JETS"

AIAA Paper 2016-3118, June 2016, Washington, DC.

The safe reduction of separation distance between airplanes can be achieved by modifying the wingtip vortices. Modifications in a near-field wake by using spanwise jets were studied on a NACA 0012 wing model. Experiments were conducted in the wind tunnel at 15 m/s and at an angle of attack of 7.5 degrees. Two chambers were integrated in the interior of the wing model with two angled jet slots in the wingtip. The jets pulsed at 10 Hz. The jet velocity distribution was quantified with the help of a hot-wire anemometry and PIV. To investigate the evolution of wingtip vortex, the phase-locked 2D PIV measurements were conducted at 5 streamwise stations. Studies include the baseline case, spanwise steady and pulsed jet blowing on the pressure and suction sides of the wing model, and alternating phase-shifted blowing of two jets. Steady jets displace wingtip vortices upward and outward from the wing tip. Under the pulsed blowing, the vortex center oscillates along the line inclined to the horizontal. When advecting downstream, the vortex is moving in a spiral trajectory rotating in the direction of the baseline vortex rotation. The maximum circulation for alternating blowing decreases downstream at a higher rate compared to other pulsed blowing. The size of the wingtip vortex core increases with distance from the wing.

Krasny, R.

"VORTEX SHEET COMPUTATIONS: ROLL-UP, WAKES, SEPARATION"

Lectures in Applied Mathematics, Vol. 28, 1991, pp. 385-402.

Chorin's vortex blob method has been proposed to extend vortex sheet motion past the singularity formation time, into the physically important roll-up regime. Basic questions are: (1) Does the vortex blob method converge to an infinite spiral as the smoothing parameter tends to zero? (2) Do vortex blob computations approximate the real fluid motion? This paper will present and discuss three computations which are relevant to these issues: a) periodic roll-up, b) wake patterns in a thin soap film, c) separation at a sharp edge.

Krasny, R.

"A VORTEX-DIPOLE SHEET MODEL FOR A WAKE"

Phys. Fluids A, Vol. 1, No. 2, February 1989, pp. 173-175.

A vortex model for a free shear layer with a wake component is proposed. The layer is represented by a curve which supports both a vortex sheet and a vortex-dipole sheet. The vortex sheet yields a monotonic velocity profile that connects the outer flows on either side of the shear layer. The vortex-dipole sheet captures the effect of oppositely signed vorticity that is present in the wake due to boundary layers upstream from the separation point. The equations governing a vortex-dipole sheet

are given and a temporal instability calculation for a free sinusoidal wake shows the development of a vortex sheet.

Krasny, R.

"COMPUTING VORTEX SHEET MOTION"

Proceedings of the International Congress of Mathematicians, 1990, Kyoto, Japan, pp. 1573-1583.

Coherent vortex structures occur in many types of fluid flow including mixing layers, jets and wakes. A vortex sheet is a mathematical model for such structures, in which the shear layer is approximated by a surface across which the tangential fluid velocity has a jump discontinuity. Vortex sheet motion belongs to the field of vortex dynamics, one of the main approaches to understanding fluid turbulence. Careful numerical experiments have helped advance the mathematical study of vortex sheets. Difficulties arise in computing vortex sheet motion due to short wavelength instability, singularity formation, and spiral roll-up. This paper reviews the problem of computing vortex sheet motion and presents several applications.

Krasny, R.

"COMPUTATION OF VORTEX SHEET ROLL-UP IN THE TREFFTZ PLANE"

J. Fluid Mech., Vol. 184, 1987, pp. 123-155

Two vortex-sheet evolution problems arising in aerodynamics are studied numerically. The approach is based on desingularizing the Cauchy principal value integral which defines the sheet's velocity. Numerical evidence is presented which indicates that the approach converges with respect to refinement in the mesh-size and the smoothing parameter. For elliptic loading, the computed roll-up is in good agreement with Kaden's asymptotic spiral at early times. Some aspects of the solution's instability to short-wavelength perturbations, for a small value of the smoothing parameter, are inferred by comparing calculations performed with different levels of computer round-off error. The tip vortices' deformation, due to their mutual interaction, is shown in a long-time calculation. Computations for a simulated fuselage-flap configuration show a complicated process of roll-up, deformation and interaction involving the tip vortex and the inboard neighboring vortices.

Krasny, R.

"VORTEX SHEET ROLL-UP DUE TO THE MOTION OF A FLAT PLATE"

International Symposium on Nonsteady Fluid Dynamics, Vol. 92, American Society of Mechanical Engineers, 1990, pp. 449-453.

The vortex-blob method is extended to compute vortex sheet separation at a sharp edge. A smoothing parameter controls the amount of detail occurring in the rolled-up spiral. Calculations are presented for the case of vortex sheet roll-up due to an impulsively started flat plate.

Krasny, R.

"NUMERICAL SIMULATION OF VORTEX SHEET EVOLUTION"

Fluid Dynamics Research, Vol. 3, 1988, pp. 93-97.

Recent research on the numerical simulation of vortex sheet evolution is discussed. Applications are presented to a periodic vortex sheet and to the vortex sheet shed behind a finite-span wing.

Krasny, R.

"COMPUTATION OF VORTEX SHEET ROLL-UP"

Proceedings of the UCLA Workshop on Vortex Methods, Lecture Notes in Mathematics, Vol. 1360, 1988, Springer, pp. 9-22.

In this article we shall review some recent developments for computing vortex sheet roll-up. First, results for the periodic vortex sheet will be reviewed. Then an application to some vortex sheet problems occurring in aerodynamics will be discussed in more detail. Finally, some open questions and directions for further research will be summarized.

Krause, E.

"BREAKDOWN OF SLENDER VORTICES: THE STATE OF THE ART"

In Vortex Dominated Flows, edited by D. Blackmore, E. Krause and C. Tung, 2005, World Scientific, New Jersey, Chapter 8, pp. 135-156.

The flow near the axis of slender vortices is investigated with particular emphasis on the deceleration of the axial flow, leading to a stagnation point and bursting or breakdown of the vortex. The Euler equations are reduced for steady, inviscid, incompressible, axially symmetric flow in a stream tube of small radius. The angular velocity is found to be directly proportional to the axial velocity component, implying that a deceleration of the axial flow can cause the angular velocity to vanish and breakdown to occur. The extension of the analysis to viscous incompressible flow identifies a thin viscous layer immediately upstream of the stagnation point, its thickness being inversely proportional to the Reynolds number. An approximate solution for the viscous flow shows that the angular velocity does not vanish at the stagnation point of the axial flow. The results are compared with experimental and numerical data of the recent literature.

Krause, E.

"ON VORTEX LOOPS AND FILAMENTS: THREE EXAMPLES OF NUMERICAL PREDICTIONS OF FLOWS CONTAINING VORTICES"

Vortex motion plays a dominant role in many flow problems. This article aims at demonstrating some of the characteristic features of vortices with the aid of numerical solutions of the governing equations of fluid mechanics, the Navier-Stokes equations. Their discretized forms will first be reviewed briefly. Thereafter three problems of fluid flow involving vortex loops and filaments are discussed. In the first, the time-dependent motion and the mutual interaction of two colliding vortex rings are discussed, predicted in good agreement with experimental observations. The second example shows how vortex rings are generated, move, and interact with each other during the suction stroke in the cylinder of an automotive engine. The numerical results, validated with experimental data, suggest that vortex rings can be used to influence the spreading of the fuel droplets prior to ignition and reduce the fuel consumption. In the third example, it is shown that vortices can also occur in aerodynamic flows over delta wings at angle of attack as well as pipe flows: of particular interest for technical applications of these flows is the situation in which the vortex cores are destroyed, usually referred to as vortex breakdown or bursting. Although reliable breakdown criteria could not be established as yet, the numerical predictions obtained so far are found to agree well with the few experimental data available in the recent literature.

Krause, E.

"A CONTRIBUTION TO THE PROBLEM OF VORTEX BREAKDOWN"

In Aerodynamic of Vortical Type Flows in Three Dimensions, AGARD-CP-342, July 1983, pp. 26-1 - 26-4.

Associated with the breakdown process is the formation of a stagnation point on the axis of the vortex. This requires the deceleration of the axial velocity component, which must be enforced by a positive axial pressure gradient. The analysis presented here shows, how the pressure gradient along the axis of the vortex is influenced by the radial and azimuthal velocity components. An explicit expression for $dp/dx(x,0)$ can be obtained by integration of the momentum equation for the radial velocity component with respect to the radial and subsequent differentiation of the integral with respect to the axial direction. In an order of magnitude analysis, it is then demonstrated that for large Reynolds numbers one component of the frictional force in the azimuthal direction cannot be neglected. In order to obtain an estimate for the pressure gradient rigid body rotation is assumed for the vortex core, and a distribution similar to that of a potential vortex $w = kr$ to the $-n$ power, for the outer portion. The estimate shows that a positive axial pressure gradient can exist only, if the radial velocity component is positive and if the exponent n is less than unity. It is also verified that a potential vortex cannot support an axial pressure gradient, that the pressure gradient in magnitude is directly proportional to the square of the maximum of the azimuthal velocity, referenced to the freestream velocity.

Krause, E.

"STAGNANT VORTEX FLOW"

Acta Mechanica, Vol. 209, 2010, pp. 345-351.

With the aid of the vorticity transport equation, it is shown that in inviscid, incompressible, axially symmetric vortex flow the axial vorticity component near the axis of the vortex approaches zero if the axial velocity component approaches a stagnation point, and vice versa, the axial vorticity component is increased, if the axial flow is accelerated. This result, obtained in earlier investigations by simplifying the momentum equations for the neighborhood of the axis of the vortex, is already contained in the vorticity transport equation as formulated by von Helmholtz in 1858. In laminar flow, with viscous forces acting near the stagnation point, the angular velocity does not necessarily vanish with the axial velocity component. These questions are discussed in the following.

Krause, E.

"ON AN ANALOGY TO THE AREA-VELOCITY RELATION OF GASDYNAMICS IN SLENDER VORTICES"

Acta Mechanica, Vol. 201, 2008, pp. 23-30.

Inviscid compressible flow in a slender longitudinal vortex with the axis parallel to the main flow direction is discussed. The Euler equations for steady, axially symmetric flow are simplified for the neighborhood of the axis of the vortex. The resulting relations, expressing the angular velocity in terms of the axial mass flow, when recast and integrated, represent an analogy to the area-velocity and the area-Mach number relation of one-dimensional gas dynamics. By restricting the analysis to the flow in a Rankine vortex with constant stagnation enthalpy, the static pressure on the axis can be related to the free-stream pressure far away from the axis and the maximum value of the azimuthal velocity. The influence of a radial wake-like distribution of the axial velocity component on the axial pressure is discussed. Its dependence on variable external boundary conditions is given. A condition is formulated, which must be satisfied for the formation of a free stagnation point on the axis.

Krause, E.

"BREAKDOWN OF COMPRESSIBLE SLENDER VORTICES"

Computational Science and High Performance Computing II, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 91, 2006, pp. 1-12.

Slender vortices of compressible flow are studied; in particular, the deceleration of the axial flow to a free stagnation point on the axis, causing bursting or breakdown of the vortex. Steady, inviscid, compressible, axially symmetric flow conditions are assumed to enable a reduction of the Euler equations for a stream tube of small radius. The angular velocity near the axis is shown to be directly proportional to the axial mass flux, indicating that a decelerated axial flow can cause the angular velocity to vanish and breakdown to occur. This behavior is reversed in supersonic flow. A breakdown criterion is derived for a Rankine vortex with isentropic and normal-shock deceleration of the axial flow. The results are compared with available experimental data.

Krause, E.

"REVIEW OF SOME VORTEX RELATIONS"

ICASE Report No. 84-46, Hampton, VA, September 1984.

The evaluation of the circulation from numerical solutions of the momentum and energy equations is discussed for incompressible and compressible flows. It is shown how artificial damping directly influences the time rate of change of the circulation.

Krause, E.

"SHOCK INDUCED VORTEX BREAKDOWN"

International Conf. on the Methods of Aerophysical Research, July 2000, Novosibirsk, Russia, pp. 109-114.

Breakdown of longitudinal vortices occurs as well in supersonic external and internal flows as in incompressible flows. Although a large number of theoretical and experimental investigations was carried out on the latter in the past decade, a criterion according to which the various modes of breakdown can be predicted, could not be derived as yet. Nevertheless, the formation of a free stagnation point on the axis is confirmed as a necessary condition for breakdown to occur. In a recent investigation P. Huerre and his coworkers cast this condition into a simple form, which yields results that are in good agreement with experimental data. In the present paper considerations like those just mentioned will be extended to compressible flows. Stagnation point criteria will be derived for a Rankine vortex first for isentropically decelerated axial flow and then for the case of transition through a normal shock.

Krause, E., Schroder, W., Klass, M. and Thomer, O.

"INTERSECTION OF SLENDER LONGITUDINAL VORTICES BY SHOCK WAVES"

ICCES, Vol. 5, No. 1, 2008, pp. 41-46.

In supersonic flow the leading-edge vortex of delta wings can encounter intersection by an oblique or a normal shock. The resulting interaction between the two influences the aerodynamic forces; in particular the lift, especially if vortex breakdown occurs. This problem was studied in an idealized form by assuming an isolated slender vortex being intersected by an oblique and a normal shock, respectively. The investigation was carried out in two coordinated companion studies, one using numerical solutions of the Euler and Navier-Stokes equations, and the other experimental techniques, i.e. flow visualization methods, and Laser-Doppler and particle-image velocimetry. The measurements yielded profiles of the axial velocity component, visualizations of the shock deformation, and the deflection of the vortex core for the case of the oblique-shock-vortex interaction. The numerical solutions yielded detailed profiles of all flow quantities including those of vortex breakdown.

"INVESTIGATION OF WIND CONDITIONS DURING EARLY MORNING HOURS AT LOS ANGELES INTERNATIONAL AIRPORT"

FAA-RD-77-116, October 1977, Lockheed Missiles & Space Co., Huntsville, AL

Los Angeles International Airport (LAX) uses a unique runway utilization pattern to minimize noise pollution between midnight and 0600. During these hours, all approaches are conducted to the east, and all takeoffs are conducted to the west. The low-altitude portions of all takeoff and landing operations are thereby conducted over the Pacific Ocean. During these operations, pilots have occasionally reported encountering unusual wind conditions. It is the objective of this study to use the Lockheed-Huntsville mobile laser Doppler unit velocimeter unit to monitor winds and wake vortices in the approach zone of runway 6R to identify the sources of the wind anomalies reported by the pilots. No incidents of pilot-reported wind anomalies occurred during the five-week data collection period.

"DEVELOPMENT OF THEORY AND EXPERIMENTS TO IMPROVE UNDERSTANDING OF LASER DOPPLER SYSTEMS"

LMSC-HREC TR D306632, June 1973, Lockheed Missiles & Space Company, Huntsville, Alabama.

This final report documents work conducted during the period January 1971 through June 1973. It encompasses theoretical, analytical, and experimental studies, the object of which was to improve understanding of laser Doppler system operation for remote measurement of wind motion. An evaluation of the feasibility of three velocity component measurements was also conducted, and further optimization and design of new systems were accomplished.

"REMOTE MEASUREMENT UTILIZING NASA'S SCANNING LASER DOPPLER SYSTEM, VOLUME I: LASER DOPPLER WAKE VORTEX TRACKING AT KENNEDY AIRPORT"

LMSC-HREC-TR-D496633-V1, March 1976, Lockheed Missiles & Space Co., Huntsville, A.

Test operations of the Scanning Laser Doppler System (SLDS) at Kennedy International Airport (KIA) during August 1974 through June 1975 are reported. A total of 1619 data runs was recorded with a totally operational system during normal landing operations at KIA. In addition, 53 data runs were made during cooperative flybys with the CV-880 for a grand total of 1672 recorded vortex tracks. Test crews were at KIA for 31 weeks, of which 25 weeks were considered operational and the other six were packing, unpacking, setup and check out. Although average activity equates to 67 recorded landing operations per week, two periods of complete runway inactivity spanned 20 days and 13 days, respectively. The operation frequency therefore averaged about 88 operations per week.

Kriebel, A. R.

"PARTICLE TRAJECTORIES IN A GAS CENTRIFUGE"

Journal of Basic Engineering, September 1961, pp. 333-339.

The motion of spherical particles injected into a cylinder of gas which rotates as a solid body has been studied. The particle trajectory is expressed explicitly as a function of two dimensionless parameters: an injection-velocity parameter and an inertial parameter which is roughly the ratio of centrifugal force to drag force on the particle. The main results are the dependence on particle size of the time for particles to be centrifuged and of deposition angle. These results indicate performance limitations for an idealized cyclone separator and a centrifugal particle-size analyzer. Experimental data are presented for an air centrifuge which was designed to approximate the analytical flow model. Reasonably good agreement with theoretically predicted deposition angles was found for spherical glass beads and irregularly shaped chalk crystals, even for Reynolds numbers in excess of the Stokes flow regime for which the analysis applies. Particles as small as 2 microns may be classified with the present centrifuge configuration; however, by modification it might be used to classify particles in the submicron-size region.

"THREE-DIMENSIONAL BLADE-VORTEX INTERACTION IN THE STRONG VORTEX REGIME"

Physics of Fluids, Vol. 10, No. 11, November 1998, pp. 2828-2845

A study of three-dimensional interaction between a blade and an initially columnar vortex was performed using flow visualization experiments and computer simulations for problems where the blade is translated normal to and impacts upon the vortex core. The reported research focuses on cases where the vortex is sufficiently strong that the blade boundary layer separates before the blade penetrates the vortex core. The study examines the topology and evolution of the separated secondary vorticity from the blade and its interaction with the primary vortex. In particular, it is observed that the separated vorticity from the blade has the form of a series of vortex loops that wrap around the outer surface of the primary vortex core and spread both upstream and downstream along the vortex axis. Both the initial formation of these vortex loops and their eventual interaction with the primary vortex are investigated. Computations based on a series of idealized models of the secondary vorticity are performed in order to examine the primary vortex response to wrapped vortex loops.

Krishnamoorthy, S., Gossler, A. A. and Marshall, J. S.

"NORMAL VORTEX INTERACTION WITH A CIRCULAR CYLINDER"

AIAA Journal, Vol. 37, No. 1, January 1999, pp. 50-57

Interaction of a columnar vortex with a long circular cylinder translated normal to the vortex axis is examined for the case where the cylinder diameter is much larger than the vortex core radius. The study focuses on understanding and quantifying the limitations of traditional vortex filament models

arising from vortex-induced separation of the cylinder boundary layer and vortex core shape deformation. These limitations are examined over a wide range of values of the impact parameter, defined as the ratio of the ambient normal velocity past the cylinder to the maximum vortex azimuthal velocity. Filament model predictions of vortex displacement are compared to experimental data both before and after vortex-induced boundary-layer separation. Experimental data are presented showing the importance of the ambient normal velocity to the cylinder in delaying vortex-induced boundary-layer separation, so that for cases with high impact parameter the flow is governed by inviscid effects even as the vortex moves quite close to the cylinder surface. The inviscid shape deformation of the vortex core is modest in the cases examined, even for close vortex-cylinder interaction, and is shown to have small effect on the surface pressure. The topology of secondary vorticity structures ejected from the cylinder boundary layer is examined using a two-color laser-induced fluorescence technique and is found to be qualitatively different for cases with high and low values of the impact parameter.

"WIND TURBULENCE ESTIMATES IN A VALLEY BY COHERENT DOPPLER LIDAR"

Meteorological Applications, Vol. 18, 2011, pp. 361-371.

In this paper, the effect of several turbulence parameters during various flow conditions in Owens Valley, deduced from coherent Doppler lidar data have been studied. Radial velocity structure functions are processed to estimate the turbulent kinetic energy (TKE) dissipation rate, integral length scale and velocity variance, assuming a theoretical model for isotropic wind fields. Corrections for turbulence measurements have been considered to address the complications due to inherent volumetric averaging of radial velocity over each range gate, noise of the lidar data, and the assumptions required to estimate effects of smaller scales of motion on turbulence quantities. Using data from the Terrain-induced Rotor Experiment (T-REX) in April-May 2006, vertical profiles of wind and turbulence parameters have been retrieved. During T-REX, unusual valley flows were detected by the lidar data, for example on 19 and 27 March 2006, daytime down-valley and night time up-valley flows, respectively, were observed. This paper focuses on understanding various turbulence parameters during these flow events. Turbulence estimates during daytime down-valley conditions were observed to be constant for most of the day, while for night time up-valley circumstances the turbulence increased steadily as the day progressed. Good comparison was observed between lidar and tower measurements, which validate the lidar turbulence retrieval assumptions. Comparison between TKE estimates from lidar and the Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS) model is also presented. This analysis will be helpful for improving the current turbulence parameterization schemes in COAMPS. Finally, differences and similarities in turbulence measurements between both the flow regimes are discussed.

"COHERENT DOPPLER LIDAR FOR WIND FARM CHARACTERIZATION"

Wind Energy, Vol. 16, 2013, pp. 189-206.

Coherent Doppler lidar measurements are of increasing interest for the wind energy industry. Wind measurements are fundamental inputs for the evaluation of potential energy yield and performance of wind farms. Three-dimensional scanning Doppler lidar may provide a new basis for wind farm site selection, design, and optimization. In this paper, the authors discuss Doppler lidar measurements obtained for a wind energy development. The possibility of using lidar measurements to more fully characterize the wind field is discussed, specifically terrain effects, spatial variation of winds, power density and the effect of shear at different layers within the rotor swept area. Vector retrieval methods have been applied to the lidar data, and results are presented on an elevated terrain-following surface at hub height. The vector retrieval estimates are compared with tower measurements, after interpolation to the appropriate level. Doppler lidar data are used to estimate the spatial power density at hub height (for the period of the deployment). An example wind farm layout is presented for demonstration purposes based purely on lidar measurement, even though the lidar data acquisition period cannot be considered climatological. The strength of this approach is the ability to directly measure spatial variations of the wind field over the wind farm. Also, because Doppler lidar can measure winds at different vertical levels, an approach for estimating wind power density over the rotor swept area (rather than only the hub height) is explored. Finally, advanced vector retrieval algorithms have been applied to better characterize local wind variations and shear.

Krishnan, M.

"A MODEL FOR THE ONSET OF BREAKDOWN IN AN AXISYMMETRIC COMPRESSIBLE VORTEX"

Phys. Fluids, Vol. 8, No. 12, December 1996, pp. 3338-3345

A simple inviscid model to predict the onset of breakdown in an axisymmetric vortex is proposed. Three problems are considered: the shock-induced breakdown of a compressible vortex, the breakdown of a free compressible vortex, and the breakdown of a free incompressible vortex. The same physical reasoning is used in all three problems to predict the onset of breakdown. It is hypothesized that breakdown is the result of the competing effects of adverse pressure rise and streamwise momentum flux at the vortex centerline. Breakdown is assumed to occur if the pressure rise exceeds the axial momentum flux. A formula with no adjustable constants is derived for the critical swirl number in all three problems. The dependence of the critical swirl number on parameters such as upstream Mach number, excess/deficit in centerline axial velocity, and shock oblique angle is explored. The predictions for the onset of shock-induced breakdown and free incompressible breakdown are compared to experiment and computation, and good agreement is observed. Finally, a new breakdown map is proposed. It is suggested that the adverse pressure rise at the vortex axis be plotted against the axial momentum flux to determine the onset of breakdown. The proposed map allows the simultaneous comparison of data from flows ranging from incompressible breakdown to breakdown induced by a shock wave.

Kristensen, L.

"CUPS, PROPS AND VANES"

Riso-R-766(EN), August 1994, Riso National Laboratory, Roskilde, Denmark.

We discuss the dynamics of the cup anemometer, the propeller anemometer, and the wind vane. The phenomenological model by Kristensen (1993) is modified to describe the motion of the propeller anemometer. We use the well-known second-order differential equation describing the motion of the wind vane to study the properties of the vane itself and the vane in combination with a cup and a vane. It is argued that even the simplest question about how to record the signal from a cup anemometer has an ambiguous answer and can lead to a, not necessarily small, systematic error in the measured mean wind speed. We show how it is possible to measure the entire wind direction variance by utilizing the fact that an underdamped vane by 'overshooting' may compensate for the high-frequency variance loss if the damping coefficient is about 0.4. Finally, we discuss possible sources of bias on the measured mean-wind speed when using a propeller-vane anemometer. It turns out that this anemometer has the same type of biases from the lateral and vertical wind fluctuations as has the cup anemometer. In addition, there are bias contributions from misalignment between the mean wind and the propeller axis and from the translatory motion of the propeller itself with respect to the vertical wind-vane axis.

Kristensen, L.

"THE PERENNIAL CUP ANEMOMETER"

Wind Energy, Vol. 2, 1999, pp. 59-75.

A short version of the history of the cup anemometer precedes a more technical discussion of the special features of this instrument. These include its extremely linear calibration and the non-linearity of its response to wind speed changes. A simple conceptual model by Schrenk is used to demonstrate this and to explain why the cup anemometer can start from a zero rotation rate at zero wind to one corresponding to a sudden change in the ambient wind speed to a finite value. The same model is used to show that the cup anemometer should be characterized by a distance constant rather than by a time constant. The bias in the measured mean wind speed due to the random variations in the three velocity components is discussed in terms of standard, semi-quantitative turbulence models, and the main thesis is that this bias is overwhelmingly dominated by the fluctuations of the lateral wind velocity component, i.e. the wind component perpendicular to the mean wind direction, and not, as is often assumed, by the longitudinal wind velocity component. It is shown theoretically and tested experimentally that the bias due to lateral wind velocity fluctuations can be significantly reduced by means of a special data processing of the simultaneous signals from a cup anemometer and a wind vane. This means that, with care, the overall over-speeding can be reduced to less than 1 percent.

Kristensen, L. and Hansen, F.

"DISTANCE CONSTANT OF THE RISO CUP ANEMOMETER"

Riso-R-1320(EN), April 2002, Riso National Laboratory, Roskilde, Denmark.

The theory for cup-anemometer dynamics is presented in some detail, and two methods of obtaining the distance constant l are discussed. The first method is based on wind tunnel measurements: with a

constant wind speed the cup anemometer is released from a locked position of the rotor and the increasing rotation rate recorded. It is concluded that the rapid increase in rotation rate makes the method very inaccurate. The second method consists of an analysis of turbulent, atmospheric wind speed as measured by the cup anemometer and a fast-responding sonic anemometer with a spatial eddy resolution, which is significantly better than that which can be obtained by a cup anemometer. The ratio between the measured power spectra of the horizontal wind speed by the two instruments contains the necessary information for determining the response characteristics of the cup anemometer and thereby I . The conditions for this last method to be accurate are discussed. Field measurements are used to demonstrate how I is determined for the Riso cup anemometer, model P2546.

Kristensen, L., Hansen, O. F. and Hajstrup, J.

"SAMPLING BIAS ON CUP ANEMOMETER MEAN WINDS"

Wind Energy, Vol. 6, 2003, pp. 321-331.

The cup anemometer signal can be sampled in several ways to obtain the mean wind speed. Here we discuss the sampling of series of mean speeds from consecutive rotor rotations, followed by unweighted and weighted averaging. It is shown that the unweighted averaging creates a positive bias on the long-term mean wind speed, which is at least one order of magnitude larger than the positive bias from the weighted averaging, also known as the sample-and-hold method. For a homogeneous, neutrally stratified flow the first biases are 1-2 percent. For comparison the biases due to fluctuations of the three wind velocity components and due to calibration non-linearity are determined under the same conditions. The largest of these is the v -bias from direction fluctuations. The calculations pertain to the Riso P2546A model cup anemometer.

Kroo, I.

"DRAG DUE TO LIFT: CONCEPTS FOR PREDICTION AND REDUCTION"

Ann. Rev. Fluid Mechanics, Vol. 33, 2001, pp. 587-617

This article describes some of the fundamental ideas underlying methods for induced-drag prediction and reduction. A review of current analysis and design methods, including their development and common approximations, is followed by a survey of several approaches to lift-dependent drag reduction. Recent concepts for wing planform optimization, highly nonplanar surfaces, and various tip devices may lead to incremental but important gains in aircraft performance. Focusing on relatively high-aspect-ratio subsonic wings, the review suggests that opportunities for new concepts remain, but the greatest challenge lies in their integration with other aspects of the system.

Krothapalli, A., Buzyne, G. and Lourenco, L.

"STREAMWISE VORTICES IN AN UNDEREXPANDED AXISYMMETRIC JET"

Physics of Fluids, Vol. 3, Part A, No. 8, August 1991, pp. 1848-1851.

This Letter describes an experimental investigation demonstrating the existence of streamwise vortices in an under-expanded jet issuing from a convergent axisymmetric nozzle at a moderate pressure ratio of 5.1, and at a Reynolds number of 1,800,000. These vortices are quite strong and are in the supersonic region of the jet between the intercepting shock and the jet boundary. They seem to play a significant role by enhancing mixing between the ambient and jet fluids in the supersonic region of the jet. The scale of these vortices increases with downstream distance by a process of vortex merging.

Krothapalli, A., King, C. J. and Strykowski, P. J.

"THE ROLE OF STREAMWISE VORTICES ON THE SOUND GENERATION OF SUPERSONIC JETS"

AIAA Paper No. 1993-4320, Long Beach, CA, October 1993

Sound generation from supersonic axisymmetric jets in the presence of streamwise vortices was experimentally investigated. When streamwise structures are generated using small triangular tape elements placed in the laminar boundary layer upstream of the nozzle exit, they show insignificant effect on the far-field noise. Delta-tabs placed at the nozzle exit to generate streamwise vortices will reduce shock associated noise while increasing the turbulent mixing noise. Using a counterflowing nozzle, it is shown that increased mixing in supersonic jets may not result in noise suppression.

"STUDY OF A ROTOR FLAP-INFLOW MODEL INCLUDING WAKE DISTORTION TERMS"

RTO-MP-11, Proceedings RTO SCI Symposium on System Identification for Integrated Aircraft Development and Flight Testing, May 1998, Madrid, Spain, pp. 26-1 - 26-10.

For many years, analysts have been puzzled by the fact that the off-axis coupling of a helicopter exhibits the opposite sign in flight tests as compared to simulations. Recently, researchers have shown that the effect may be attributable to the bending of the wake during a pitching maneuver, which introduces a fore-to-aft gradient in induced flow that can reverse the predicted sign of the roll coupling. Other research has shown that this result can also be obtained with momentum and vortex theory. There are many issues still under debate regarding the magnitude of wake distortion and its effectiveness in predicting off-axis dynamics. In the present work, a generalized dynamic wake model is augmented to include wake distortion. This model is then coupled with a flap model for simulation in low-speed forward flight. Frequency responses from the simulation are collected with and without wake distortion, and these are compared with wind tunnel test data.

"NUMERICAL SIMULATIONS OF WIND MEASUREMENTS AT AMSTERDAM AIRPORT SCHIPHOL"

Journal of Wind Engineering and Industrial Aerodynamics, Vol. 91, 2003, pp. 1215-1223

In this paper two typical results of numerical simulations of wind measurements at an airport are discussed. The first case deals with the long reach of some isolated individual 'roughness elements'. The positioning of the farms and haystacks result in a weak vortex which travels over a very long distance. The second case is about the influence of an industrial complex just outside the airport premises. In this case the actual wake behind the buildings is the dominant flow feature. The numerical simulations are able to explain the measured disturbances.

Kubberud, N., Oye, I. and Norstrud, H.

"ON THE INTERACTION BETWEEN TOPOGRAPHICAL WIND AND LANDING AIRCRAFT"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 24-1 to 24-12

The present paper gives a qualitative study of the flow interaction between a representative landing aircraft and the wind induced vortical flow. Separate numerical analysis for the wind flow over the given terrain and the flow structure around the lifting airplane is given. The interaction is performed by superposing the two solutions in various crossflow planes along the glide path direction of the aircraft. This leads to an estimate of the change of circulation for the lifting body and the associated need for corrective control forces.

Kucab, J. R.

"FREE WAKE ANALYSIS OF HELICOPTER ROTOR FLOW FIELDS USING A COUPLED VORTICITY EMBEDDING/FRACTIONAL STEP METHOD"

MS Thesis, August 2000, University of Tennessee, Knoxville, TN.

A hybrid CFD (Computational Fluid Dynamics) method combining a potential-based Vorticity Embedding method with an Euler solver is presented and validated for isolated rotor flows. First, a formulation of Vorticity Embedding is developed and validated for Cartesian grids. This formulation is utilized together with simple lifting lines to represent an isolated rotor in hover. The results for an isolated rotor are then compared with experiment. The method is then hybridized by coupling the Vorticity Embedding grid containing the rotor to a region containing a ground plane where a standard finite difference Euler solver is utilized. Initial results from this hybrid scheme are presented including a demonstration of the code's potential to calculate the ground vortex roll-up generated by a rotor in ground effect in the presence of a cross-wind.

"FREE WAKE ANALYSIS OF HELICOPTER ROTOR FLOW FIELDS USING A COUPLED VORTICITY EMBEDDING/FRACTIONAL STEP METHOD"

Report ARO 34260.3-EG-AAS, November 2000, University of Tennessee Space Institute, Tullahoma, TN.

A hybrid CFD (Computational Fluid Dynamics) method combining a potential-based Vorticity Embedding method with a Euler solver is presented and validated for isolated rotor flows. First, a formulation of Vorticity Embedding is developed and validated for Cartesian grids. This formulation is utilized together with simple lifting lines to represent an isolated rotor in hover. The results for an isolated rotor are then compared with experiment. The method is then hybridized by coupling the Vorticity Embedding grid containing the rotor to a region containing a ground plane where a standard finite difference Euler solver is utilized. Initial results from this hybrid scheme are presented including a demonstration of the code's potential to calculate the ground vortex roll-up generated by a rotor in ground effect in the presence of a cross-wind.

Kuchemann, D.

"TURBULENCE AND VORTEX MOTIONS"

Zeitschrift fur Flugwissenschaften, Vol 19, August-September 1971, pp. 305-308.

To find some concepts which might bring some order into what are usually described as turbulent motions, some thoughts are presented, which might lead to an interpretation of some of these motions in fluids of small viscosity in terms of inviscid flows involving vortex sheets and rolled-up vortex cores.

Kuchemann, D. and Weber, J.

"VORTEX MOTIONS"

Zeitschrift fur Angewandte Mathematik and Mechanik, Vol. 45, No. 7-8, December 1965, pp. 457-474

This work demonstrated that the key features of the vortex core flows are the same, whether the model used involves a vortex sheet in irrotational flow or a swirling flow with distributed vorticity. Some complete flows are described and the problems involved are briefly discussed, using the example of a lifting slender wing.

Kudela, H. and Kosior, A.

"PARALLEL COMPUTATIONS IN 3D VORTEX PARTICLE METHOD"

AIAA Paper No. 2011-3225, June 2011, Honolulu, Hawaii.

The paper presented an attempt to implement Vortex In Cell (VIC) method on Graphics Processing Units. The 3D VIC method was shortly described. To show correctness of the code the motion of a vortex ring was simulated. At first the numerical calculations were done on a single processor (x86) architecture. Disadvantage of the single processor computation is time consumption. To manage this problem, we switched to the parallel architecture. In our first approach to the multicore architecture, we tested algorithms for the solution of the algebraic system of equations that results from

discretization of the Poisson equation. For parallel computations CUDA architecture was used. We used the Multigrid and the Full Multigrid methods. It permitted us to speed up the solution of algebraic system using the Full Multigrid method 10 times. Finally, the whole VIC was implemented on the GPU. A 15-times speedup was obtained.

Kudela, H. and Regucki, P.

"VORTICITY PARTICLE METHOD FOR SIMULATION OF 3D FLOW"

Lecture Notes in Computer Science, Vol. 3037, 2004, pp. 356-363

The vortex-in-cell method for three-dimensional, viscous flow was presented. A viscous splitting algorithm was used. Initially the Euler inviscid equation was solved. Following that, the viscous effect was considered by the solution of the diffusion equation. The diffusion equation was then solved by the particle strength exchange (PSE) method. Validation of the method was tested by simulation of the leap-frogging phenomenon for two vortex rings moving along a common axis of symmetry and the reconnection phenomenon of two colliding vortex rings for viscous flow.

Kuethe, A. M.

"EFFECT OF STREAMWISE VORTICES ON WAKE PROPERTIES ASSOCIATED WITH SOUND GENERATION"

Journal of Aircraft, Vol. 9, No. 10, October 1972, pp. 715-720

Experiments in the turbulent-boundary-layer range of Reynolds numbers show that the Karman vortex street is suppressed and spanwise periodicity is induced in the wake behind an airfoil by the introduction of inclined surface waviness near the trailing edge. Both effects will reduce the intensity of sound sources in many applications.

Kuhn, G. D.

"LEAST-SQUARES ANALYSIS OF VELOCITY MEASUREMENTS IN THE WAKE OF AIRCRAFT WITH TAILORED SPAN LOADING"

NEAR TR-78, December 1974, Nielsen Engineering and Research Inc., Mountain View, CA

A method is presented for analyzing experimental velocity measurements behind aircraft with multiple wake vortices. The method assumes the vortices can be represented by inviscid vortices. The nonlinear mathematical expressions so produced are linearized around a 'first guess' of the positions and strengths of the vortices. The resulting expressions are solved for the unknown perturbations from linearity by the method of least squares. The 'first guess' is updated and the process repeated until the solution converges.

Kuhn, G. D. and Jacobsen, R. A.

"ANALYSIS OF WAKE VORTEX FLIGHT TEST DATA BEHIND A T-33 AIRCRAFT"

NASA CR-137669, April 1975, Nielsen Engineering & Research Inc., Mountain View, CA

Measurements of the vortex system behind a T-33 aircraft were obtained by a Learjet equipped with a boom carrying a three-wire, hot-wire anemometry probe and other instrumentation. Analysis of the measurements using a computerized geometric method indicated the vortices had a core radius of approximately 0.11 meter with a maximum velocity of 25 meters per second. No longitudinal instabilities, buoyant effects or vortex breakdowns were evident in the data which included vortex wake cross sections from 0.24 to 5.22 kilometers behind the T-33.

Kuhn, G. D. and Nielsen, J. N.

"ANALYTICAL STUDIES OF AIRCRAFT TRAILING VORTICES"

AIAA Paper No. 1972-0042, San Diego, CA, 1972.

The effects of turbulent mixing and buoyancy on the motion and persistency of a trailing vortex wake behind an aircraft are considered. A model for the characteristics of a turbulent vortex, based on an analogy to a turbulent boundary layer, is presented. A theory of trailing-vortex characteristics behind an aircraft is presented based on considerations of the angular and linear momentum of the vortex and the total pressure variation along the axis. Comparisons between the predictions of the theory and recent NASA wind tunnel data exhibit good agreement. The turbulent shear of the axial flow was shown to be the dominant mechanism for the growth of the core radius, the decay of the peak tangential velocity and the decay of the axial velocity defect.

Kuhn, R. E.

"AN INVESTIGATION TO DETERMINE CONDITIONS UNDER WHICH DOWNWASH FROM VTOL AIRCRAFT WILL START SURFACE EROSION FROM VARIOUS TYPES OF TERRAIN"

NASA TN D-56, February 1960, NASA Langley Research Center, Hampton, VA.

Results of an investigation with small-scale equipment of the conditions under which the downwash from a hovering vertical-take-off-and-landing (VTOL) aircraft will start surface erosion indicate that the onset of erosion depends only on the dynamic pressure of the outward flow of air near the surface. For a rotor or propeller at a height of about 1 slipstream diameter above the surface, this surface dynamic pressure was found to be equal to the disk loading. For the VTOL aircraft supported by a ducted fan, the surface dynamic pressure with the ducted fan exit at a height of about 1 slipstream diameter is equal to one-half the exit-area loading. The surface dynamic pressure decreases rapidly with increasing height of the VTOL device. Erosion of sand and loose dirt started at surface dynamic pressures of 1 to 3 lb/sq ft, which is in general agreement with helicopter experience. Thoroughly soaking the sand and loose-dirt surfaces increased the resistance to erosion to surface dynamic

pressures of 30 to 50 lb/sq ft. Spray from water started at surface dynamic pressures of 1.5 to 2.5 lb/sq ft. Sod withstood dynamic pressures up to about 1,000 lb/sq ft.

Kuibin, P. A. and Okulov, V. L.

"SELF-INDUCED MOTION OF HELICAL VORTICES"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany, pp. 53-62.

The self-induced velocity of helical vortices in an infinite space as well as in a cylindrical tube is studied. Investigation was based on an analysis of the formula for determination of the self-induced velocity of a helical vortex with a uniform vorticity distribution inside a core. A simple formula for the velocity, that permitted to fulfill its complete analysis, was derived for the first time with the help of an explicit separation of singularities in analytical solutions for velocity fields induced by an infinitely thin helical filament in an infinite space and in a cylindrical tube. As a result, the main factors are established that influence the velocity of vortices rotation and determine existence of immobile vortex structures as well as rotating in the opposite direction to the flow swirling.

"ANALYSIS OF JET BLAST IMPACT OF EMBARKED AIRCRAFT ON DECK TAKEOFF ZONE"

Aerospace Science and Technology, Vol. 45, 2015, pp. 60-66.

The jet blast impact of embarked aircraft on the takeoff zone is studied to support carrier-aircraft adaptation. The geometric model of carrier-aircraft system is built in CATIA Software and an unstructured mesh of the model is generated in Workbench Software. The jet blast impact of embarked aircraft on flight deck and jet blast deflector while taking off from takeoff zone is numerically simulated with standard k- ϵ and three-dimensional N-S equations based on CFD theory. Thermal coupling of wind over deck and jet blast is also taken into consideration. The distribution of temperature, pressure, velocity and streamline of the coupling flow is numerically simulated through Fluent Software and the temperature characteristics distribution on axes is also obtained. The results indicate: (1) the method presented in the paper can analyze fluid mechanics problems of complicated geometric models and obtain highly reliable simulation results; (2) the safe operation region for personnel, the suitable outfitting of jet blast deflector and proper layout of takeoff zone can be obtained.

Kulwatz, N.

"BEITRAGE ZUR BESTIMMUNG DER FLUGZEUGREAKTION BEIM EINFLOG IN WIRBELSCHLEPPEN SEHR GROSSER TRANSPORTFLUGZEUGE"

PhD Thesis, 2010, Technical University of Berlin, Berlin, Germany.

This thesis analyzes the influence of wake vortices resulting from very large transport aircraft, so-called 'mega-liners', on encountering aircraft. The analysis considers the vortex induced forces and moments acting on the encountering aircraft and the resulting dynamic behavior of manually controlled aircraft in real-time flight simulations. A flight mechanical model will be presented, which can describe the influence of small wind fields on the aircraft behavior within real-time flight simulation. Here the aerodynamic model takes a key role utilizing a lifting surface method. This lifting surface method is applied to the wing, the horizontal and the vertical tail plane and considers control surface deflections as well as flap positions. Furthermore, this aerodynamic model is suitable to calculate downwash distributions on the horizontal tail plane. Beyond that a vortex model is presented, which derives the wind velocities in wake vortices behind mega-liners. This model meets the high requirements of real-time flight simulations and describes the wake vortex as a pair of counter rotating vortices. The models are deployed initially to determine stationary forces and moments on two generic aircraft. In the analysis process variations of the encountering situation as well as variations of the wake vortex parameters are taking place. The focus of this thesis is directed on the analysis of the dynamic behavior of controlled aircraft during wake vortex approach. Therefore, measured data as well as pilot ratings are considered which are based on more than 700 simulated landing approaches. These landing approaches are conducted with several airline pilots on a state-of-the-art flight simulator with a visual and a motion system respectively. Recorded data is made accessible by statistic parameters of a descriptive analysis, to summarize the subjective ratings of several pilots during wake vortex encounter and to enable generic statements of the wake vortex hazard potential. Based on results from the flight simulations an equation is developed which describes the probability of a Go-Around maneuver. To determine the probability of a Go-Around maneuver both parameters of the wake vortex and parameters of the encountering aircraft are considered. The results of this investigation create a basis to determine a possible interference on aircraft which are following the mega-liners in approach and therefore to avoid unacceptable interferences by wake vortices during landing approach. [In German.]

"PARAMETER ESTIMATION USING UNSTEADY DOWNWASH MODEL FROM REAL FLIGHT DATA OF HANSA-3 AIRCRAFT"

Aeronautical Journal, Vol. 115, No. 1170, September 2011, pp. 577-588.

The paper presents the estimation of longitudinal aerodynamic parameters from simulated as well as real flight data using an unsteady downwash model. The task of parameter estimation was accomplished using the Maximum Likelihood method in the frequency domain for the Hansa-3 aircraft. The presented work pertains to the aircraft having a semi-sweptback wing configuration, however, the work reported earlier considered a rectangular wing configuration. A simple vortex system was used to model downwash effects in the longitudinal equations of motion. First, it was established that the indicial lift function had a minor or negligible influence on aircraft motion and on the estimated aerodynamic parameters using simulated data for the configuration of Hansa-3 aircraft. Next, two parameter extraction algorithms were used for parameter estimation using simulated data (with unsteadiness only in downwash) and real flight data (Hansa-3 aircraft). The first algorithm included

unsteadiness only in downwash while the second neglected all the unsteady effects. It was observed from the results obtained that if unsteady effects were omitted from the parameter estimation algorithms, the extracted parameters included the effects of unsteady aerodynamics. Therefore, application of the extraction algorithm in the two modes provides a convenient means of separating steady-state and acceleration derivatives.

"SCHEDULING AIRCRAFT LANDINGS TO CLOSELY SPACED PARALLEL RUNWAYS"

ATM 2009, June-July 2009, Napa, CA.

An optimization model for a scheduling problem for closely spaced parallel approaches has been formulated. It takes temporal, pairing, sequencing, separation route and grouping constraints into account. Simulations investigated possible advantages of advanced scheduling methods over first-come-first-served scheduling. Also, this study evaluated the performance differences between the computation of optimal solutions using mixed integer linear programming and computing solutions using genetic algorithms. The influence of the scheduling method, as well as the influence of varying the sizes of the pairing and estimated arrival time windows, have been investigated. A set of 20 aircraft, distributed over 30 minutes, was used as traffic data. Inputs to the model were the earliest and latest estimated arrival times, aircraft wake category, aircraft pairing group and route information. A schedule at a specific coupling point where aircraft are coupled for parallel approach was then computed. It is generally expected that closely spaced parallel approaches greatly enhance arrival throughput. The results of this study underpin this assumption. Further findings were: (1) for a sufficiently varied traffic mix, advanced scheduling methods can improve arrival throughput by approximately one parallel approach pair per half an hour compared to first-come-first-serve scheduling in visual meteorological conditions. Average delay can be reduced over first-come-first-serve scheduling in visual meteorological

conditions by up to 36 percent. (2) schedules computed by an improved genetic algorithm are of similar quality as optimal solutions and can be made available after short computation times; (3) when minimizing make-span i.e., the arrival time of the last aircraft in a sequence, the size of the estimated arrival time window does not influence the characteristics of the computed schedules.

"A SIMPLE MODEL OF DRY CONVECTIVE HELICAL VORTICES (WITH APPLICATIONS TO THE ATMOSPHERIC DUST DEVIL)"

Dynamics of Atmospheres and Oceans, Vol. 40, Issue 3, December 2005, pp. 151-162

An asymptotic solution of inviscid Boussinesq equations for a 'dry convective Rankine vortex' with prescribed buoyant forcing is given. The obtained vortex solution demonstrates monotonic growth with height of the vortex core radius, which becomes infinite at a certain critical altitude, and the corresponding attenuation of the vertical vorticity. This idealized vortex is then embedded in a convectively unstable boundary layer; the resulting approximate vortex solution has been applied to determine the maximum rotational wind speed and diameter of dry convective dust-devil like vortices.

"CHARACTERISTICS OF WAKE VORTEX GENERATED BY A BOEING 727 JET TRANSPORT DURING TWO-SEGMENT AND NORMAL ILS APPROACH FLIGHT PATHS"

NASA TN D-8222, April 1976, NASA Ames Research Center, Moffett Field, CA

A series of flight tests was conducted to evaluate the vortex wake characteristics of a Boeing 727 (B727-200) aircraft during conventional and two-segment ILS approaches. Twelve flights of the B727, which was equipped with smoke generators for vortex marking, were flown and its vortex wake was intentionally encountered by a Lear Jet model 23 (LR-23) and a Piper Twin Comanche (PA-30). The tests showed that at a given separation distance there were no readily apparent differences in the upsets resulting from deliberate vortex encounters during the two types of approaches. Timed mappings of the position of the landing configuration vortices showed that they tended to descend approximately 91 m (300 ft) below the flight path of the B727. The flaps of the B727 have a dominant effect on the character of the trailed wake vortex. The clean wing produces a strong, concentrated vortex but as the flaps are lowered, the vortex system becomes more diffuse. Pilot opinion and roll acceleration data indicate that 4.5 n.mi. would be a minimum separation distance at which roll control of light aircraft (less than 5,670 kg (12,500 lb) could be maintained during parallel encounters of the B727's landing configuration wake.

"MODIFICATION OF VORTEX IDENTIFICATION METHOD BASED ON NORMALIZED ANGULAR MOMENTUM"

AIAA Paper 2017-3556, June 2017, Denver, CO.

The vortex identification method based on normalized angular momentum functions is revisited. In the original method, the scalar function used to locate the vortex center is not a Galilean invariant. In order to overcome this drawback, the function was modified by adding the convective velocity term defined as the average velocity over the vortex core. This method was then verified through numerical simulations of the Lamb-Oseen vortex in the freestream. Applications of this method to velocity fields obtained by Particle Image Velocimetry (PIV) through wind tunnel experiments on a wing and a propeller are discussed. This modified method with enhanced Galilean invariance showed an overall better accuracy and robustness of vortex detection.

"AZIMUTHAL VORTICITY GRADIENT IN THE FORMATIVE STAGES OF VORTEX BREAKDOWN"

J. Fluid Mech., Vol. 569, 2006, pp. 1-28.

This paper is motivated by an observation in the nascent state of vortex breakdown before it develops into a full-grown radial expansion, an initially straight vortex core first swells, and does so even in a straight pipe for no apparent reason. Although this initial swelling may be explained in many ways according to the perspectives chosen, we offer our own interpretation framed solely within vorticity dynamics: the radial swelling as well as the subsequent growth are induced by the azimuthal vorticity gradient decreasing downstream. The negative azimuthal vorticity gradient first appears at start-up and moves eventually into the region where the circulation reaches its steady-state value. The vorticity gradient can become negative without necessarily being accompanied by a sign-switch of the azimuthal vorticity itself. The key point - that the negative azimuthal vorticity gradient induces initial radial swelling and its growth - is demonstrated in two analyses. First, a kinematic analysis results in an equation for the radial velocity where the azimuthal vorticity gradient appears as a source term. Its solution shows, in general and explicitly, that the negative azimuthal vorticity gradient does induce radially outward velocity. Two heuristic examples serve to illustrate this point further. In the second analysis, using the equation of motion in the streamline coordinates, the negative azimuthal vorticity gradient is shown to diverge the meridional streamlines radially. A numerical simulation using a modified vortex filament method not only corroborates this role of the azimuthal vorticity gradient in initiating and promoting the radial expansion, but also adds details to track the formation process. Both analyses and simulation support our interpretation that the initial radial swelling and its subsequent growth are induced by the negative azimuthal vorticity gradient.

"INTERCHANGEABILITY OF VORTEX-BREAKDOWN TYPES"

Experiments in Fluids, Vol. 34, 2003, pp. 77-86

To investigate the connection between the bubble and the spiral form of vortex breakdown, experiments were conducted: an external disturbance in the form of an azimuthally spinning waveform was imposed in a pipe. The azimuthal wave number was varied by adjusting the phase difference among four oscillating pistons mounted circumferentially on the pipe. By imposing a disturbance of zero azimuthal wave number, a spiral was transformed into a bubble, and this occurred only for selective piston frequencies; the vortex breakdown which altered from the spiral to the bubble moved upstream, where it remained as a bubble as long as the external disturbance remained. Once the disturbance was removed, the bubble returned to a spiral. By imposing a disturbance of azimuthal wave number $+1$ (the first circumferential mode rotating in the same direction as the mean swirl), a bubble was transformed into a spiral for selective piston frequencies, and the spiral moved downstream. These preferred frequencies were found to be the same as the unexcited frequencies observed in the spiral in its natural state. As long as the external disturbance was imposed, the breakdown altered from the bubble to the spiral remained as a spiral; once the disturbance was removed, the spiral reverted to a bubble. By imposing a disturbance with azimuthal wave number -1 (the first circumferential mode rotating in the opposite direction to the mean swirl), no change was detected in either bubble or a spiral. By imposing a disturbance with azimuthal wave number 2 (the second circumferential mode), for selective piston frequencies a bubble was transformed into what appears to be the so-called two-tailed type. Thus, it appears that hydrodynamic instability plays a role in interchanging vortex breakdown types, and a comparison with available stability theories is discussed.

"BEITRAGE ZUR BESTIMMUNG DER FLUGZEUGREAKTION BEIM EINFLUG IN WIRBELSCHLEPPEN SEHR GROSSER TRANSPORTFLUGZEUGE"

PhD Thesis, May 2010, University of Berlin, Berlin, Germany.

This thesis analyzes the influence of wake vortices resulting from very large transport aircraft, so-called 'mega-liners', on encountering aircraft. The analysis considers the vortex induced forces and moments acting on the encountering aircraft and the resulting dynamic behavior of manually controlled aircraft in real-time flight simulators. A flight mechanical model will be presented, which can describe the influence of small wind fields on the aircraft behavior within real-time flight simulation. Here the aerodynamic model takes a key role utilizing a lifting surface method. This lifting surface method is applied to the wing, the horizontal and the vertical tail plane and considers control surface deflections as well as flap positions. Furthermore, this aerodynamic model is suitable to calculate downwash distributions on the horizontal tail plane. Beyond that a vortex model is presented, which derives the wind velocities in wake vortices behind mega-liners. This model meets the high requirements of real-time flight simulations and describes the wake vortex as a pair of counter rotating vortices. The models are deployed initially to determine stationary forces and moments on two generic aircraft. In the analysis process variations of the encountering situation as well as variations of the wake vortex parameters are taking place. The focus of the thesis is directed on the analysis of the dynamic behavior of controlled aircraft during wake vortex approach. Therefore, measured data as well as pilot ratings are considered which are based on more than 700 simulated landing approaches. These landing

approaches are conducted with several airline pilots on a state-of-the-art flight simulator with a visual and a motion system respectively. Recorded data is made accessible by statistic parameters of a descriptive analysis, to summarize the subjective ratings of several pilots during wake vortex encounter and to enable generic statements of the wake vortex hazard potential. Based on results from the flight simulations an equation is developed which describes the probability of a Go-Around maneuver. To determine the probability of a Go-Around maneuver both parameters of the wake vortex and parameters of the encountering aircraft are considered. The results of this investigation create a basis to determine a possible interference on aircraft which are following the mega-liners in approach and therefore to avoid unacceptable interferences by wake vortices during landing approach.

Kurylowich, G.

"THE WAKE TURBULENCE RESEARCH PROGRAM AT AFFDL"

Proceedings of the AFFDL/NASA/FAA Wake Turbulence Work Shop, Air Force Flight Dynamics Laboratory, AFFDL-TM-75-16-FGC, 1974, pp. 3-9

A review is given of the Flight Dynamics Laboratory wake turbulence program; the program was prompted by the evaluation of accidents and incidents within the Air Force. A large percentage of the vortex encounters occurred during military operations quite distinct from the usual civil related terminal operations (mid-air refueling, minimum interval takeoff, formation flight, and mixed mode operations with nearby helicopters). Future high-performance fighters will be more susceptible to vortex upsets because of their light weight and low moments of inertia. The primary concern of the Air Force is the near wake. The experimental and theoretical efforts on the near wake are reviewed as well as a vortex encounter simulation.

Kurylowich, G.

"A SIMPLIFIED VORTEX ENCOUNTER MODEL FOR SIMULATING WAKE TURBULENCE ON USAF TRAINERS AND SIMULATORS"

AFFDL-TM-75-91-FGC, June 1975, Air Force Flight Dynamics Lab., Wright-Patterson Air Force Base, OH

A simplified model for the calculation of rolling moment on an aircraft encountering wake turbulence is presented. The model is implemented on appropriate trainers and simulators for the purpose of educating the pilots on the extent of a wake turbulence encounter as part of their training curriculum.

Kurylowich, G.

"A METHOD FOR ASSESSING THE IMPACT OF WAKE VORTICES OF USAF OPERATIONS"

AFFDL-TR-79-3060, July 1979, Air Force Flight Dynamics Lab., Wright-Patterson AFB, OH

Experience as a consultant to the Safety Office at Norton AFB led to compiling the engineering tools presented so that this report can be used by engineering personnel to investigate future

incidents/accidents and existing USAF operations that are impacted by the vortical wake hazard. The approach presented is amenable to easy hand computations. Mixed airplane/helicopter operations can be assessed, since the engineering tools to determine the location and strength of the rotor downwash field behind a helicopter are presented. Finally, a simplified mathematical model is given to represent this hazard for use in USAF simulators, to make pilots aware of the problems associated with operating in wake-contaminated airspace.

Kurylowich, G.

"A STUDY OF AIR FORCE WAKE TURBULENCE ACCIDENTS"

AFFDL-TM-72-3-FGC, March 1972, Air Force Flight Dynamics Lab., Wright-Patterson Air Force Base, OH.

USAF accident statistics have been analyzed for the 1965-1971 time-period. The number of accidents probably caused by wake encounters, as well as the percentage of total and terminal area losses they represent, are given. A short-term program for the study of wake turbulence as related to USAF operations is proposed.

Kurylowich, G.

"WAKE TURBULENCE ABATEMENT BY BLOWING AND OTHER MEANS"

Fluid Dynamics Panel, AGARD, 1973

The current state of knowledge concerning the turbulent breakup and bursting of aircraft trailing vortices is reviewed. Efforts towards the forcing of premature vortex breakup are placed in the context of an Air Force related wake turbulence program.

Kurylowich, G.

"ANALYSES RELATING TO AIRCRAFT VORTICAL WAKES"

AFFDL-TM-73-23-FGC, February 1973, Air Force Flight Dynamics Lab., Wright-Patterson Air Force Base, OH

A comprehensive literature review of all analyses and experimental investigations related to vortical wake structure is presented. Various mathematical models for the flow field in the far wake are given and then compared to experiment. The possibility of causing premature vortex break-up by such means as wingtip spoilers and mass injection is also discussed.

Kurylowich, G. and Nelson, R. C.

"ANALYSIS OF A WAKE TURBULENCE HAZARD IN USAF OPERATIONS (T-38 ACCIDENTS)"

AFFDL-TM-74-132-FGC, June 1974, Air Force Flight Dynamics Lab., Wright-Patterson Air Force Base, OH

Analyses related to the investigation of a T-38 accident which appeared to be caused by an encounter with the wake of an L-382 are presented. It is shown that the T-38 could have encountered wake turbulence through modelling the atmospheric propagation of the L-382 wake. The severity of the encounter is estimated through modelling of wake decay and the effects of dynamic encounters.

Kusmarwanto, I.

"GROUND EFFECT ON A ROTOR WAKE"

PhD Thesis, March 1985, Cranfield Institute of Technology, Cranfield, Bedford, UK.

The effect of the ground on a rotor wake in forward flight has been investigated experimentally in the working section of an 8ft x 4ft straight-through wind tunnel. A three bladed fully articulated rotor with a solidity ratio of 0.07 and diameter of 1.06m, powered by a hydraulic motor, has been tested at a height of 0.47 rotor diameter above a solid ground board which has an elliptical leading edge. Tests have been run at various low advance ratios (less than 0.1) with two collective pitch settings. A three-element hot wire anemometer probe has been used to measure the average value of the three components of velocity simultaneously in the forward half (advancing side) of the rotor wake and in the main stream surrounding it. The rotor wake and the ground vortices have been visualized by smoke. Surface flow patterns on the ground board have located the interaction region between the rotor wake and the oncoming flow on the ground board. Both experimental results and theoretical estimates show that the ground-induced interference is an upwash and a decrease in forward velocity. The upwash interference opposes the vertical flow through the rotor, and have large effects on the rotor performance in producing thrust. The streamwise interference decelerates the mainstream and becomes more noticeable as the wake boundary is approached.

Kusunose, K.

"DRAG PREDICTION BASED ON A WAKE-INTEGRAL METHOD"

AIAA Paper No. 1998-2723, June 1998, Albuquerque, NM.

This paper discusses the analytical aspects of the determination of drag acting on a model in a wind tunnel under subsonic or transonic flow conditions. The drag integral is derived from the integral form of the momentum equation to take the compressible flow effects into account. The drag integral can be broken down into profile drag (including wave drag) and induced drag. An analytical expression for induced drag has been developed to minimize the grid dependency problem, which is inherent in the numerical solution procedure. This analytical approach allows us to evaluate the effect of the wind tunnel walls on the drag. Predicted drag numbers from several different formulas are compared with experimental measurements.

"EXTENSION OF WAKE SURVEY ANALYSIS METHOD TO COVER COMPRESSIBLE FLOWS"

Journal of Aircraft, Vol. 39, No. 6, November-December 2002, pp. 954-963

This paper summarizes the work accomplished over the last several years on wake-survey analysis method developments at Boeing. In this paper, Betz and Maskell's lift and drag equations are extended to cover compressible flows. The small perturbation method is employed to expand the general lift and drag equations in the momentum integral forms, assuming downstream states that differ only slightly from the state of approach. Introducing new, simpler, and cleaner expansion procedures, it is proven that both the lift and drag of an airplane model can be accurately predicted by simply measuring flow variables inside of the model wake region. This result enables the practical application of quantitative wake surveys for accurate lift and drag predictions of airplane models. To demonstrate the current lift and drag prediction capabilities, some wake survey analysis results from previously published data are re-calculated using newly developed lift and drag formulas. Since wake surveys are not needed outside of the model wake region, one complete wake survey analysis for a non-powered engine case, including data acquisitions and reductions, can now be finished in approximately 10-15 minutes. These wake survey analysis results demonstrate that both wake-integrated lift and drag typically agree with the internal strain-gauge balance to within a few percentage points.

"THE VELOCITY FIELD INDUCED BY A TRAILING VORTEX IN SUPERSONIC FLOW"

Japan Society of Aeronautical Space Sciences, Vol. 58, 2010, pp. 45-53.

To estimate the velocity field induced by a trailing vortex which is located along the free-stream direction in supersonic flow, we extend the Biot-Savart law, that is originally proven for subsonic flow, to supersonic flow. During the derivation we use the linearized perturbation potential equation that can be applied to both subsonic and supersonic (inviscid) flows. It is shown that our current formula reduces to the original Biot-Savart law when the flow speed reduces from supersonic to subsonic one. It is also shown in the appendix that the Kutta-Joukowski theorem is still applicable to supersonic flows within the supersonic thin-airfoil approximations.

"INSTALLED POWERED ENGINE EFFECTS ON DRAG USING A WAKE-INTEGRAL METHOD"

AIAA Paper No. 2000-2400, June 2000, Denver, CO.

This study focuses on the derivation of drag components of airplane models equipped with powered engines using the flow variables measured within the model wake region. To take the powered engine effects into account, the drag equation in the momentum integral form is modified by using the continuity and energy equations. Then, the drag equation is expanded into a perturbation form assuming downstream states that differ only slightly from the state of approach, to identify major individual drag components of an airplane model. Because of the work added by the powered engines, total temperature measurements (in addition to pressure measurements) are required at the wake survey station. However, it is shown for low-subsonic flows that the total temperature will not play a major role in the drag analysis. Because of the accelerated flows inside the jet plumes, higher order velocity terms in the drag equation are not necessarily small enough to be neglected inside the engine exhaust regions. Some of the preliminary wake survey analysis results of the High Wing Transport test (at the NASA Ames 12-Foot Pressure Wind Tunnel) are presented to demonstrate the powered engine capability in the drag analysis.

"EXPERIMENTAL AND NUMERICAL EXAMINATION OF A HELICOPTER HOVERING IN GROUND EFFECT"

CEAS Aeronautical Journal, Vol. 4, Issue 4, December 2013, pp. 397-408.

This study collects experimental data of a helicopter hovering in ground effect and intends to prove the capability to compute the flow field around the measured helicopter rotor with the use of the flow solver FLOWer. Firstly, the wake trajectory of a Hughes 300C helicopter hovering in ground effect was obtained by introducing fog in the rotor disk, while visualizing the blade tip vortices with a laser light sheet and a high-speed camera. Secondly, the isolated rotor of the Hughes 300C was modeled numerically and computed with the block-structured second-order flow solver FLOWer from DLR, to provide a computational validation for full size rotors in ground effect hover. Blade dynamics were neglected and the rotor was trimmed to the experimental thrust. It was found that the flow solver can simulate the flow around a full-size helicopter rotor during hover in ground effect. The wake trajectories are convected downwards slightly faster than in the experiment. The radial wake path fits well with the experimental one until high wake ages, where the numerically as well as experimentally

reproduced trajectory becomes unstable. The development of the thrust value was analyzed with a Fourier transform. Disturbances due to the ground can be detected especially at higher harmonics of the blade passing frequency. For comparison, the rotor was also examined numerically out of ground effect. As expected, the oscillations are more periodic than close to the ground. An analysis of the performance data led to a benefit of 21 percent due to the ground effect.

Kuwahara, K.

"SIMULATION OF VORTEX-DOMINATED FLOW"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

Vortex structure behind a bluff body looks very complicated because of the separated vortices. Many experimental investigations have been done, but nobody yet can tell the dominant structure even for a simple sphere. On the other hand, in two dimensions, Karman vortex street is known to be most dominant. To find the essential three-dimensional structures, we computed these flows extensively and visualized them. From these computations, in this paper, we suggest the most important structure behind a bluff body is the U-shape vortex attached partially to the body and two tail flows down. Computation is now easier and more effective to see those phenomena than experiments.

Kuzmin, V. P.

"ANALYSIS OF THE VORTEX WAKE EFFECT ON AN AIRCRAFT IN LANDING APPROACH"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 227-238

The work outlines a method for calculating the parameters and shape of vortices in the atmospheric boundary layer and for calculating the spectral densities of unstable oscillations of four vortices (two actual and two imaginary), with atmospheric turbulence parameters and distances between the vortices being variable, the latter resulted from the interaction of the vortices with the ground surface. A technique is given for forming random realizations of the vortices to be used in statistical simulation of the following aircraft. A computer code created is intended for simulating random realizations of the vortex sheet and enables determining the location of vortex cores and cross-flow plane downwash angle distribution as a function of the range covered by the following aircraft. Included in the mathematical model as its constituents are the model of varying vortex core radius and circulation, model of the vortices transport in the ground proximity and the model of the random unstable oscillation of the vortices. The model presented is the modification of that described in (Kuzmin 1997). Numerical estimates are presented of the influence of various parameters of the wake mathematical model on the landing accuracy of the following aircraft.

Kuzmin, V. P.

"ESTIMATION OF WAKE-VORTEX SEPARATION DISTANCES FOR APPROACHING AIRCRAFT"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 209-224

This paper presents an approximate method of determining safe distances between aircraft of any leader-follower pair during approach operations. The need for maintaining certain distances between aircraft is associated with the possibility of the encountering of following aircraft with the vortex wake generated by a leading aircraft. Described in the paper are approximate mathematical models of the vortex wake and its effect on the following aircraft, which are needed to estimate safe distances. The mathematical model of the vortex wake considers the movement of vortices near the ground and the possibility of their decay due to effects of atmospheric turbulence. The degree of vortices hazard is determined by the rolling moment that they induce on the following aircraft. The wake-vortex separation distances are determined by a stochastic criterion.

"THE NUMERICAL HISTORY OF AIRPLANE MANUFACTURING IN XX CENTURY"

31st Congress of the International Council of the Aeronautical Sciences (ICAS 2018), September 2018, Belo Horizonte, Brazil.

The database containing information about more than 18000 airplane models, created during XX century, their characteristics and production dates is prepared by author. Analysis of this database information gives answers on many questions about the aviation history. How many airplanes were built during XX century? How did it performances grow? What is common and different in the development of aviation industry of countries? When the rises and falls were happened, were their reasons local, national, or worldwide? Some answers are given in this report.

"DYNAMICS OF VORTEX AND MAGNETIC LINES IN IDEAL HYDRODYNAMICS AND MHD"

Lecture Notes in Physics, Vol. 536, 1999, pp. 346-368

Vortex line and magnetic line representations are introduced for description of flows in ideal hydrodynamics and MHD, respectively. For incompressible fluids it is shown that the equations of motion for vorticity and magnetic field with the help of this transformation follow from the variational principle. By means of this representation it is possible to integrate the system of hydrodynamic type with the Hamiltonian. It is also demonstrated that these representations allow to remove from the noncanonical Poisson brackets, defined on the space of divergence-free vector fields, degeneracy connected with the vorticity frozenness for the Euler equation and with magnetic field frozenness for ideal MHD. For MHD a new Weber type transformation is found. It is shown how this transformation can be obtained from the two-fluid model when electrons and ions can be considered as two independent fluids. The Weber type transformation for ideal MHD gives the whole Lagrangian vector invariant. When this invariant is absent this transformation coincides with the Clebsch representation analog introduced in [1].

"APPROXIMATE CALCULATION OF THE VELOCITY FIELD AND THE MOTION OF VORTICES IN THE WAKE OF A LOW-FLYING BIPLANE"

Uchenye Zapiski, Vol. 8, No. 4, January 1977, pp. 92-96

The paper describes a method for calculating the velocity field some distance behind a low-flying biplane. The vortex wake is modeled as a system of four infinite free vortices, and the screening effect of the earth surface is considered by the introduction of four additional specularly reflected vortices. The motion of the vortices is studied as a function of flight altitude.

"ON THE COMPUTATION OF DYNAMIC LOADING OF AN AIRCRAFT DUE TO A VORTEX WAKE"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 169-177

The problem of structural strength is one of the major problems in providing aircraft flight safety in the cases of encountering vortex wakes behind other aircraft. The method and computer codes were developed for calculating dynamic structural loading. The aircraft was considered to perform under vortex disturbances simultaneously both symmetric (pitching) and antisymmetric (lateral) motion with the excitation of corresponding modes of elastic structural oscillations. A series of parametric computations was performed for two airplanes with straight wings (weight 1300 and 22000 kg). The vortex wake was simulated with two vortex filaments with parameters variable in a wide range: the radius where the tangential velocity reaches its maximum, the distance between the vortices, the elevation of the encountering aircraft, its speed, the angle between the flight direction and the vortex axis. An analysis of transient processes has shown that the maximum load experienced by encountering aircraft is induced by the second vortex and the most dangerous from the standpoint of structural strength is the angle in the range of 90 ± 60 degrees. It was revealed that the maximum permissible vortex velocity for these two airplanes is of order 7-14 m/s. [In Russian.]

"PREDICTION OF AIRCRAFT DISPLACEMENTS IN TURBULENT FLOW"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 265-273

Problem statement and a method for predicting vertical displacements of an aircraft immersed in a turbulent flow are outlined. Using the heavy IL-96 aircraft as an example, spectral characteristics of displacement of the aircraft center of gravity and wing tips were computed.

Kuznetsov, O. A. and Osminin, R. I.

"WIND-TUNNEL INVESTIGATION OF AN AIRCRAFT MODEL DYNAMIC LOADS DUE TO VORTEX GUSTS"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 157-168

This paper presents a description of a device in the form of a lattice of deflectable airfoils for generating vortex gusts. Examples of such gust flow fields are given for various laws of airfoils detection together with the characteristics of an aeroelastic aircraft model. The methodology and results of measurements of model dynamic response (wing bending moments) both in free flight and in the case of the fixed fuselage are described. An evaluation of experimental accuracy is presented.

Kuznetsov, O. A. and Vyshinsky, V. V.

"VORTEX-WAKE SAFETY: AIRCRAFT-STRENGTH ASPECTS OF THE PROBLEM"

AIAA Paper No. 1998-2523, Albuquerque, NM, June 1998

The whole safety problem of an aircraft penetrating a vortex wake is divided into three main parts: determination of the wake characteristics, calculation of a response to its action, and, finally, determination of safe distances, based on maximum permissible values of this response.

Kuznetsov, O. A., Orlova, T. I. and Chizhov, V. M.

"EVALUATION OF SAFE SEPARATION DISTANCES BETWEEN AIRCRAFT FROM THE STRENGTH STANDPOINT"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 138-147

This paper describes an approximate methodology developed for computing parameters of the vortex wake behind a wake generating aircraft (B-747) together with a method of determining dynamic loads due to the action of the wake on another aircraft. Results of computations are presented of distances (passage times) from a wake generating aircraft to a following aircraft at the instant of time when the latter experiences maximum allowable loads from the strength standpoint. Parametric investigations of effects of various factors are discussed, including wake characteristics, type of aircraft, flight speed and degree of atmospheric turbulence.

Kuznetsov, O. A., Orlova, T. I. and Osminin, R. I.

"DYNAMIC LOADING OF THE AIRCRAFT MODEL INDUCED BY VORTEX GUSTS: EXPERIMENTAL AND COMPUTATION"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 148-156

The paper presents computational and experimental methods used in investigation of dynamic loads on an aircraft model subject to vortex gusts generated in the wind-tunnel flow. Based on the comparison of computed results and experimental data, the applicability is assessed of the approach proposed to the determination of loads and separation distances between leading and following aircraft safe from the structural-strength standpoint and the conditions are found in which the strength issues for the second aircraft can affect the safe-separation distance.

"INDUCED DRAG REDUCTION USING MULTIPLE WINGLETS, LOOKING BEYOND THE PRANDTL-MUNK LINEAR MODEL"

AIAA Paper No. 2004-2120, Portland, Oregon, June 2004.

A redefinition of multiple winglet configurations is proposed in order to understand and facilitate exploiting the massive induced drag reductions of streamwise staggered multiple winglets, which, using the Prandtl-Munk vortex sheet model are not predicted. Multiple winglets are either staggered streamwise (feathered wingtips) or have no such stagger (Cone tip boxes, end-plates and other classic configurations). This contribution considers the fact, that we have on the one hand well understood and replicated winglet systems (no stagger) which are rendered with sufficient accuracy by the Prandtl-Munk model of a fixed vortex sheet in streamwise direction, free of drag, neglecting rolling up. On the other hand, selected cases new and old, such as the Spiroid, Split-Wing or the Winggrid are being reported which exhibit streamwise staggered winglets and where the experimental results point to much smaller induced drag than predicted with the Prandtl-Munk linear model. The paper shows, how including a grid effect of staggered multiple winglets on the deflected mass-flow of a wing system within linear models. The actual gap for conceptual understanding and calculating between experiment and prediction by linear models is bridged to a new perspective beyond the linear Prandtl-Munk model. Out of this new perspective follows a reassessment of selected multiple winglet configurations with superior performance potential.

"WING-GRID, A NOVEL DEVICE FOR REDUCTION OF INDUCED DRAG ON WINGS"

ICAS-1996, Sorrento, Italy, 1996.

A new wing-tip device for reduction of induced drag on wings is reported. Relative reductions of induced drag compared to elliptical planar wing up to 50% have been verified. The well-known equation of Spreiter and Sacks for rolled-up vortex geometry has two parameters, that define the relative induced drag of any wing and wingtip configuration: In the so-called Trefftz plane behind a wing the trailing vortices have spacing and vortex-core radius. The contribution of a wingtip to increase the vortex spacing and/or the vortex core radius for reduction of induced drag is used for the

classification of wingtips. Simultaneous exploitation of increasing vortex spacing and increasing vortex radius leads to configurations exceeding the potential of the known classic configurations by a wide margin. Known is the Spiroid by Dr. Louis Gratzer. Another is the WING-GRID treated in this paper. Both have been included in our wind tunnel verifications and are identified to belong to the same class. The paper reports the tests made and a preliminary description of the working principle of the wingtips belonging to this class as well as a description of the design information arrived at for the WING-GRID.

Labbe, O.

"LARGE-EDDY SIMULATION OF A TURBULENT JET AND WAKE VORTEX INTERACTION"

13th International Conference on Fluid Flow Technologies, September 6-9, 2006, Budapest, Hungary.

Temporal Large-Eddy Simulations of the interaction between a turbulent jet flow and a trailing vortex are described in this study. Three cases are analyzed: in the first one, the jet and the vortex axes are sufficiently well separated to not interact immediately, while in the second case the distance between the jet and the vortex is reduced to the half. In the last case the jet blows in the vortex core. In the two first cases, as the jet spreads, it is progressively deflected by the continuous input of crossflow momentum, so that it acquires azimuthal and radial component of velocity, causing the emergence of three-dimensional structures of azimuthal vorticity around it. When the jet and the vortex are superimposed, the turbulent kinetic energy does not increase, the vortex core is extremely buffeted. Results of the numerical simulation of the convection-diffusion of a passive scalar show that its distribution (initially in the jet) cannot penetrate inside the vortex core, due to its solid rotation, for the cases where the jet is initially outside the vortex and when it is injected in the vortex wake, its value remains very high and cannot get out of the vortex core.

"RECONSTRUCTION OF INITIAL FIELD FROM EXPERIMENTAL DATA FOR NUMERICAL SIMULATIONS OF REALISTIC AIRCRAFT WAKES"

Progress in Computational Fluid Dynamics, Vol. 3, No. 1, 2003, pp. 1-12

The development of wake vortex behind an A300 Airbus model in high-lift configuration is computed by solving the unsteady Navier-Stokes equations for an incompressible fluid with a second order accurate scheme in time and space. Both two- and three-dimensional simulations are carried out, which allow us to compare the main vortex trajectory with data measured by three-component LDV system in the Onera facility. The study is focused on the way of initializing the computational entrance section based on the experimental data and the consequential effects of main vortex position up to nine wing spans downstream of the model. Several ways to reconstruct the initial velocity field for the simulations are investigated. The circulation distributions around the main vortex are compared and results obtained show that the circulation level is not a pertinent parameter to define a correct initialization. Numerical results show that a better agreement with experimental data is obtained when

a large domain is covered by experiments at the inlet section. A technique to reconstruct adequate initial data solving an inverse problem is also presented.

"UNSTEADY WAKE VORTICES SIMULATION BEHIND A A300 MODEL"

AIAA Paper No. 2003-4022, Orlando, FL, June 2003

The development of wake vortex behind an A300 Airbus model in high-lift configuration is computed by solving the three-dimensional unsteady Navier-Stokes equations for an incompressible fluid with a second order accurate scheme in time and space. The vortices are liable to a global unsteadiness, in erratic displacement form around their mean position, called meandering. The aim of this study is to reproduce numerically the unsteady properties of the vortices and to compare the different frequencies with those measured experimentally and to analyze the squared coherence spectra to exhibit the combined movement of the main vortex.

labbe, O. and Sagaut, P.

"NUMERICAL SIMULATION BEHIND AN A300 AIRBUS MODEL"

ICMAR 2004, Novosibirsk, Russia, June 2004

The development of wake vortex behind an A300 Airbus model in high-lift configuration is computed by solving the three-dimensional unsteady Navier-Stokes equations for an incompressible fluid with a second order accurate scheme in time and space. The vortices are liable to a global unsteadiness, in erratic displacement form around their mean position, called meandering. The aim of this study is to reproduce numerically the unsteady properties of the vortices and to compare the different frequencies with those measured experimentally and to analyze the squared coherence spectra to exhibit the combined movement of the main vortex.

"LARGE-EDDY SIMULATION OF A TURBULENT JET AND WAKE VORTEX INTERACTION"

Computers and Fluids, Vol. 36, 2007, pp. 772-785

In this study, temporal large-eddy simulations of the interaction between a turbulent jet flow and a trailing vortex are described. Three cases are analyzed: in the first one, the jet and the vortex axes are sufficiently well separated to not interact immediately, while in the second case, the distance between the jet and the vortex is reduced by half. In the last case the jet blows in the vortex core. In the two first cases, as the jet spreads it is progressively deflected by the continuous input of crossflow momentum. Thus, it acquires azimuthal and radial components of velocity, causing the emergence of three-dimensional structures of azimuthal vorticity around it. When the jet and the vortex are superimposed, the turbulent kinetic energy does not increase, the vortex core is very buffeted.

Numerical simulation results of the convection-diffusion of a passive scalar show that its distribution (initially in the jet) cannot penetrate inside the vortex core due to its solid rotation. For the cases where the jet is initially outside the vortex and when it is injected in the vortex wake, its value remains very high and cannot get out of the vortex core. This phenomenon confirms the existence of a stabilizing 'dispersion buffer', adjacent to the core, which prevents amplification of the turbulence generated inside the core.

"NEAR-TO MIDFIELD WAKE: NUMERICAL PREDICTION"

Proceedings 3rd ONERA-DLR Aerospace Symposium, Paris, France, June 2001, pp. S3-1/1-11

A chain of flow solvers for simulating the flow around an aircraft and the downstream evolution up to the midfield vortex wake is presented. In the first part the predictive capability of an Euler code using unstructured grids for the nearfield vortex wake calculation of the DLR-ALVAST model in landing configuration is demonstrated. The simulation quality of the vortex formation and spatial development is analyzed by comparison to experimental five-hole-probe and PIV data. In a second step, the development of the near- to midfield wake vortex behind a A300 Airbus model in high-lift configuration is computed with 2D Navier-Stokes calculations. A first validation is carried out with a comparison between the results of the near wake with those obtained in a wind tunnel. Furthermore, the calculated main vortex trajectory up to 80 spans is compared with data measured by laser tomography in the ONERA catapult facility.

"PROPAGATION OF SOUND THROUGH A TURBULENT VORTEX"

Physical Review Letters, Vol. 81, No. 7, August 1998, pp. 1413-1416

We report an experimental study of sound propagation in the bulk of a homogeneous flow made of a single intense vortex in air. By using an adaptive-coherent average technique, the mean amplitude and phase of the distorted wave fronts are reconstructed. A large phase shift is observed on the wave fronts on either side of the 'shadow' region behind the vortex. The shape of the averaged amplitude, as a function of space coordinates, shows that caustics are also formed in the acoustic field. In a nonstationary flow, these effects make it possible to monitor the vortex strength and position.

"EVALUATION OF A POTENTIAL THEORETICAL MODEL OF THE WAKE BEHIND A WING VIA COMPARISON OF MEASUREMENTS AND CALCULATIONS"

NLR TR-74063-U, July 1974, National Aerospace Lab., Amsterdam, The Netherlands.

The validity of the representation of the wake by discrete trailing vortices as common practice in potential theoretical calculations is considered. Theoretical results, obtained with a method developed at NLR, are compared with experimental results obtained at NLB for a 30 deg sweptback wing. The shape of the vortex sheet as well as the velocity distribution downstream from the wing are predicted reasonably well; however, the wake model appears to be not completely satisfactory in the wing tip region. The numerical method requires improvement with respect to the description of the rolling up process of the vortex sheet.

"ELLIPTIC INSTABILITY IN A STRAINED BATCHELOR VORTEX"

J. Fluid Mech., Vol. 577, 2007, pp. 341-361.

The elliptic instability of a Batchelor vortex subject to a stationary strain field is considered by theoretical and numerical means in the regime of large Reynolds number and small axial flow. In the theory, the elliptic instability is described as a resonant coupling of two quasi-neutral normal modes (Kelvin modes) of the Batchelor vortex of azimuthal wavenumbers with the underlying strain field. The numerical study considers a system of two counter-rotating Batchelor vortices in which the strain field felt by each vortex is due to the other vortex. The characteristics of the most unstable linear modes developing on the frozen base flow are computed by direct numerical simulations for two axial flow parameters and compared to the theory. In both cases, a very good agreement is obtained for the most unstable modes. Less unstable modes are also identified in the numerics and shown to correspond to peculiar resonances involving Kelvin modes from branches of different labels.

"IMPLEMENTATION OF AVOSS WAKE TURBULENCE MODEL INTO THE FAA'S AIRSPACE SIMULATION AND ANALYSIS FOR TERPS (ASAT) MONTE-CARLO SIMULATION SYSTEM"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

This presentation discusses three major points, namely: 1) The philosophy behind the development of the FAA's Airspace Simulation and Analysis for TERPS, also known as ASAT. 2) The Monte-Carlo style implementation of the wake turbulence model developed for AVOSS. 3) The manner the combined system has been utilized in a critical wake turbulence study regarding simultaneous parallel approaches to closely spaced parallel runways at San Francisco International Airport, California, USA.

Laforgia, A., Leoncini, X., Kuznetsov, L. and Zaslavsky, G. M.

"PASSIVE TRACER DYNAMICS IN 4 POINT-VORTEX FLOW"

Eur. Physics J. B, Vol. 20, 2001, pp. 427-440

The advection of passive tracers in a system of 4 identical point vortices is studied when the motion of the vortices is chaotic. The phenomenon of vortex-pairing has been observed and statistics of the pairing time is computed. The distribution exhibits a power-law tail with exponent about 3.6 implying finite average pairing time. This exponent agrees with its computed analytical estimate of 3.5. Tracer motion is studied for a chosen initial condition of the vortex system. Accessible phase space is investigated. The size of the cores around the vortices is well approximated by the minimum inter-vortex distance and stickiness to these cores is observed. We investigate the origin of stickiness which we link to the phenomenon of vortex pairing and jumps of tracers between cores. Motion within the core is considered and fluctuations are shown to scale with tracer-vortex distance r as r to the sixth power. No outward or inward diffusion of tracers are observed. This investigation allows the separation of the accessible phase space in four distinct regions, each with its own specific properties: the region within the cores, the reunion of the periphery of all cores, the region where vortex motion is restricted and finally the far-field region. We speculate that the stickiness to the cores induced by vortex-pairings influences the long-time behavior of tracers and their anomalous diffusion.

"METHODS FOR CALCULATING THE FLOW IN THE TREFFTZ-PLANE BEHIND SUPERSONIC WINGS"

Journal of the Aeronautical Sciences, March 1951, pp. 170-190.

By means of the linearized non-viscous theory, methods are developed, using the complex functions of conical flow, for finding downwash and sidewash in the Trefftz-Plane -- i.e., at an infinite distance downstream, behind a supersonic wing. Equations are derived which describe this flow field behind several types of 'flat plate' wings: the wide delta wing, the trapezoidal wing (wide delta wing with cutoff tips), and the delta control surfaces (a narrow delta wing, the two sides of which are deflected differentially). Graphs are included which show the results for these cases. As observed previously in connection with other cases, in the plane of the wing the flow field is characterized by infinite upwash straight behind the wing tips and, in the case of the delta wings and control surfaces, by a region of constant downwash behind the wing. These conditions are modified immediately upon moving above or below the plane of the wing. It is found that the flow field behind the delta control surfaces, the two sides deflected equal amounts in the opposite direction, does not vary with changes in Mach Number. In applying the results presented here, one must, of course, take into consideration corrections due to effects of fuselage interference, nonlinearity, viscosity, etc. These effects are not, however, the subject matter of this paper.

Lai, D. Y., Jacob, D., Lo, F. A. and Delisi, D. P.

"ASSESSMENT OF PULSED LIDAR MEASUREMENTS OF AIRCRAFT WAKES USING A LIDAR SIMULATOR: VORTEX POSITION ESTIMATES FOR IGE, LINKING, AND OBLIQUE VIEWING, AND DEPENDENCE OF VORTEX LIFETIME ON SNR"

AIAA Paper 2011-3197, June 2011, Honolulu, Hawaii.

A lidar simulator tool was developed to simulate realistic raw lidar signal data generated from a wake vortex velocity field as measured by the existing Lockheed Martin Coherent Technologies (LMCT) WindTracer pulsed lidar, currently used in the field to measure aircraft wake vortices. The raw lidar data is processed and the resulting product files are input into the existing LMCT Wake Vortex Processing Algorithm to estimate position and circulation strength versus wake age. The estimates from the Wake Vortex Processing Algorithm are then compared to truth data used to generate the raw lidar signal data. Accuracy of the Wake Vortex Processing Algorithm estimates of lateral and vertical position is evaluated by exercising the lidar simulator using input wake vortex fields based on analytical vortex models and 3-D Large Eddy Simulation computations for two aircraft types under IGE, OGE linking, and oblique viewing conditions. This study shows that the mean biases of the vortex position estimates for IGE and OGE linking vortices are small and similar to those for non-linking vortices in the OGE region reported in an earlier study. The use of the lidar at oblique angles relative to the trailing line vortices does not introduce significant differences in the position biases. An analysis of the vortex lifetime estimates with SNR variations suggests avoiding lidar measurements for SNRs below 0 dB.

Lai, D., Jacob, D. and Delisi, D. P.

"ASSESSMENT OF PULSED LIDAR MEASUREMENTS OF AIRCRAFT WAKE VORTEX POSITIONS USING A LIDAR SIMULATOR"

AIAA Paper No. 2010-7988, Toronto, Canada, August 2010.

A lidar simulator tool was developed to simulate realistic raw signal data generated from a wake vortex velocity field as measured by the existing Lockheed Martin Coherent Technologies (LMCT) pulsed lidar currently being used in field measurements of aircraft wake vortices. The raw lidar data is processed and the resulting product files are input into the existing LMCT's Wake Vortex Processing Algorithm for determining position and circulation strength versus wake age. Outputs from the Wake Vortex Processing Algorithm are then compared to the truth data used to generate the raw lidar signal data. Accuracy of the lidar measurements of lateral and vertical vortex positions is evaluated by exercising the lidar simulator, using input wake vortex fields based on analytical vortex models and 3-D Large Eddy Simulation numerical model outputs for different aircraft vortex, lidar and environment conditions. This study shows that the mean biases for the lidar measurements for vortex positions are small, about 4-7m for the lateral position and 1-3m for the vertical position.

Lai, J. Y.

"WAKE VORTEX VELOCITY TRACKING VIA KALMAN FILTERING"

Radar Systems Laboratory Electrical and Computer Engineering Technical Memorandum, May 1996, Clemson Univ., Clemson, SC

Current wake vortex detection methods basically involve the segmentation of the lidar return signal into partially overlapped data blocks and the wind speed estimation for individual data block using FFT or AR modeling. However, these methods can be very computationally involved, depending on the

dimension of the data vectors. The purpose of this memo is to introduce a computationally efficient way of tracking the line-of-sight velocity of a wake vortex pair. The idea is to model the pulsed lidar return signal from vortices as a dynamic (time-varying) second order AR process and to estimate the AR parameters via Kalman filtering. The data used in this memo are generated by RTI's simulation package which incorporates the AIAA standards model for vortex.

Laitone, E. V.

"LIFT-CURVE SLOPE FOR FINITE-ASPECT-RATIO WINGS"

Journal of Aircraft, Vol. 26, No. 8, August 1989, pp. 789-790.

Recently derived exact solutions for the lift produced by an elliptic planform flat plate in steady incompressible potential flow are applied to improve the commonly used approximations for the lift curve slope of finite aspect-ratio wings. An excellent approximation is derived for the initial lift-curve slope when the aspect ratio less than or equal to 2. For large aspect ratios, the lift-curve-slope equation is improved so that it can more accurately calculate the corresponding two-dimensional lift-curve slope from the wind tunnel test data of a finite-aspect-ratio wing.

Lake, H.

"AIRCRAFT WAKE VORTEX BEHAVIOR STUDY, METEOROLOGY AND AIRCRAFT VORTEX TRANSPORT AND DECAY"

ER-73-4299, July 1973, Raytheon Company, Sudbury, MA

This report identifies and defines the meteorological parameters that have been observed to affect the behavior of aircraft generated vortices. The most commonly observed effect (observed with smoke entrainment) was the drift of vortices with the mean wind. More recently other meteorological parameters have been identified as affecting the manner and rate at which vortices behave.

"DETAILED COMPUTATIONAL INVESTIGATION OF A HOVERING MICROSCALE ROTOR IN GROUND EFFECT"

AIAA Journal, Vol. 51, No. 4, April 2013, pp. 893-909.

A compressible, structured, overset Reynolds-averaged Navier-Stokes-based solver is used to simulate a micro=hovering rotor in ground effect to demonstrate the capability of the code to provide accurate tip-vortex-flowfield predictions, and to provide a good understanding of the ground-wake interaction in conditions prevalent in helicopter brownout. The performance validation at different rotor heights above the ground shows good correlation with the experimental thrust and power measurements. A detailed comparison of the predicted tip-vortex flowfield shows good agreement with the vorticity contours and radial-velocity profiles obtained from the particle-image-velocimetry measurements

during experiments. The examination of the in-ground effect tip-vortex flowfield suggests high degree of instabilities close to the ground. The induced velocities arising from the proximity of the rotor tip vortices cause flow separation at the ground. An analysis of the eddy-viscosity contours near the ground indicates higher turbulence levels in the flowfield at smaller rotor heights above the ground. With a decreasing rotor height, the increased interactions between the tip vortices and the ground boundary layer result in the intermixing of eddy viscosity from the tip vortex to the ground boundary layer.

Lakshminarayan, V., Sitaraman, J. and Wissink, A.

"APPLICATION OF STRAND GRID FRAMEWORK TO COMPLEX ROTORCRAFT SIMULATIONS"

AIAA Paper 2016-3130, June 2016, Washington, DC.

The strand grid approach is a flow solution method where a prismatic-like grid using 'strands' is grown to a short distance from the body surface to capture the viscous boundary layer and the rest of the domain is covered using an adaptive Cartesian grid. The approach offers several advantages in terms of nearly automatic grid generation and adaptation, ability to implement fast and efficient flow solvers that use structured data in both the strand and Cartesian grids, and the development of an efficient and highly scalable domain connectivity algorithm. An earlier work by the authors introduced a strand grid solver called mStrand, which will appear in future versions of the HPCMP CREATE(TM)-AV Helios framework. This paper presents application of mStrand/Helios grid framework for complex rotorcraft problems. The test cases presented are the UH-60A high speed forward flight and high-altitude stall problems as well as the HART II blade-vortex interaction problem. The results show that the solution obtained using the strand grid framework is as good as that obtained using well-established structured and unstructured solution methodologies.

Lamar, J.

"A CAREER IN VORTICES AND EDGE FORCES"

The Aeronautical Journal, Vol. 116, No. 1176, February 2012, pp. 101-152.

This lecture recognizes the background and distinguished work of Frederick William Lanchester, and notes that my background has a few similarities with his. These include a shared interest in wings, lift and vortices. My career at the NASA Langley Research Center spans the time-frame from America's Super Sonic Transport through 2009. An early emphasis involved wind-tunnel testing of research aircraft models and the development of computer codes for subsonic aerodynamics of wing planforms. These attached-flow codes were applied to various configurations, including those with variable-sweep, dihedral, and more than one planform in both the analysis- and design-modes. These codes were used to provide a connection between leading-edge forces and the associated additional lift on delta-wings with shed-vortex systems through the leading-edge suction analogy of Edward C. Polhamus. Subsequently, I extended the suction analogy to configurations with side-edges to predict the vortical-flow aerodynamics on complex configurations, including wing-strake combinations. These analysis

codes could also be used in a design-by-analysis mode for configurations with leading-edge shed vortices. Later, I was involved in vortical-flow flight research with the F-106B and the F-16XL aircraft at cruise and maneuver conditions. Associated CFD predictions, generated by me and other members of the RTO/AVT-113 task group, have increased our understanding of the flight flow-physics measured on the F-16XL aircraft.

Lamar, J. E.

"PREDICTION OF VORTEX FLOW CHARACTERISTICS OF WINGS AT SUBSONIC AND SUPERSONIC SPEEDS"

Journal of Aircraft, Vol. 13, No. 7, July 1976, pp. 490-494

The leading-edge suction analogy of Polhamus, which has been successful in the prediction of vortex lift characteristics on wings with pointed tips at subsonic and supersonic speeds, has recently been extended to account for the vortex flow characteristics for wings with side edges. Comparisons of experimental data and other currently used methods with the extended method are made for wings having side edges at subsonic and supersonic speeds. Recent data obtained for a low-aspect-ratio cropped-delta wing with various amounts of asymmetrical tip rake, simulating a roll control device, are also presented.

Lamar, J. E.

"A VORTEX-LATTICE METHOD FOR THE MEAN CAMBER SHAPES OF TRIMMED NONCOPLANAR PLANFORMS WITH MINIMUM VORTEX DRAG"

NASA TN D-8090, June 1976, NASA Langley Research Center, Hampton, VA.

A new subsonic method has been developed by which the mean camber surface can be determined for trimmed noncoplanar planforms with minimum vortex drag. This method uses a vortex lattice and overcomes previous difficulties with chord loading specification. This method uses a Trefftz plane analysis to determine the optimum span loading for minimum drag, then solves for the mean camber surface of the wing, which will provide the required loading. Sensitivity studies, comparisons with other theories, and applications to configurations which include a tandem wing and a wing-winglet combination have been made and are presented.

Lamarre, F. and Paraschivoiu, I.

"EFFICIENT PANEL METHOD FOR VORTEX SHEET ROLL-UP"

Journal of Aircraft, Vol. 29, No. 1, January-February 1992, pp. 28-33

In order to improve the accuracy of a potential flow three-dimensional wing panel method, wake deformation must be considered. This leads to a better knowledge of the large-scale flow behavior. In this paper, a computational method modeling the vortex sheet behind a wing is presented. The sheet deformation is computed using a two-dimensional unsteady analogy in the crossflow plane. The local

velocities are induced by linear vorticity panels with smoothed velocity fields. The sheet is re-discretized at each time step with an adaptive curvature-dependent paneling scheme. The vortex sheet model produces good results for the typical cases of elliptic loading, wing/flap configuration, and ring wing. Coupling of the wake model with a three-dimensional wing panel method gives wake geometries that compare well with those obtained with other codes.

Lambourne, N. C.

"THE BREAKDOWN OF CERTAIN TYPES OF VORTEX"

ARC-C-915, September 1965, Aeronautical Research Council, London, England. (Also, NPL-AERO-1166 and ARC-27200.)

Two observed forms of vortex breakdown are compared and experimental evidence is presented to suggest that the spiral form is a derivative of the axisymmetric form. Theoretical examination of the effect of an imposed adverse pressure gradient on a vortex core shows that drastic changes of flow structure must occur when certain critical conditions are exceeded. The theoretical predictions are to some extent consistent with the observed breakdown.

Lambourne, N. C. and Bryer, D. W.

"THE BURSTING OF LEADING-EDGE VORTICES - SOME OBSERVATIONS AND DISCUSSIONS OF THE PHENOMENON"

ARC-22775, April 1961, Nat. Phys. Lab., Great Britain. (Also, ARC R&M-3282.)

Bursting refers to the abrupt structural change from a regular spiral motion to a weaker turbulent motion which can occur at some position along a vortex generated by a sweptback leading edge of a wing. The phenomenon is examined by flow visualization, its sensitivity to several factors is investigated and the reasons for its occurrence are discussed. The burst is found to be sensitive to several factors, in particular, an increase of pressure gradient along the vortex seems conducive to the occurrence of a burst. It is suggested that a condition essential for the burst to occur is a low total pressure within the vortex core coupled with an adverse pressure gradient along the axis.

Lampe, T., Sedin, Y. and Weinerfelt, P.

"FLIGHT TEST VERIFICATION OF A WAKE VORTICES MODEL"

RTO-MP-SCI-162, 2005, Paper 4. Neuilly-sur-Seine, France

A simulation model for encounters of wake vortices has been developed at Saab in Linköping, Sweden. Distribution of incremental forces on the aircraft surfaces is calculated for different locations related to the vortices and also for different relative attitudes of the aircraft. Also, the response of the angle-of-attack and angle-of-sideslip vanes is calculated. For simulation, multidimensional tables are created describing the increments in forces, moments and vane angles as function of relative position and attitude. The model, represented by table lookup algorithms for these particular tables as well as some

scaling algorithms, was in the year 2000 added to an experimental version of a 6-DOF Gripen simulator. The results seemed promising because the response of the aircraft flying through the vortices was, seen from a pilot's view, realistic. However, it was evident that the model also needed to be verified with and, most likely, adjusted (scaled) to flight test data. The need for accurate estimates of the aircraft's trajectory through the vortices requires special attention. Regardless of the ability to accomplish that accuracy in relative position between two aircraft, we still have to determine, also very accurately, where the vortices are, regarding cores and size. Local wind fluctuations and the self-induced motion of the vortices away from the flight path contribute with uncertainties in the range of a couple of meters. From that standpoint, we have too large uncertainties. Our best solution so far is to use a closed-loop verification of the model where we use a subset of the output parameters to identify a two-dimensional position bias that gives us the most likely trajectory. We use the angle-of-attack and angle-of-sideslip vane signals for that purpose. The result is not only a method for verification of a trailing vortex simulation model but also a tool to map out in detail where we have been in wake vortex penetration tests. With respect to the simplifying assumptions used in the design of the current model, the agreement with flight test data is surprisingly good.

"EXPERIMENTAL AND NUMERICAL ANALYSIS OF A STREAMWISE VORTEX DOWNSTREAM OF A DELTA WING"

AIAA Journal, Vol. 58, No. 7, July 2020, pp. 2857-2868.

The present paper analyzes the vortical flow downstream of a delta wing. The delta wing is designed to generate a vortex that resembles the vortex of a nacelle strake. The experimental results of stereoscopic particle image velocimetry measurements performed at different positions downstream of the delta wing display the streamwise development of the vortex. Details of the postprocessing of the measurement data and a quantification of the uncertainties are presented. The evaluation of the mean axial and tangential velocity components and Reynolds stresses provides insights to the vortex characteristics and their development in the streamwise direction. In addition, results of numerical simulations with the DLR TAU-code applying the Menter-Shear Stress Transport (SST) eddy viscosity model and the Speziale-Sarkar-Gatski/Launder-Reece-Rodi (SSG/LRR)-Omega Reynolds stress model show the ability of the turbulence models to capture the vortex development. The experimental results indicate a preservation of the vortex strength and structure downstream of the delta wing. The Menter-SST model does not predict this preservation; rather it computes a rapid decay of vortex strength and an increase in vortex size. In contrast, the results of the SSG/LRR-Omega model are in good agreement with the experiments concerning the mean flow development. However, both turbulence models underpredict the turbulence in the vortex core.

Landa, T., Klug, L., Radespiel, R., Probst, S. and Knopp, T.

"EXPERIMENTAL AND NUMERICAL ANALYSIS OF A STREAMWISE VORTEX DOWNSTREAM OF A DELTA WING"

AIAA Paper 2018-4157, June 2018, Atlanta, GA.

The present paper analyzes the vortical flow downstream of a delta wing. The delta wing is designed to generate a vortex which resembles the vortex of a nacelle strake. The experimental results of stereo-PIV measurements performed at different positions downstream of the delta wing display the streamwise development of the vortex. The distributions of the mean axial and tangential velocity components and Reynold-stresses characterize the vortex development. In addition, results of numerical simulations with the DLR TAU-code applying the Menter-SST eddy viscosity model and the SSG/LRR-w Reynolds-Stress model show the ability of the turbulence models to capture the vortex development. The experimental results indicate a preservation of the vortex strength and structure downstream of the delta wing. The Menter-SST model does not predict this preservation, rather it computes a rapid decay of the vortex strength and an increase of the vortex size. In contrast, the results of the SSG/LRR-w model are in good agreement with the experiments concerning the mean flow development. However, turbulence in the vortex core is underpredicted by both turbulence models.

"VORTEX CONTROL"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 137-155

The fluid dynamical aspects of the control of free vortices emanating from the wing or other parts of a flight vehicle are reviewed. Simple calculations based on slender-body theory are used to demonstrate the importance of controlling the strength, position and core stability and thickness of such vortices. From the equations describing vortex motion, conclusions are drawn as to how vortex properties can be influenced. Simple energy arguments are used to clarify the phenomenon of vortex bursting and to draw conclusions as to what can be done to prevent or induce bursting.

Landgrebe, A. J.

"AN ANALYTICAL METHOD FOR PREDICTING ROTOR WAKE GEOMETRY"

AIAA Paper 1969-196, February 1969, Atlanta, GA.

An analytical method for predicting the distorted geometry of a helicopter rotor wake is described. The development of this method is ultimately directed toward proving a more accurate aerodynamic theory for computing the instantaneous rotor flow field and associated blade airloads. It is shown that: (1) realistic self-induced distortions of a rotor wake represented by numerous discrete vortex elements can be computed by application of the classical Biot-Savart law and numerical integration techniques and (2) by dividing the wake into a series of near and far wake regions, the computation requirements which have previously prohibited the use of such an analysis as a cost-effective engineering tool can be appreciably reduced. Sample comparisons of analytical and experimental wake geometries of a rotor in forward flight are presented and indicate the ability of the analysis to predict the characteristic distortion features of the wake.

Landgrebe, A. J.

"NEW DIRECTIONS IN ROTORCRAFT COMPUTATIONAL AERODYNAMICS RESEARCH IN THE U.S."

Aerodynamics and Aeroacoustics of Rotorcraft, AGARD-CP-552, August 1995, pp. 1-1 to 21-12.

Recent research activities in the United States are presented that are representative of the directions of research for computational aerodynamics for rotorcraft. Emphasis is given to Navier-Stokes methodology for airflow and airload prediction, and specifically the fundamental technical challenges associated with grid systems and achieving wake generation without numerical diffusion. Although the current rotorcraft CFD methods have not yet generally demonstrated sufficient accuracy for the helicopter industry, the recent rate of progress is encouraging.

Landgrebe, A. J.

"AN ANALYTICAL METHOD FOR PREDICTING ROTOR WAKE GEOMETRY"

J. Am. Helicopter Society, Vol. 14, No. 4, October 1968, pp. 20-32.

An analytical method for predicting the distorted geometry of a helicopter rotor wake is described. The development of this method is ultimately directed toward proving a more accurate aerodynamic theory for computing the instantaneous rotor flow field and associated blade airloads. It is shown that: (1) realistic self-induced distortions of a rotor wake represented by numerous discrete vortex elements can be computed by application of the classical Biot-Savart law and numerical integration techniques and (2) by dividing the wake into a series of near and far wake regions, the computation requirements which have previously prohibited the use of such an analysis as a cost-effective engineering tool can be appreciably reduced. Sample comparisons of analytical and experimental wake geometries of a rotor in forward flight are presented and indicate the ability of the analysis to predict the characteristic distortion features of the wake.

"THE WAKE GEOMETRY OF A HOVERING HELICOPTER ROTOR AND ITS INFLUENCE ON ROTOR PERFORMANCE"

28th Annual Forum, American Helicopter Association, Washington, DC, May 1972

Systematic model rotor performance and wake geometry data were acquired to evaluate the influence of wake geometry on rotor hover performance. Analysis of the wake data resulted in (1) the development of a simple generalized representation of the near wake which facilitates the rapid estimation of realistic wake geometries for a wide range of rotor designs and operating conditions and (2) the discovery of a reduction in wake stability with increasing distance from the rotor. The results of a theoretical method for predicting the wake geometry are also presented. Results of a prescribed wake analysis for predicting rotor hovering performance show that the incorporation of a realistic wake

geometry provides significantly improved predictions of rotor performance characteristics. Finally, initial results of advanced experimental techniques for determining rotor wake characteristics are presented along with a brief discussion of other current efforts at UARL pertaining to rotor wake geometry and performance.

Landgrebe, A. J.

"AN ANALYTICAL AND EXPERIMENTAL INVESTIGATION OF HELICOPTER ROTOR HOVER PERFORMANCE AND WAKE GEOMETRY CHARACTERISTICS"

Report 0538827, June 1971, United Aircraft Research Labs., East Hartford, CT.

An analytical and experimental investigation was conducted to acquire systematic model rotor performance and wake geometry data and to evaluate the accuracy of various analytical methods in predicting the effects on performance of changes in helicopter rotor design and operating parameters. Both classical hover performance analyses and analytical methods recently developed at the United Aircraft Research Laboratories were evaluated. Of primary concern in the study was the assessment of assumptions in the analyses regarding the geometry of the rotor wake. Of particular interest was the prediction by the analyses of an instability of the tip vortex helix at moderate distances from the rotor which appeared to be substantiated by available experimental results.

Landgrebe, A. J. and Bellinger, E. D.

"AN INVESTIGATION OF THE QUANTITATIVE APPLICABILITY OF MODEL HELICOPTER ROTOR WAKE PATTERNS OBTAINED FROM A WATER TUNNEL"

USAAMRDL Tech Report 71-69, Dec. 1971, United Aircraft Corp. Research Laboratories, East Hartford, CT.

An analytical investigation was conducted to evaluate quantitative applications of available model rotor tip vortex patterns from a water tunnel. This evaluation consisted of reducing selected photographic wake data to coordinate form, and comparing the resulting wake geometries with both theoretical results and available experimental data taken in air. Additionally, the study included an examination of the sensitivity of water tunnel wake geometry to the water tunnel test parameters which did not duplicate full-scale rotor values and the applicability of a water tunnel wake geometry to determine the airloads of a full-scale rotor. Finally, the possibility of developing simplified wake documentation and generalization procedures and improved water tunnel test techniques was assessed.

"ROTOR WAKES -- KEY TO PERFORMANCE PREDICTION"

Symposium on Status of Testing and Modeling Techniques for V/STOL Aircraft, Mideast Region of the American Helicopter Society, October 1972, Easington, PA.

The history of helicopter performance prediction methods and the influence of rotor wakes are traced from the simple momentum techniques used in the early years of propellers and rotors to the current state-of-the-art computer programs simulating the rotor's complex vortex structure. Early methods became inadequate as disc loadings increased and wake effects became increasingly important, particularly for hovering and low forward speed conditions where the tip vortex could induce stall at critical points on the blades. Analytical and experimental techniques are described which define the geometry of the vortex field of a hovering rotor and its effect on rotor performance. It was concluded that the most important factor which influences the prediction of hover performance was the interference caused by the tip vortex during its first revolution. Integrated performance in forward flight was generally not sensitive to variable inflow; however, when combined with unsteady airfoil data, variable inflow produced significant effects on blade torsional responses.

"ROTORCRAFT WAKE ANALYSIS FOR THE PREDICTION OF INDUCED VELOCITIES"

USAAMRDL-TR-75-45, January 1976, United Technologies Research Center, East Hartford, CT

A rotorcraft wake analysis for computing flow velocities induced by the rotors and wing of a helicopter is described, and predicted induced velocities are compared with experimental data from many sources. Combined in a single computerized analysis are the capabilities for calculating three components of time-averaged and instantaneous induced velocities on or off the rotor(s) of single-rotor, dual-rotor, and winged helicopter configurations, in hovering and forward flight.

"HELICOPTER AIRFLOW AND WAKE CHARACTERISTICS FOR LOW SPEED AND HOVERING FLIGHT FROM ROCKET INTERFERENCE INVESTIGATIONS"

37th Annual Forum, American Helicopter Society, New Orleans, LA, May 1981

With the development of laser velocimetry, specialized flow visualization techniques, and analytical wake methods, measurement and prediction of detailed helicopter airflow and wake characteristics have become feasible. This was demonstrated in a series of experimental and analytical research programs directed toward the investigation of the airflow at selected rocket trajectory, wind sensor, and rotor wake locations of a model helicopter simulating hover and low speed flight conditions. Considering the current increased interest in low speed, low level flying, results of these investigations are presented to provide insight into the airflow and wake characteristics associated with hover and low speed flight near and away from the ground. It is the intent of this paper to present demonstrations of the advanced experimental and analytical techniques employed, and to provide selective rotor wake and airflow velocity information, to contribute to the understanding of the aerodynamics of low-speed helicopter flight. Laser velocimeter and flow visualization data are

presented and compared with theory to provide indications of the influence of airspeed, flight direction, fuselage presence, thrust level, ground effect, and blade-vortex interaction on rotor airflow velocities and wake geometry. The blade-vortex interaction data present significant implications for helicopter low speed performance, vibrations, aerodynamic interference, and noise.

Landgrebe, A. J., Taylor, R. B., Egolf, T. A. and Bennett, J. C.

"HELICOPTER AIRFLOW AND WAKE CHARACTERISTICS FOR LOW SPEED AND HOVERING FLIGHT"

J. American Helicopter Society, Vol. 27, No. 4, October 1982, pp. 74-83

With the development of laser velocimetry, specialized flow visualization techniques, and analytical wake methods, measurement and prediction of detailed helicopter airflow and wake characteristics have become feasible. This was demonstrated in a series of experimental and analytical research programs directed toward the investigation of the airflow at selected rocket trajectory, wind sensor, and rotor wake locations of a model helicopter simulating hover and low speed flight conditions. Results of these investigations are presented to provide insight into the airflow and wake characteristics associated with hover and low speed flight near and away from the ground. Laser velocimeter and flow visualization data are presented and compared with theory to provide indication of the influence of airspeeds, flight direction, fuselage presence, thrust level, ground effect, and blade-vortex interaction on rotor airflow velocities and wake geometry and to demonstrate theory-test correlation.

"THE THREE-DIMENSIONAL INSTABILITY OF STRAINED VORTICES IN A VISCOUS FLUID"

Physics of Fluids, Vol. 30, No. 8, August 1987, pp. 2339-2342.

The recent theory describing 3-D exact solutions of the Navier-Stokes equations is applied to the problem of stability of 2-D viscous flow with elliptical streamlines. An intrinsically inviscid instability mechanism persists in all such flows provided the length scale of the disturbance is sufficiently large. Evidence is presented that this mechanism may be responsible for 3-D instabilities in high Reynolds number flows whose vortex structures can be locally described by elliptical streamlines.

Landry, S. J. and Jacko, J.

"PILOT PROCEDURE-FOLLOWING BEHAVIOR DURING CLOSELY SPACED PARALLEL APPROACHES"

International Journal of Human-Computer Interaction, Vol. 28, No. 2, 2012, pp. 131-139.

A flight simulator experiment was run to examine pilot procedure-following behavior during closely spaced parallel approaches. Such approaches are being considered under the Next Generation Air Transportation System (NextGen) to increase the capacity of runway systems, possibly without the need to increase the footprint of airports. Pilots flying these approaches utilized a simple heuristic to fly the procedure consistently, despite the heuristic being suboptimal for any of the three conditions.

Moreover, procedure compliance was relatively low, but noncompliance itself was not unsafe unless accompanied by situation awareness problems. In some cases, noncompliance could be shown to be a better choice than compliance. These results have implications for assumptions regarding procedure-following by pilots utilizing novel procedures in NextGen.

Landry, S. J. and Lynam, A.

"SAFE ZONE FOR CLOSELY SPACED PARALLEL APPROACHES"

Journal of Guidance, Control, and Dynamics, Vol. 34, No. 2, March-April 2011, pp. 608-613.

A safe zone can be computed that provides protection against blunders for a predetermined period of time. This safe zone has a reasonable width under most conditions, and adhering to the safe zone should improve capacity over current methods for closely spaced parallel approaches. The safe zone is influenced by the time needed for responding to an alert, the speed difference between two aircraft, the lateral separation between the paths of the aircraft, and the crosswind speed. Greater speed differences, larger speed differences, and wider lateral separations result in more distant in-trail separations. Higher crosswind speeds reduce the width of the safe zone. A practical safe zone exists up to approximately 40 kt different in speed and 40 kt crosswind for runways, down to 750 ft lateral separation. Implementing the safe zone, while reducing capacity when compared with independent operations, has a significant improvement over current operations. The guidance can be applied to current visual approaches, without the addition of any instrumentation, to improve the safety of those approaches without substantially impacting capacity. If a depiction is provided on a primary or secondary flight instrument, the safe zone may allow for closely spaced parallel approaches in instrument conditions to runways down to 750 ft lateral separation.

Landry, S. J. and Pritchett, A. R.

"INCORPORATING PROCEDURAL INFORMATION IN A PAIRED APPROACH PAIR"

Proceedings of the Human Factors and Ergonomics Society, 46th Annual Meeting, October 2002, Baltimore, MD, pp. 106-110.

This study focused on pilot performance at simultaneously flying simulated instrument approaches and self-separating from an aircraft on approach to a closely spaced parallel runway. The participant pilots flew approaches on Georgia Tech's Reconfigurable Flight Simulator and were instructed to remain within the 'safe zone' -- an area in which the subject aircraft was safe from collision danger and wake vortices from the other aircraft -- as depicted on their navigation display. Two underlying bases for calculating the safe zone were used: a 'predicted' safe zone utilizing procedural information, and an 'actual' safe zone utilizing real-time information. No display effects were found for pilot performance or behavior, despite the very different implications of the two safe zone depictions. Also, pilots monitored the other aircraft closely for compliance, but could not recognize the implications of noncompliance for their own approach. This suggests that pilots have a particular, persistent, and perhaps poor, strategy for this task.

"AN ASSESSMENT OF A THREE-BEAM DOPPLER LIDAR WIND PROFILING METHOD FOR USE IN URBAN AREAS"

Journal of Wind Engineering and Industrial Aerodynamics, Vol. 119, 2013, pp. 53-59.

Currently there are few observations of the urban wind field at heights other than rooftop level. Remote sensing instruments such as Doppler lidars provide wind speed data at many heights, which would be useful in determining wind loadings of tall buildings, and predicting local air quality. Studies comparing remote sensing with traditional anemometers carried out in flat, homogeneous terrain often use scan patterns which take several minutes. In an urban context the flow changes quickly in space and time, so faster scans are required to assure little change in the flow over the scan period. We compare 3993 h of wind speed data collected using a three-beam Doppler lidar wind profiling method with data from a sonic anemometer (190 m). Both instruments are located in central London, UK; a highly built-up area. Based on wind profile measurements every 2 min, the uncertainty in the hourly mean wind speed due to the sampling frequency is 0.05-0.11 m/s. The lidar tended to overestimate the wind speed by about 0.5 m/s for wind speeds below 20 m/s. Accuracy may be improved by increasing the scanning frequency of the lidar. This method is considered suitable for use in urban areas.

"DETECTION OF AIRCRAFT EXHAUST IN HYPERSPECTRAL IMAGE DATA"

Proceedings SPIE, Vol. 8158, Imaging Spectrometry XVI, September 2011, pp. 815800-1 - 815800-8.

The use of a hyperspectral imaging system for the detection of gases has been investigated, and algorithms have been developed for various applications. Of particular interest here is the ability to use these algorithms in the detection of the wake disturbances trailing an aircraft. A dataset of long wave infrared (LWIR) hyperspectral datacubes taken with a Telops Hyper-Cam at Hartsfield-Jackson International Airport in Atlanta, Georgia is investigated. The methodology presented here assumes that the aircraft engine exhaust gases will become entrained in wake vortices that develop; therefore, if the exhaust can be detected upon exiting the engines, it can be followed through subsequent datacubes until the vortex disturbance is detected. Gases known to exist in aircraft exhaust are modeled, and the Adaptive Coherence/Cosine Estimator (ACE) is used to search for these gases. Although wake vortices have not been found in the data, an unknown disturbance following the passage of the aircraft has been discovered.

Lane, T.

"PROCESSES UNDERLYING NEAR-CLOUD TURBULENCE"

In *Aviation Turbulence*, edited by R. Sharman and T. Lane, Chapter 16, 2016, Springer International Publishing Switzerland, pp. 317-334.

Thunderstorms generate turbulence both within cloudy air and in the clear air surrounding them. Both in-cloud and out-of-cloud turbulence are an aviation hazard, and the latter can pose a risk of unexpected encounters because it is invisible and is unable to be detected using standard on-board radar technology. In recent years there has been a significant improvement in the understanding of out-of-cloud turbulence generation mechanisms, including identifying the importance of breaking atmospheric gravity waves. In this chapter, numerical modelling studies are used to explain the processes leading to turbulence outside of cloud, including near the cloud boundary and above storms. Turbulence near the cloud boundary is explained by local instabilities associated with storm-induced wind shear. Turbulence further aloft is related to gravity wave breaking that is well explained by linear theory. Very high-resolution simulations are also used to quantify the intensity of turbulence and how it varies spatially. These simulations demonstrate that, although the main convective regions of storms possess the most intense turbulence, notable regions of turbulence can extend significant distances vertically and horizontally from the cloud boundary.

Lang, S.

"STL DATA COLLECTION CAMPAIGN - STATUS AND ANALYSIS PLANS"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

The FAA and NAS are jointly investigating wake turbulence avoidance strategies for eventual implementation into the National Airspace System (NAS). They have jointly developed a phased approach to increase airport capacity through safe reduction of existing wake turbulence constraints. The objective of the first phase of the program is the development of procedural wake avoidance solutions for CFSR airports and is led by the FAA. The objective of the second phase of the program is the development of wind-dependent procedures for wake avoidance that include wind prediction algorithms and simple controller tools to support decision making. This phase also targets CFSR airports and is led jointly by the FAA and NASA. The objective of the third phase of the program is the development of active wake avoidance solutions including technologies for wake prediction and monitoring and is led by NASA. In the first phase of the program, the FAA is seeking to make a near-term change to the 2500-foot rule for CFSR arrivals to define a lesser runways centerline separation minimum for avoidance of wakes generated by Small-and-Large aircraft. The objective is to permit today's dependent (1.5 NM diagonal separation) CFSR approach procedures between Large-and-Small aircraft and for any type aircraft trailing a Large or Small leading aircraft on the parallel runway. The first data collection and analysis campaign for this effort is being conducted at STL. This campaign is designed to support the safety assessments to be conducted by the FAA's Flight Standards organization in support of the procedure change.

"PROGRESS ON JOINT FAA/EUROCONTROL EFFORT TO DEVELOP AN ICAO WAKE TURBULENCE RE-CATEGORIZATION"

8th USA/EUROPE Air Traffic Management Research & Development Seminar, June/July 2009, Napa, CA.

Planned improvements in Air Traffic Management, as described by NextGen in the US and SESAR in Europe, have a common goal of enhancing capacity and harmonizing separation standards. Wake vortices are a product of lift from aircraft and are one of the major constraints in the reduction of separation standards that are one of the solution avenues that NextGen and SESAR are pursuing in the goal for increased capacity. The existing separation standards based on wake turbulence are significantly different between the US and ICAO. Furthermore, both the ICAO and US categories, and associated separation minima among the categories, represent two very safe systems but are optimized for fleet mixes that existed 15 or more years ago. As an example, the last re-categorization effort in the US was performed in 1994. Better knowledge of wake behavior obtained through research and improved sensors that measure wake turbulence provide an opportunity to develop a new set of common categories that provide the same or increased safety over the existing US and ICAO categories while optimizing for current and future traffic demands in the US and Europe. This paper describes a joint FAA/EUROCONTROL methodology for developing and evaluating new candidate wake turbulence categories. The paper provides examples and rough estimates of capacity gains that some examples show over today's US and ICAO categories. Finally, the paper highlights the key steps yet to be completed in achieving a joint recommendation to ICAO in 2010.

Lang, S., Domino, D. A., Mundra, A. and Bodoh, C.

"ATC FEASIBILITY OF POTENTIAL NEAR-TERM WAKE TURBULENCE PROCEDURES"

23rd Digital Avionics Systems Conference, Vol. 1, Oct. 2004, pp. 5.B.4-1-5.B.4-15

This paper documents the results of controller (human-in-the-loop, HITL) simulations to evaluate a proposed change of standards involving the wake turbulence separation required for closely spaced parallel runways with center line separation less than 2500 feet. Under current rules, dependent, diagonal separation between arrivals on adjacent parallel runways can be used when runway center line separation is at least 2500 ft. The Federal Aviation Administration is investigating the reduction of this required minimum runway separation value to 1000 ft. when the leading airplane is in the Large-or-Small weight category. If the lead aircraft is a B-757 or Heavy then standard wake turbulence separation would apply. This change would enable continued operation of dual arrival streams in instrument conditions, increasing airport capacity and reducing delay. Real time simulations were conducted with controllers from a busy U.S. ATC facility to determine if such a change in standard would be acceptable and feasible. Both approach control and tower control positions were simulated. Results indicate that ATC operations with the proposed new standards were feasible, controller workload was acceptable as measured in the simulation environment, and that significant capacity benefits may be achieved both for arrivals and departures in instrument meteorological conditions (IMC) for such runway geometries. The paper includes a discussion of the procedures and strategies developed by the controllers in implementing the proposed change in standards, and presents results regarding controller workload, achieved arrival and departure rates, and various spacing values of

interest on final approach relevant to a safety analysis of the procedure. The paper also suggests some steps that may help develop authorization of such a procedure.

"A PHASED APPROACH TO INCREASE AIRPORT CAPACITY THROUGH SAFE REDUCTION OF EXISTING WAKE TURBULENCE CONSTRAINTS"

Air Traffic Control Quarterly, Vol. 11, No. 4, 2003, pp. 331-356

Previous wake turbulence research has suggested that using knowledge of wake turbulence behavior to develop candidate arrival and departure procedures would increase capacity at a variety of US airports. This paper outlines the operational issues involved as well as the process through which the Federal Aviation Administration (FAA) and The MITRE Corporation's Center for Advanced Aviation System Development analyzed an evolving set of candidate procedures. This work is part of the broader effort to implement an FAA/National Aeronautics and Space Administration Wake Turbulence Research Management Plan. We describe in detail two candidate procedures, their operational variations, and the expected capacity benefits at selected airports. The first procedure is a near-term proposed change to the 2500-foot runway centerline separation minimum for dependent approaches to two closely spaced parallel runways. When visual separation cannot be provided, the current FAA rule requires parallel runways spaced less than 2500 ft. to be treated as a single runway. While in-trail wake separation standards are dependent on wake categories of the generating and encountering aircraft, this rule is not. This paper shows that, by refining this standard to reflect the wake generation differences of different weight classes, substantial capacity benefits may be possible. Variations on this procedure are analyzed to explore the sensitivity of the capacity benefits to the underlying assumptions. The second procedure is a mid-term proposed change to reduce wake constraints for departures from parallel runways spaced closer than 2500 ft. using a short-term prognosis of crosswinds at and near the area of aircraft rotation. A brief outline is provided of activities planned during 2004 to advance towards the specific design and implementation of these procedures. One such activity is additional wake data collection at St. Louis.

"A PHASED APPROACH TO INCREASE AIRPORT CAPACITY THROUGH SAFE REDUCTION OF EXISTING WAKE TURBULENCE CONSTRAINTS"

Fifth EUROCONTROL/FAA ATM R&D Seminar, June 2003, Budapest, Hungary

This paper outlines the operational issues involved in using knowledge of wake turbulence behavior to develop candidate terminal approach procedures that would increase arrival capacity at a variety of United States airports. Later procedures build incrementally on the experience that would be gained with these initial procedures. The process by which the Federal Aviation Administration (FAA) and The Mitre Corporation's Center for Advanced Aviation System Development (MITRE/CAASD) have been analyzing these candidate procedures will be discussed. This process is part of the broader effort to

implement an FAA/National Aeronautics and Space Administration (NASA) Wake Turbulence Research Management Plan (RMP). Two candidate procedures, and their operational variations, are described in detail, along with expected capacity benefits at selected airports. The analysis methodology is described. The first procedure is a near-term proposed change to the 2500-foot separation minimum for dependent approaches to two parallel runways. The second procedure is a mid-term proposed change to reduce wake constraints for departures from parallel runways spaced closer than 2500 feet using a short-term prognosis of crosswinds at and near the area of aircraft rotation. Activities, such as additional wake data collection at a field site, that are planned during the current year to advance towards the specific design and implementation of the procedures are also briefly outlined.

"AN ANALYSIS OF POTENTIAL CAPACITY ENHANCEMENTS THROUGH WIND DEPENDENT WAKE TURBULENCE PROCEDURES"

6th USA/Europe Air Traffic Management Research and Development Seminar, June 2005, Baltimore, MD.

The Federal Aviation Administration (FAA) and National Aeronautics and Space Administration (NASA) are jointly embarking on a multi-phased research and development program to develop and implement wake avoidance solutions that can safely reduce separations and improve capacity at airports in the National Airspace System (NAS). The mid-term phase of the research focuses on the potential application of wind-dependent procedures for improved departure operations from Closely Spaced Parallel Runways (CSPR) in the U.S. This paper describes the research performed to date by a few members of the larger research team, including the FAA, Lambert St. Louis International Airport operational staff, MIT Lincoln Laboratory and MITRE Center for Advanced Aviation System Development (CAASD). It describes the operational concept, the wind prediction algorithms being developed to support this concept, and an analysis of expected algorithm performance. In addition, this paper addresses the information requirements for a decision support tool to support this procedure and the potential benefits that may be realized by this procedure at several CSPR airports in a weather and traffic demand environment. NASA is in early stages of extending this wind-dependent solution for other operations such as single runway departures. The paper also describes the thrust of these evolutionary concepts and the directions of research.

"PROGRESS ON AN ICAO WAKE TURBULENCE RE-CATEGORIZATION EFFORT"

AIAA Paper No. 2010-7682, August 2010, Toronto, Canada.

This paper describes progress on an ICAO tasking to the FAA and Eurocontrol to lead an effort to harmonize wake turbulence separation standards for existing and new aircraft and to safely increase capacity. The first phase of the re-categorization effort looked at placing the existing traffic mix of both the U.S. and Europe into 6 categories. The second phase of the effort will determine static pair-wise

spacing that will work for all atmospheric conditions. The final phase of re-categorization will provide dynamic pair-wise spacing that will vary with atmospheric conditions and aircraft performance. This paper provides the methodology of the first phase of re-categorization and gives examples of new aircraft categories that show capacity increases over today's U.S. and ICAO categories.

"WAKE TURBULENCE MITIGATION FOR DEPARTURES FROM CLOSELY SPACED PARALLEL RUNWAYS: A RESEARCH UPDATE"

1st CEAS European Air and Space Conference, Berlin, Germany, CEAS-2007-176, September 2007, pp. 3371-3381

The Federal Aviation Administration (FAA) and National Aeronautics and Space Administration (NASA) have embarked on a multi-phased research and development program to develop and implement wake avoidance solutions that can safely reduce separation between aircraft and improve capacity at airports in the United States National Airspace System (NAS). The mid-term phase of the research focuses on the application of wind-dependent procedures for improved departure operations from Closely Spaced Parallel Runways (CSPRs) in the U.S. These procedures are referred to collectively as Wake Turbulence Mitigation for Departures (WTMD). This paper reports on recent findings of the joint research performed to date by members of the research team, which includes FAA, Lambert St. Louis International Airport Air Traffic Control operational staff, Massachusetts Institute of Technology (MIT) Lincoln Laboratory, MITRE Center for Aviation System Development (CAASD), NASA Langley Research Center, and the Volpe National Transportation Systems Center. In this paper, we review the WTMD concept, including potential benefits that may be derived from its use, report on the most recent work in the development of wind forecast algorithm, provide results of a recent simulation study of controller use of the new procedures, and conclude with a description of the initial prototype installation and validation of controller information requirements.

Langweil, L.

"WAKE VORTEX AVOIDANCE SYSTEM PROGRAM"

Flight in Turbulence, AGARD, CP-140, 1973, pp. 12-1 to 12-9.

The paper describes the Wake Vortex Avoidance System program now being carried out by the FAA. The program's basic objective is to design a predictive system which will increase runway capacity by eliminating the need for the large fixed separations now required between aircraft. These will be replaced by a dynamic safe spacing tailored to the aircraft type and prevailing meteorological conditions. The program consists of three major task areas: sensor development, vortex behavior, hazard definition and the integration of these tasks into an overall system design.

Lanham, C.

"INERTIA CALCULATION PROCEDURE FOR PRELIMINARY DESIGN"

ASD-TR-79-5004, March 1979, Wright-Patterson AFB, Ohio.

This report explains the methods involved in estimating aircraft moments of inertia for preliminary design purposes. Assumptions that were made for this procedure and the derivation of equations that evolved from these assumptions are included. This procedure requires a knowledge of the major aircraft group weights, the location of major components (landing gear, avionics bay, etc.), geometry information, and inertias of some major subsystem items. Using this data, the moments of inertia about the roll, pitch, and yaw axes are calculated as well as the roll-yaw cross-product of inertia.

"SAN FRANCISCO INTERNATIONAL AIRPORT SIMULTANEOUS OFFSET INSTRUMENT APPROACH PROCEDURES (SOIA)"

DOT-FAA-AFS-420-84, March 2000, FAA Standards Development Branch, Oklahoma, OK.

This study is based on a United Airlines/Air Line Pilots Association (UAL/ALPA) joint concept of operations proposal that introduces a Simultaneous Offset Instrument Approach (SOIA) procedure with an ILS straight in to runway 28L and an LDA with glide slope and a side step to runway 28R at the San Francisco International (SFO) Airport. Proponents believe an offset LDA with electronic glide slope usable throughout the visual approach segment, a Precision Runway Monitor (PRM) system, Distance Measuring Equipment (DME), and a MAP located 3,000 feet to 3,400 feet abeam of the parallel localizer course will have significantly enhanced flying qualities and provide increased operational efficiency and safety. The Flight Procedure Standards Branch (AFS-420) was asked to evaluate LDA approaches using a 3 deg offset LDA with glide slope; i.e., non-precision instrument approaches, to runway 28R. The proponents have suggested a MAP, denoted LDA_D, from which the visual transition to the landing runway, runway 28R, can be suitably performed by all current air carrier airplanes, including heavy aircraft, such as the Boeing 747-400 while simultaneously approaching with landings to runway 28L. Three test approaches, identified as LDA_A, D, and E, using a 3 deg offset LDA with glide slope and DME were designed and tested using a qualified, level C flight simulator. Statistical analysis indicated that LDA_A and LDA_D, should be the preferred approaches among the three tested and that the criteria for success, as stated in the test plan, were all met or exceeded by LDA_A and LDA_D. Because of the similarity in flyability qualities and the lower minimums provided by LDA_D, LDA_D is the preferred procedure. LDA_D is recommended for implementation with several operational requirements.

"CLEVELAND-HOPKINS INTERNATIONAL AIRPORT SIMULTANEOUS OFFSET INSTRUMENT APPROACH WAKE VORTEX EVALUATION "

DOT-FAA-AFS-440-13, August 2005, Flight Operations Simulation and Analysis Branch, Oklahoma City, OK.

This report presents the results of a wake vortex evaluation performed on the proposed CLE SOIA operations. The proposed SOIA operations at CLE incorporate straight-in Instrument Landing System (ILS) approaches to runways 24R and 6L and Localizer-type Directional Aid (LDA) approaches with glide slope to runways 24L and 6R. After the LDA MAP, the SOIA aircraft must perform a lateral maneuver to align with the landing runway. It is during this, the visual segment of the approach, that the landing aircraft get laterally closer to one another and where wake vortex concerns must be addressed. The analysis shows that the proposed SOIA operation to runways 6L/R at CLE poses no wake turbulence hazard. Thus, any and all aircraft wake turbulence classes (except Heavy) may be paired for the SOIA operation. Unrestricted use of the proposed SOIA operation to runways 24L/R, however, does pose a wake turbulence hazard for the participating aircraft; therefore, in accordance with FAA Order 8260.49, specific wake turbulence mitigation strategies are recommended. The LDA approaches developed for the CLE SOIA were not designed for Heavy wake turbulence class aircraft, therefore, this analysis does not address Heavy aircraft as part of the SOIA operation.

Lankford, D., McCartor, G., Greene, G., Yates, J. and Ladecky, S.

"LAMBERT-ST. LOUIS INTERNATIONAL AIRPORT WAKE VORTEX STUDY FOR RUNWAYS 30L AND 30R"

DOT-FAA-AFS-420-89, November 2001, FAA Standards Development Branch, Oklahoma City, OK.

The Airspace Simulation and Analysis for TERPS system was used to determine the risk of a wake vortex encounter associated with simultaneous operations to runways 30L and 30R at St. Louis Lambert International Airport (STL) using the enhanced ASAT wake vortex model version 1.2. Five sets of 100,000 ASAT runs were executed. Each set of runs was executed at a selected initial in-trail separation distance ranging from 0.5 NM to 2.5 NM at 0.5 NM increments. The runs were executed using the current aircraft fleet mix and conservative wind conditions. A sensitivity analysis was performed to determine whether a high-risk wake vortex encounter window exists and can be defined. The simulation was conducted with a ground level, direct crosswind from the right at 10 KT increasing logarithmically to 20 KT at 2,000 feet. The simulation did not detect a high-risk wake vortex encounter window. This can be attributed to the relative positions of the runways. The runway centerlines are spaced 1,300 feet apart and the thresholds are staggered 1,698 feet. Therefore, an aircraft approaching runway 30L with a 10 KT or less direct crosswind from the right that increases logarithmically to 20 KT at 2,000 feet is unlikely to encounter a wake vortex that was generated by an aircraft approaching runway 30R. The probability of an encounter is not affected by category combination or in-trail separation provided the aircraft approaching 30R leads the aircraft approaching 30L.

Lankford, D., McCartor, G., Ladecky, S. and Moore, C.

"SAFETY STUDY REPORT ON SAN FRANCISCO INTERNATIONAL AIRPORT SIMULTANEOUS OFFSET INSTRUMENT APPROACH (SOIA) WAKE VORTEX RE-EVALUATION"

DOT-FAA-AFS-440-8, April 2005, Flight Standards Service, Oklahoma, OK.

In order to increase capacity at San Francisco International Airport during periods of inclement weather, the FAA has implemented a SOIA operation. The SOIA operation consists of a straight-in Instrument Landing System (ILS) approach to runway 28L and a Localizer Directional Aid (LDA) approach with glide slope to runway 28R. Since the runways in question are separated by only 750 feet, one of the primary safety concerns, as reported in Volume I, was that of wake turbulence. Volume I recommended a wake turbulence mitigation strategy based on the concept of an 'operational window.' The SOIA operation calls for the RWY 28L aircraft to lead and the RWY 28R to trail while approaching to land at SFO. To avoid wake vortex encounters, the trailing aircraft must remain within an 'operational window' behind the leading aircraft. In Volume I, the size of the operational window was determined to be 0.6 NM for a heavy aircraft following a heavy aircraft. Since Volume I was published, actual wake vortex data has been collected and analyzed at SFO runways 28 L and R. This study concludes that the size of the operational window can be increased to approximately 1 NM (depending on the speed of the leading aircraft) based on the SFO wake vortex data collection and analysis.

Lanoix, P.

"PERSPECTIVE OF CANADIAN AIRPORTS COUNCIL"

International Wake Vortex Meeting, Transport Canada, Ottawa, Canada, Dec, 1997

For most Canadian airports, separation on final is not an issue because the demand is not there. For the few airports with high demand, facilities have to be built to cater to those demands. As the demand increases, it is critical to identify any capacity gain that could be acquired through reduced separation on final. Numerous Canadian airports are going through major changes to handle the increased traffic. Planning and building capacity sometimes require long lead times. In addition, environmental constraints can add to the time required to build an extra runway should the demand be there and the present runway capacity not be available. Each airport is a unique environment: traffic demand, local weather, aircraft types, environment, etc. Every airport, therefore, requires to be considered individually when planning to invest in any vortex prediction model or facility.

Laporte, F.

"INSTABILITIES OF WAKE VORTEX MODELS IN THE NEAR AND FAR FIELDS"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Ensuring accelerated wake vortex decay under any kind of atmospheric conditions is one of the most promising approaches to the wake vortex problem. Enhanced decay might be obtained by acting on the potential instability mechanisms that are likely to develop in wake vortex systems. The knowledge of the stability properties of the vortex systems shed by aircraft is a necessary pre-requisite to the control of these flows. Near field flows (of downstream extension between 1 and 20 wingspans, orders of magnitude) are modeled by considering a single-flap wing shedding two co-rotating vortices, corresponding to the flap and tip vortices. The stable interaction between these vortices corresponds

to the well-known merging phenomenon resulting in a single stable vortex. The simulations reveal also the possible development of a three-dimensional elliptic instability in these two vortices, confirming and extending the recent discovery of Meunier and Lewke in a low Reynolds number experiment. The instability would lead to an unstable merging resulting in a turbulent final vortex. The characteristics associated to the final vortex are found to be potentially significantly different with or without the instability. Far field flows (of downstream extension larger than 10-20 wingspans) are modeled by considering the wake vortex system shed by an aircraft formed after completion of the roll-up process. For many aircraft types in the fleet, this results in a unique pair of counter-rotating vortices, which can be characterized by a single control parameter. The linear, nonlinear and transitional regimes are simulated in the case of the development of the long-wavelength Crow instability, and in the case of the development of the short-wavelength elliptic instability. The influence of the control parameter on the dynamics is discussed, and the late stages of the flows are characterized in terms of hazard. Potential benefits and disadvantages brought by the use of these instability phenomena to accelerate the vortex decay are detailed. The optimal control conditions for an efficient wake destabilization using these mechanisms are interpretable in terms of wing design.

Laporte, F. and Corjon, A.

"A NUMERICAL STUDY OF THE ELLIPTIC INSTABILITY OF A VORTEX PAIR"

Lecture Notes in Physics, Issue 555, 2000, pp. 190-204

The elliptic instability developing in a laminar vortex pair with a high ratio of the vortex core size to the separation distance between the vortices is studied by direct numerical simulations. The computations allow the prediction of both the linear regime of the instability development and the non-linear regime including the transition to a locally turbulent flow.

"METHOD OF CONTROLLING AN AIRCRAFT IN FLIGHT, ESPECIALLY TO REDUCE WAKE VORTICES"

US Patent 8,118,263 B2, February 2012.

The flight of an aircraft is controlled by controlling the aircraft propulsion thrust and adjusting aerodynamic control elements so that the aircraft flies along a specified flight path. In order to reduce wake vortices generated by and trailing behind the aircraft, a wake vortex parameter is determined as a function of a spoiler deflection, and a spoiler element is adjusted to a spoiler deflection value in an optimum range in which the spoiler influence on the wake vortex parameter is maximized and the spoiler influence on the aircraft performance is at its lowest level for achieving that maximum spoiler influence on the wake vortex parameter.

Laporte, F. and Hansen, H.

"METHOD OF CONTROLLING AN AIRCRAFT IN FLIGHT, ESPECIALLY TO REDUCE WAKE VORTICES"

US Patent No. 7,874,523 B2, Jan. 2011, Airbus Deutschland, Hamburg, German.

The flight of an aircraft is controlled by controlling the aircraft propulsion thrust and adjusting aerodynamic control elements so that the aircraft flies along a specified flight path. In order to reduce wake vortices generated by and trailing behind the aircraft, a wake vortex parameter is determined as a function of a spoiler deflection, and a spoiler element is adjusted to a spoiler deflection value in an optimum range in which the spoiler influence on the wake vortex parameter is maximized and the spoiler influence on the aircraft performance is at its lowest level for achieving that maximum spoiler influence on the wake vortex parameter.

"ELLIPTIC INSTABILITY OF COUNTER-ROTATING VORTICES: EXPERIMENT AND DIRECT NUMERICAL SIMULATION"

AIAA Journal, Vol. 40, No. 12, December 2002, pp. 2483-2494

The short-wavelength elliptic instability of a pair of closely spaced counter-rotating vortices is analyzed using water tank experiments and direct numerical simulations. Qualitative and quantitative comparison shows excellent agreement and validates each of these complementary approaches. Both sets of results are used to give a detailed description of the instability characteristics. In the initial phase, the vortices are subject to a three-dimensional perturbation of their internal structure, with a wavelength scaling on the vortex core size and a distinct phase relationship between the two vortices. In the nonlinear evolution of the flow, the growth of the perturbations leads to the generation of secondary vortices and the breakdown of the initial pair into small-scale turbulence, accompanied by a rapid decrease of the average circulation. The growth rate of the instability is found to be higher than the one of the well-known Crow instability. The interaction between both mechanisms is also investigated, and an even faster decay of circulation is observed than for the cases where each instability acts alone. The relevance of these results for realistic aircraft trailing wakes is discussed.

Laporte, F., Darracq, D. and Corjon, A.

"ON THE VORTEX-TURBULENCE INTERACTION: DNS OF ELLIPTIC INSTABILITY OF A VORTEX PAIR"

AIAA Paper No. 1999-3417, Norfolk, VA, June-July 1999

The objective of this study is to perform direct numerical simulations (DNS) of the three-dimensional short-wavelength elliptic instability developing in a counter-rotating vortex pair. The structure of this instability is different from the well-known long-wavelength Crow instability, but interactions between these two instabilities may exist. The aim of the present work is to reproduce numerically a water-tank experiment. The main features of the elliptic instability are recovered by the simulations. In particular, the growth rate of the most amplified wavelength during the first phase of the simulation corresponds to both experimental measurements and linear stability analysis predictions. The long-term evolution is also simulated. The complete simulation starts with a two-dimensional laminar flow and is stopped

when the flow has become three-dimensional and turbulent. The stages leading to transition to turbulence are described.

Larin, A.

"VORTEX WAKE BEHIND A HELICOPTER"

Aviatiya i kosmonavtika, No. 3, 1973, pp. 32-33

Research into the vortex wake behind a helicopter was recently carried out. It was found that vortex cords are cores created behind a helicopter are complex structures and are quite stable. The phenomenon of 'secondary vortex generation' was studied on a model with various numbers of blades.

Larson, R. S. and Robbins, K. W.

"REFRACTION OF SOUND BY AIRCRAFT WING TIP VORTICES"

AIAA Paper No. 1980-0975, Hartford, CT, June 1980.

A detailed study was conducted to define the effect of a wing tip vortex on aircraft flyover noise. The Lamb vortex, the modified Lamb vortex, and a turbulent vortex were three models used to simulate a wing tip vortex. A theoretical geometrical acoustics model was developed to predict the effect of an aircraft's wing tip vortex on acoustic measurements obtained in typical sideline noise tests. Theoretical predictions demonstrated that the refraction and convective amplification effects from a wing tip vortex can cause large distortions in the acoustic field radiated by an engine.

Latham, M.

"APPLICATION CONSIDERATIONS FOR MOSQUITO CONTROL"

International Conf. on Pesticide Application for Drift Management, October 2004, Hawaii, pp. 143-149

Mosquito control aerial adulticiding sprays rely on the drift of aerosol spray clouds with drop sizes less than 50 microns in diameter. These sprays by their very nature will drift for a long distance. To minimize biologically significant off-target drift, careful planning derived from a good understanding of all aspects influencing spray cloud dispersal is essential. Three phases of vertical spray cloud dispersal occur between emission at the aircraft nozzle and depositing out at ground level: entrainment within the descending aircraft vortices, general atmospheric turbulence, and sedimentation. These three phases of movement are influenced by four major factors (assuming aircraft type, speed and weight are constant): Droplet size, Spray altitude, horizontal wind speed and atmospheric stability. For the small drop sizes effective against adult mosquitoes, sedimentation velocity is very small and so sedimentation plays a minimal role in their vertical transport from aircraft to ground level. But it may be important in regards to the larger droplet fraction produced by inefficient 'conventional' spray systems which produce a spray cloud with a VMD between 50 and 100 microns. There is a paucity of research data describing spray cloud movement in mosquito control aerial adulticiding. Advancements in research

equipment such as LIDAR and SODAR may provide the technology to better understand the spray cloud movement and the meteorology in which it occurs. Future research on these subjects must be supported by the mosquito control industry, chemical/equipment manufacturers and the government.

"INVESTIGATION OF THE ROLE OF POLYMER ON THE DELAY OF TIP VORTEX CAVITATION"

Journal of Fluids Engineering, Vol. 126, September 2004, pp. 724-729.

Cavitation tunnel measurements have shown tip vortex cavitation inception is delayed when polymers are injected from the hydrofoil tip. Experiments with polymers have also shown that the polymers cause the cavitation to become more violent. To better understand the role of polymer in the delay of tip vortex cavitation, a theoretical analysis of tip vortex cavitation inception in pure water and in polymer solution is presented. The analysis shows that while polymer injection causes instability in small bubbles, its main effect is an increase in tip vortex core radius, resulting in the delay of tip vortex cavitation inception.

"GROUND-BASED WAKE VORTEX PREDICTION IN THE EN-ROUTE EUROPEAN AIRSPACE"

AIAA Paper 2018-2879, June 2018, Atlanta, GA.

The present study deals with ground-based prediction of enroute wake turbulence encounters in the European airspace. Due to an increasing overall volume of air traffic with required navigation performance within highly congested enroute airspaces, wake turbulence encounters above flight level 100 are becoming more frequent during the last years. The prediction of enroute wake vortex encounters provides information about airspaces with an increased encounter probability as well as specific characteristics of potential encounters. Apart from safety-related benefits, this information may be applied during flight- and capacity planning processes. Two different types of models are coupled with each other: an air traffic flow management model and a wake vortex decay and transport model. The results provide information about the predicted number of en-route encounters, dominant spatial encounter configurations and their locations.

Lau, A., Lorenz, S. and Holzaepfel, F.

"INDIVIDUAL WAKE VORTEX SEPARATIONS: CAPACITY AND DELAY IMPACT ON SINGLE AND DUAL DEPENDENT RUNWAY SYSTEMS"

AIAA Paper 2012-5641, September 2012, Indianapolis, Indiana.

Airport capacity constraints and growing traffic demand in air transportation cause congestion and delay on the ground and in the air. Conservative wake turbulence separation minima in the approach phase guarantee a minimum of in-flight wake encounters of trailing aircraft. On the other hand, in

many situations weather-based separation minima could support more efficient runway utilization. This work estimates delay reduction and capacity gains of DLR's Wake Vortex Prediction and Monitoring System (WSVBS) through the application of reduced time-based approach separations for a single and dual dependent runway system. The system dynamically adjusts approach separations without compromising safety. Delay calculations are conducted with a dynamic runway queuing model, which is capable to process time varying approach separations. It provides the relevant delay data, where several representative operational scenarios enabled through the application of reduced separations on a single and dual dependent runway system are considered. Capacity profiles are created by processing WSVBS separation data with the actual traffic demand. The results give insight about possible delay reductions as well as related operational impact under given implementation assumptions. It is shown that the WSVBS provides efficiency gains on both runway systems, whereas operational requirements regarding the single runway system need to be considered applying reduced individual separations. Regarding the dual dependent runway system, an average hourly delay reduction up to 15 minutes maximum is revealed for the defined scenario setup.

"TIP-VORTEX LOCALIZATION FOR CROSS-STREAM POSITION CONTROL OF A MULTI-HOLE PROBE
RELATIVE TO A STATIONARY WING IN A FREE-JET WIND TUNNEL"

AIAA Paper 2017-1484, January 2017, Grapevine, TX.

The continuing development of fully autonomous aircraft requires advanced sensing and control systems to complete difficult tasks such as aerial refueling and close formation flight. To accomplish such maneuvers, an aircraft must be able to measure the location of nearby aircraft and position itself relative to these other flight vehicles. In visually degraded environments where vision sensors might struggle, wake sensing provides an effective means of locating other aircraft. Using onboard velocity measurements, we combine a point-vortex model with a Bayesian filter to estimate a leader aircraft location through the sensing of wingtip wake vortices. We demonstrate the filtering strategy by estimating the position of a wing using experimental data in an open-jet wind tunnel. An experimental test-bed rapidly positions a flow measurement system within the wake of a wing in a free stream. A flow survey of the tip vortex within the aerodynamic wake of a leader aircraft, conducted with a multi-hole probe, measures velocities in the cross-stream plane. The wake position estimates are used for closed-loop control of the sensor position. This paper presents the estimation strategy and model, experimental data, closed-loop control simulation, and real-time wind tunnel feedback control results. In ongoing work, we are considering applications in which a follower aircraft senses the wake of a leader aircraft and positions itself for maximum aerodynamic efficiency.

"CALCULATION OF THE PARAMETERS OF NEAR-WAKE VORTICES"

Energetika, Vol. 22, June 1979, pp. 115-118

The analysis is carried out under the assumption that the near wake is a Karman street. The concept of a vorticity boundary layer is introduced. For given wake parameters and trailing edge thickness, a unique relationship between the boundary layer characteristics at the trailing edge and the vortex core and intensity is derived. The results of the analysis can be used to good advantage in the calculation of aerodynamic drags of bluff bodies, to-phase boundary layers, and aerodynamic noise.

Laursen, T. S., Rasmussen, J. J., Stenum, B. and Snezhkin, E. N.

"FORMATION OF A 2D VORTEX PAIR AND ITS 3D BREAKUP: AN EXPERIMENTAL STUDY"

Experiments in Fluids, Vol. 23, 1997, pp. 29-37.

Vortex pairs are studied using a dye tracing visualization technique and a particle tracking velocimetry system. The vortex pairs are produced by gravity induced inlets of water issued through a uniform gap. The inlet Reynolds number is $Re = Ud/\nu$ is approximately equal to 875 in all tests (d being the gap width and U the cross sectional mean velocity), i.e. the flow is in the laminar regime. Initially, the dipolar vortex structure is two-dimensional, but after travelling a distance of a few times its own width, the flow structure becomes unstable, breaks up and changes into a three-dimensional flow structure. The breakup appears to be caused by an axial flow in the core centers of each vortex of the dipolar structure. These axial flows are induced by boundary effects related to the von Karman viscous pump. After the breakup, it is believed that a vortex ring is formed through reconnection of rudiments from the dipolar structure mediated by the wall induced vorticity.

"WAKE VORTEX ENCOUNTER SEVERITY FOR ROTORCRAFT IN APPROACH AND LANDING"

31st European Rotorcraft Forum, Florence, Italy, September 2005.

The Advisory Council for Aeronautics Research in Europe predicts that European air traffic may nearly triple by 2020. The growth in air traffic is already an increasing problem with capacity at some airports becoming limited due to congestion. This could be alleviated by providing additional passenger capacity at hubs through the introduction of rotorcraft using new IFR procedures and operating simultaneously but independently of the fixed-wing traffic. These Simultaneous Non-Interfering operations (SNIOPs) will be enabled by a 'reconfiguration' of the airspace, taking advantage of new navigational and air traffic management systems. SNIOPs raise critical safety questions for rotorcraft wake vortex encounters (WVE's) and will require consideration of the longitudinal and lateral aircraft separation and the locations of the rotorcraft FATO's (Final Approach and Take-Off areas). This paper presents analysis from work carried out as part of the Framework 6 project 'OPTIMAL' including the development of predictive methodology and analysis for rotorcraft WVE's using a severity rating scale. In particular, scenarios are considered where the rotorcraft is following precision glideslopes of up to 12 degrees in both good and degraded visual conditions. Handling qualities criteria have already been found to be well suited to investigating severity issues, by evaluating the pilot's perception of their ability to

overcome the effects of an encounter. Within this framework, draft boundaries are proposed for the acceptable severity of an encounter. Within this framework, draft boundaries are proposed for the acceptable severity of an encounter. Furthermore, a pilot may be able to recover from an encounter, but the question of whether the required navigational precision would be compromised and a go-around required is also addressed.

Lawrence, B. and Padfield, G. D.

"WAKE VORTEX ENCOUNTER SEVERITY FOR ROTORCRAFT IN FINAL APPROACH"

Aerospace Science and Technology, Vol. 12, 2008, pp. 385-397

The Advisory Council for Aeronautics Research in Europe predicts that European air traffic may nearly triple by 2020. The growth in air traffic is already an increasing problem with capacity at some airports becoming limited due to congestion. This could be alleviated by providing additional passenger capacity at hubs through the introduction of rotorcraft using new IFR procedures and operating simultaneously but independently of the fixed-wing traffic. These Simultaneous Non-Interfering operations (SNIOPs) will be enabled by a 'reconfiguration' of the airspace, taking advantage of new navigational and air traffic management systems. SNIOPs raise critical safety questions for rotorcraft wake vortex encounters (WVE's) and will require consideration of the longitudinal and lateral aircraft separation and the locations of the rotorcraft FATO's (Final Approach and Take-Off areas). This paper presents analysis from work carried out as part of the Framework 6 project 'OPTIMAL' including the development of predictive methodology and analysis for rotorcraft WVE's using a severity rating scale. "ROTORCRAFT WAKE VORTEX ENCOUNTERS: A FLIGHT MECHANICS PERSPECTIVE"

European Rotorcraft Forum, Maastricht, The Netherlands, September 2006.

The European Commission Framework VI project OPTIMAL is developing new rotorcraft and fixed-wing procedures to increase airport capacity, improve efficiency and reduce environmental impact. Among these procedures, the concept of rotorcraft Simultaneous Non-Interfering operations (SNIOPs) with heavy, runway-based fixed-wing traffic will feature. It has been identified that these operations present a potential risk for rotorcraft encountering the wake vortices of fixed-wing aircraft. The research presented is part of an ongoing effort to understand the flight mechanics of a rotorcraft Wake

Vortex Encounter (WVE) as well developing methods to assess the severity of a WVE. Models have been used in piloted simulation experiments and desktop simulations to include comparative studies of different rotorcraft configurations in a WVE. Parameters such as mass, rotor size, rotor speed and rotor stiffness have also been considered. This study also attempts to make the connection between a particular rotorcraft's sensitivity to a wake vortex and its basic design parameters through the use of flight stability and control derivatives. Results from piloted simulations will also be presented. The results build upon work presented at previous forums, incorporating new rotorcraft types and vortex encounter geometries. The paper presents results from the effort to create criteria for assessing severity and developing methods for linking the fast-time/offline simulation results to the piloted assessments. Establishment of such methods will allow the consideration of a greater number of configurations and scenarios, for example, in the development of safety cases for particular SNIOPs proposals.

"USE OF SCINTILLATIONS TO MEASURE AVERAGE WIND ACROSS A LIGHT BEAM"

Applied Optics, Vol. 11, No. 2, February 1972, pp. 239-243.

We report the successful construction and testing of an optical wind sensor that uses the motion of the scintillation pattern to measure the transverse component of wind blowing across a laser beam. As is done for measuring ionospheric and interplanetary winds, we use a correlation method. However, in our application, the slope at zero lag of the time-lagged correlogram proves to be more useful than the more commonly used delay to the peak. The reason is that, in the atmosphere, irregularities are distributed along the entire propagation path. We use a detector spacing of 0.33 of the diameter of the first Fresnel zone to obtain a nearly uniform weighting function along the path, though the center of the path is still more effective than the ends. The sensor has been used extensively over 1-km and 15-km paths, and field tests of various applications are planned.

"THE INFLUENCE OF WIND TURBULENCE, CROP CHARACTERISTICS AND FLYING HEIGHT ON THE DISPERSAL OF AERIAL SPRAYS"

Atmospheric Environment, Vol. 13, Issue 5, 1979, pp. 711-71.

A series of aerial spray field trials using drops of size 10-230 microns were conducted to determine how the total amount of airborne spray varied with spray release height, drop size, downwind distance, turbulent airflow conditions and the nature of the underlying surface (wheat or fallow). By comparing the results with the predictions of a theoretical model of spray dispersal under turbulent conditions, it was possible to quantify both the removal efficiency of the underlying surface for various drop sizes, and the influence of the aircraft wing-tip vortices in changing the effective spray release height. The results are presented so that the total amount of airborne drift can be predicted from any atomizer, once the drop size spectrum produced by the atomizer is known. The variability due to turbulence of

the quantity of airborne spray between individual spray runs is assessed and implications drawn regarding the number of repeat trials necessary to show significant results.

Lay, J. E.

"AN EXPERIMENTAL AND ANALYTICAL STUDY OF VORTEX-FLOW TEMPERATURE SEPARATION BY SUPERPOSITION OF SPIRAL AND AXIAL FLOW, PART 2"

Journal of Heat Transfer, August 1959, pp. 213-222.

Part 2 reports on the analytical study. The free vortex motion of the gas upon entrance to the tube is mathematically superposed to a compressible sink to give a spiral flow in the plane. The characteristic existence of limit circles is corroborated by the experimental flow visualization. The solution in space is obtained by addition of a uniform axial velocity to the spiral flow. When viscosity effects are considered, the free vortex is shown to change into a forced vortex. The latter flow is one of minimum kinetic energy and maximum entropy. Energy considerations enable the determination of an optimum cold air radius to give largest stagnation temperature separation. Significantly, this was the radius that gave best performance in the experimental program.

Lay, J. E.

"AN EXPERIMENTAL AND ANALYTICAL STUDY OF VORTEX-FLOW TEMPERATURE SEPARATION BY SUPERPOSITION OF SPIRAL AND AXIAL FLOWS, PART 1"

Journal of Heat Transfer, August 1959, pp. 202-212.

This paper reports on an experimental and analytical study of compressible flow in a uniform vortex tube. Part 1 deals with an experimental study, Part 2 with the analytical study. Its purpose is to provide a better understanding of the separation of a gas stream into regions of high and low stagnation temperatures, there being at present little agreement as to the theory of operation. The problem is first approached from the experimental standpoint. A large, multipurpose vortex tube is so designed and built that pressure, temperature, and velocity traverses can be taken at six different stations throughout the length of the tube. Pressure, temperature, and velocity traverses are taken by means of hypodermic probes. Velocities are checked by means of a miniature hot-wire anemometer. Data are taken for different runs of inlet pressures and plotted against radial distance. Flow visualization is obtained by means of liquid injection. The analytical study consists of using superposition for the solution of the flow equations. It begins with potential vortex flow in the plane. The solution of this flow is characterized by the existence of sonic or limit circles. Superposition of a sink flow to the vortex solution yields a spiral flow in the plane. The general solution in space is obtained by addition of a uniform axial velocity to the spiral flow. When viscosity effects are considered, the potential vortex changes into a forced vortex, and the solution becomes a superposition of a viscous compressible sink to a forced vortex. Performance or stagnation temperature separation is expressed as function of the ratio of vortex strength to sink strength.

"IMPLEMENTATION OF PLATE LINE SYSTEM IN UKRAINE"

Proceedings of the National Aviation University, Kyiv, Ukraine, 2014, pp. 71-75.

The article is devoted to the analysis of possible Plate Line implementation in Ukraine. Problems which might occur during the installation of given system in Boryspil International airport are defined. Advantages and disadvantages of Plate Line on the example of Boryspil International airport are considered.

"NUMERICAL SIMULATIONS OF UNSTEADY AERODYNAMICS OF HELICOPTER ROTOR IN MANEUVERING FLIGHT CONDITIONS"

Aerospace Science and Technology, Vol. 8, 2004, pp. 11-25

This article presents a new time-marching fully unsteady method for simulating helicopter rotors in maneuvering flight conditions. The unsteady wake model is based on Mudry's theory which rigorously derives the evolution equation for the wake considered as a vortex sheet from the fluid dynamic equations. The numerical treatment of the sheet with a high-order panel representation allows an accurate simulation of the wake without using numerical regularization techniques. An unsteady lifting line model, based on Matched Asymptotic Expansion, is used to represent the blade and to extend the concept of induced velocities to unsteady configurations. A first application to the Bo 105 rotor in maneuvering flight shows that the method is capable to handle such kind of complex configuration.

"PREVIOUS WORK AND PRESENT KNOWLEDGE ON VORTEX INSTABILITIES AND DECAY"

AST4-CT-2005-012238, CNRS-IRPHE, Toulouse, France, December 2005

The present review has been divided in five parts: Vortex meandering and wave propagation, End effects, Vortex bursting, Elliptic instability, and Long-wave cooperative instabilities. The review of present knowledge for the works planned in task 1.1.2 (End effects and bursting) has been split in three different parts. The fundamental aspects of end effects which concern the wave propagation phenomenon is reviewed together with vortex meandering (subtask 1.1.1) by P. Brancher and D. Fabre (IMFT). The end effects related with experiments are reviewed by E. Coustols (ONERA). The specific problem of vortex bursting is reviewed by L. Nybelen (CERFACS). The reviews for subtask 1.2.1 (elliptic instability) and subtask 1.2.2 (long-wave cooperative instabilities) are done by S. Le Dizés (IRPHE) and L. Jacquin (ONERA) respectively.

"LARGE-REYNOLDS-NUMBER ASYMPTOTIC ANALYSIS OF VISCOUS CENTRE MODES IN VORTICES"

J. Fluid Mech., Vol. 585, 2007, pp. 153-180

This paper presents a large-Reynolds-number asymptotic analysis of viscous center modes on an arbitrary axisymmetric vortex with an axial jet. By a multiple-scale matching analysis, we demonstrate the existence of three different families of viscous center modes. Our results prove that any vortex with a jet (or jet with swirl) is unstable if the Reynolds number is sufficiently large. The spatial structure of the viscous center modes is obtained and simple approximations which capture the main feature of the eigenmodes are also provided. The theoretical predictions are compared with numerical results for the q-vortex model (or Batchelor vortex) for Re greater than or equal to 100,000. For all modes, a good agreement is demonstrated for both the frequency and the spatial structure.

Le Dizes, S. and Fabre, D.

"LINEAR ASYMPTOTIC STABILITY ANALYSIS OF SPECIFIC VORTICES"

AST4-CT-2005-012238, CNRS-IRPHE, Toulouse, France, January 2006

This report presents a large-Reynolds-number asymptotic analysis of viscous centre modes on an arbitrary axisymmetrical vortex with axial jet. By a multiple-scale matching analysis, we demonstrate the existence of three different families of viscous centre modes. The spatial structure of the viscous centre modes is obtained and simple approximations which capture the main feature of the eigenmodes are also provided. The theoretical predictions are compared with numerical results for the Batchelor vortex (q-vortex model). For all modes, a very good agreement is demonstrated for both the frequency and the spatial structure.

"AN ASYMPTOTIC DESCRIPTION OF VORTEX KELVIN MODES"

Journal of Fluid Mechanics, Vol. 542, 2005, pp. 69-96.

A large-axial-wavenumber asymptotic analysis of inviscid normal modes in an axisymmetric vortex with a weak axial flow is performed in this work. Using a WKBJ approach, general conditions for the existence of regular neutral modes are obtained. Dispersion relations are derived for neutral modes confined in the vortex core or in a ring. Results are applied to a vortex with Gaussian vorticity and axial velocity profiles, and a good agreement with numerical results is observed for almost all values of k . The theory is also extended to deal with singular modes possessing a critical point singularity. We demonstrate that the characteristics for vanishing viscosity of viscous damped normal modes can also be obtained. Known viscous damped eigenfrequencies for the Gaussian vortex without axial flow, in particular, are shown to be predicted well by our estimates. The theory is also shown to provide explanations for a few of their peculiar properties.

Le Dizes, S. and Lacaze, L.

"LINEAR STABILITY ANALYSIS OF THE ELLIPTIC INSTABILITY IN VORTICES WITH AXIAL FLOW"

AST4-CT-2005-012238, Inst. de Recherche sur les Phenomenes Hors Equilibre, Marseille, France, October 2005

Vortices generated by aircraft wings are known to interact with each other. Each vortex, in particular, is subjected to the strain field induced by the other surrounding vortices. This strain field is at the origin of what is now called the elliptic instability which develops in vortex cores. For vortices without axial flow, this instability is characterized by a sinuous deformation of the vortices with a wavelength proportional to the vortex core size. The purpose of the present work is to demonstrate that other unstable modes are expected when there is an axial flow in the vortex core. The theory is developed for a Batchelor vortex in a stationary strain field. This model describes the situation in the far wake where the flow is composed of two counter-rotating Batchelor vortices. Similar qualitative conclusions are expected for other types of vortices, or vortices in rotating strain fields.

Le Dizes, S. and Laporte, F.

"THEORETICAL PREDICTIONS FOR THE ELLIPTICAL INSTABILITY IN A TWO-VORTEX FLOW"

J. Fluid Mech., Vol. 471, 2002, pp. 169-201

Two parallel Gaussian vortices of circulation C_1 and C_2 , radii a_1 and a_2 , separated by a distance b may become unstable by the elliptical instability due to the elliptic deformation of their cores. The goal of the paper is to analyze this occurrence theoretically in a general framework. An explicit formula for the temporal growth rate of the elliptical instability in each vortex is obtained as a function of the above global parameters of the system, the Reynolds number, and the non-dimensional axial wavenumber of the perturbation. This formula is based on a known asymptotic expression for the local instability growth rate at an elliptical stagnation point which depends on the local characteristics of the elliptical flow and the inclination angle of the local perturbation wavevector at this point. The elliptical flow characteristics are estimated by considering each Gaussian vortex alone in a weak uniform external strain field whose properties are provided by a point vortex modelling of the vortex pair. The inclination angle is obtained from the dispersion relation for the Gaussian vortex normal modes and the local expression near each vortex center for the two helical modes of azimuthal wavenumber $m = 1$ and $m = -1$ which constitute the elliptical instability global mode. Both the final formula and the hypotheses made for its derivation are tested and validated by direct numerical simulations and large-eddy simulations.

Le Dizes, S. and Verga, A.

"VISCOUS INTERACTIONS OF TWO CO-ROTATING VORTICES BEFORE MERGING"

J. Fluid Mech., Vol. 467, 2002, pp. 389-410

The viscous evolution of two co-rotating vortices is analyzed using direct two-dimensional numerical simulations of the Navier-Stokes equations. The article focuses on vortex interaction regimes before merging. Two parameters are varied: a steepness parameter, n , which measures the steepness of the initial vorticity profiles in a given family of profiles, and the Reynolds number, Re (between 500 and 16,000). Two distinct relaxation processes are identified. The first one is non-viscous and corresponds to a rapid adaptation of each vortex to the external (strain) field generated by the other vortex. This adaptation process, which is profile dependent, is described and explained using the damped Kelvin modes of each vortex. The second relaxation process is a slow diffusion phenomenon. It is like the relaxation of any non-Gaussian axisymmetric vortex towards the Gaussian. The quasi-stationary solution evolves on a viscous-time scale toward a single attractive solution which corresponds to the evolution from two initially Gaussian vortices. The attractive solution is analyzed in detail up to the merging threshold a/b nearly equal to 0.22 where a and b are the vortex radius and the separation distance respectively. The vortex core deformations are quantified and compared to those induced by a single vortex in a rotating strain field. A good agreement with the asymptotic predictions is demonstrated for the eccentricity of vortex core streamlines. A weak anomalous Reynolds number dependence of the solution is also identified. This dependence is attributed to the advection-diffusion of vorticity towards the hyperbolic points of the system and across the separatrix connecting these points.

"LES WITH NUMERICAL DISSIPATION FOR AIRCRAFT WAKE VORTICES"

AIAA Paper No. 2006-1258, Reno, NV, January 2006

Large-Eddy Simulations of a pair of counter-rotating wake vortices in quiescent air are presented. The dissipation is entirely provided by the numerical schemes and grids since no sub-grid scale model is employed. Two numerical schemes are investigated for this purpose: an upwind scheme based on Osher's approximate Riemann solver and a MUSCL reconstruction, and a central difference scheme with fourth order artificial dissipation. The grids employed are unstructured, either entirely composed of tetrahedral cells or hybrid with a Cartesian structured core. The numerical results show that discretization scheme, grid refinement and grid topology have a strong influence on the amount of dissipation generated and hence on the accuracy of the simulations. The methodology can reproduce a realistic vortex decay with the appearance of short and long wave instabilities.

Le Roux, C.

"INCREASED AIRPORT CAPACITY THROUGH REDUCTION OF SEPARATIONS DUE TO WAKE VORTICES"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 4-1 - 4-6.

The reduction of separation standards due to wake vortices during approach and takeoff phases will allow, without any doubt, an increased airport capacity. The DGAC first goal is to define a system linked to the ATC allowing a wake vortex detection and alarm display in real time.

Le Roux, C. and Corjon, A.

"WAKE VORTEX ADVISORY SYSTEM IMPLEMENTATION AT ORLY AIRPORT FOR DEPARTING AIRCRAFT"

Air Traffic Control Quarterly, Vol. 5, No. 1, 1997, pp. 31-48.

The work done at Service Technique de la Navigation Aérienne (STNA) on wake vortices has led to the establishment of relationships between wind characteristics and potential hazards for a following aircraft. The methods that define these relationships and their validation are presented. Separation between aircraft is defined from our model as varying between 80 and 30 s for either a total wind of 12 to 20 kt or a crosswind of 5 to 8 kt. Based on these results, a first version of SYAGE (SYstème Anticipatif de Gestion des Espacements) has been defined which considers only a temporary change of the current separation matrix. This version of SYAGE will be applied only to take-off from a single runway because of the difficulty of forecasting wind characteristics, as would be required for a system applied also to landing. To optimize the system's efficiency, it is planned to link SYAGE 1 to a meteorological interface and to the Surface Movement and Guidance Control System (SMGCS) now under development. The objective is to realize a wake vortex advisory system (WVAS) for departing aircraft. Prior to implementing the WVAS at Orly Airport, a demonstration is planned to provide experience for controllers and pilots.

"NUMERICAL SIMULATION OF VORTEX BREAKDOWN BY SOLVING THE EULER EQUATIONS FOR AN INCOMPRESSIBLE FLUID"

La Recherche Aérospatiale, No. 5, 1989, pp. 35-49.

A method of calculating unsteady, three-dimensional flows of inviscid incompressible fluid has been used in research on vortex breakdown. This method is based on the solution of the unsteady Euler equations in a velocity-pressure formulation, discretized by centered finite difference schemes, accurate to the second order. The application described is a single vortex that has an initial velocity profile resembling delta wing vortices. Comparisons are made with experimental data and with other simulation methods.

"DETERMINATION DE CRITERES D'ECLATEMENT TOURBILLONNAIRE PAR RESOLUTION DES EQUATIONS D'EULER ET DE NAVIER STOKES"

Proceedings of Fluid Dynamic Panel Symposium, Vortex Flow Aerodynamics, AGARD, CP-494, Scheveningen, The Netherlands, October 1990, pp. 22-1 to 22-10.

The vortex breakdown plays a key role in aerodynamics, especially on fighter aircraft or missiles at high angles of attack. Despite many studies, the knowledge of vortex bursting phenomenon is not complete and no reliable criterion is available to characterize it. Based upon numerical simulations which solve the Euler or the Navier-Stokes equations, a parametric study is carried out on the configuration of an isolated vortex subjected to an initial perturbation. Results obtained from this study allow the specification of a criterion based upon an appropriately defined local Rossby number to determine the region where breakdown occurs.

Leblanc, S.

"ACOUSTIC EXCITATION OF VORTEX INSTABILITIES"

Physics of Fluids, Vol. 13, No. 11, November 2001, pp. 3496-3499

The asymptotic solution of Ford and Smith which describes the dynamics of a Kelvin vortex disturbed by a single large wavelength acoustic excitation, is shown to be unstable to three-dimensional short-wave nonlinear perturbations. This result might have interesting physical applications such as the destabilization of vortices in geophysics or engineering.

Leblanc, S., Le Duc, A. and Le Penven, L.

"ON THE STABILITY OF VORTICES IN AN IDEAL GAS"

Lectures in Physics, Vol. 555, 2000, pp. 205-220

Two distinct mechanisms of three-dimensional instability in compressible planar vortices in an ideal gas are presented. Both mechanisms have been obtained with the geometrical optics (WKB) stability theory which consists in studying the evolution of short-wavelength disturbances localized along the trajectories of the vortex. The first one corresponds to parametric resonances arising when a vortex is periodically compressed; the resulting instabilities are localized in the core of the vortex. On the contrary, in the second case, which corresponds to the generalization to compressible flows of the Rayleigh stability criterion for centrifugal instability, the growing perturbation surrounds the vortex at a given radius. In the latter case, the structure of the corresponding discrete eigenmodes may be described exactly, thus complementing and improving the WKB theory.

"OPENFOAM SOLUTIONS COUPLED WITH WRF FOR WIND POWER ESTIMATION"

AIAA Paper 2017-3062, June 2017, Denver, CO.

The open-source flow solver OpenFOAM is coupled with the mesoscale weather prediction software WRF in order to predict the atmospheric flows in complex terrains more accurately and to predict the daily energy production potential accurately. The low resolution, unsteady WRF solution provides the spatially varying unsteady boundary conditions for OpenFOAM solutions on high resolution terrain-fitted viscous grids. Coupled OpenFOAM solutions are successfully obtained for the Mersin/Mut region in Turkey. It is shown that the coupled solutions agree with the WRF solutions in general and compare well with the wind mast data available.

Leclaire, B., Sipp, D. and Jacquin, L.

"THE INFLUENCE OF UPSTREAM BOUNDARY CONDITIONS ON THE ONSET OF AXISYMMETRIC VORTEX BREAKDOWN IN A DUCT"

AIAA Paper No. 2008-3798, Seattle, WA, June 2008.

Past numerical studies on vortex breakdown in a duct have identified the choice of upstream boundary conditions as a source of major concern. While the choice for axial and azimuthal velocity profiles is often dictated by the experiments, the choice for the third upstream condition does not appear unanimous and its influence on the scenario of transition to breakdown is still unclear. Our purpose in this paper is to address this question in a theoretical framework. We investigate the axisymmetric flow of an inviscid fluid in a duct of constant cross-section and finite axial length. Solutions bifurcating from the columnar solution at criticality are analyzed via a weakly nonlinear expansion and computed in the fully nonlinear regime using numerical continuation, until a centerline recirculation is found at the duct outlet. The linear stability of these flows is also investigated. We apply these techniques to two typical flows frequently used in the literature: the Burgers-Rott vortex, and plug axial flow with solid body rotation.

"SIMULATION OF PARTICLE TRAJECTORIES IN A VORTEX-INDUCED FLOW: APPLICATION TO SEED-DEPENDENT FLOW MEASUREMENT TECHNIQUES"

4th International Symposium on Particle Image Velocimetry, Paper 1116, September 2001, Gottingen, Germany.

The trajectories of heavy particles ($\rho_{\text{particle}}/\rho_{\text{fluid}}$ much greater than 1) are simulated in a 2D free vortex flow. The results show that heavy particles, even with small diameters, cannot properly trace the fluid and develop a centrifugal motion. This behavior leads to a quick depletion of particles in the vortex core, which, in seed-dependent measurements as PIV or LDV, produce a marked increase of measurement errors. Some examples are given and the evolution of the particle density is simulated.

"METHODS FOR EFFICIENT RESOLUTION OF VORTICAL STRUCTURES OF AN S-76 ROTOR IN HOVER"

AIAA Paper 2017-1664, January 2017, Grapevine, TX.

Meshing and numerical techniques are investigated to resolve the vortical structures of an S-76 rotor in hover in an efficient manner. The methodology employs a quarter domain Cartesian background mesh with periodic boundary conditions to reduce the computational costs in simulating all four blades of the rotor. Mesh clustering of the background grid is performed where the strong tip vortex is expected, and overset vortex tracking grids are added to further resolve the near-field evolution of the tip vortex. A compressible, structured, overset RANS based solver (OVERTURNS) is used in this study, and simulations were performed for a swept-tapered tip at a tip Mach number of 0.65 and a collective pitch angle of 9.25 degrees. To minimize the numerical error, a fifth-order Compact-Reconstruction Weighted Essentially Non-Oscillatory (CRWENO) is employed. A first-order temporal accurate scheme is applied to avoid excessive development of small eddies around the tip vortex and severe breakdown of far rotor wake. For turbulence closure, the Spalart-Allmaras one-equation model with the rotational correction terms (SA-R) and the Spalart-Allmaras Delayed Detached Eddy Simulation (SA-DDES) with modified parameters are tested. The performance parameters are examined, and the vortical structures are analyzed in detail, such as the tip vortex trajectory, swirl and axial velocity profiles, and Eddy viscosity. It was observed that while the vortex tracking grids, mesh clustering techniques, and use of SA-DDES do not significantly affect the predicted efficiency of the rotor, they vastly improve the quality of the wake structure trailed behind the rotor blades.

Lee, D. J. and Koo, S. O.

"NUMERICAL STUDY OF SOUND GENERATION DUE TO A SPINNING VORTEX PAIR"

AIAA Journal, Vol. 33, No. 1, January 1995, pp. 20-26.

A numerical approach for the calculation of an acoustic field is applied to the case of a spinning vortex pair to investigate the sound generation by quadrupole sources in unsteady vortical flows. Based on the unsteady hydrodynamic information from the known incompressible flowfield, the perturbed compressible acoustic terms derived from the Euler equations are calculated. Nonreflecting boundary conditions are developed to obtain highly stable solutions. Calculated results are compared with analytical solutions by the method of matched asymptotic expansions. The possibility of predicting the effect of convective mean flow is also tested. It is concluded that the sound generated by the quadrupole sources of unsteady vortical flows without a sound-generating body or surface can be calculated by using the source terms of hydrodynamic flow fluctuations.

Lee, D. J. and Na, S. L.

"NUMERICAL SIMULATIONS OF WAKE STRUCTURE GENERATED BY ROTATING BLADES USING A TIME MARCHING, FREE VORTEX BLOB METHOD"

European Journal of Mechanics - B/Fluids, Vol. 18, Issue 1, January-February 1999, pp. 147-159.

Velocity fields in the wake generated by rotating blades are calculated using a time-accurate, free vortex blob method without a non-physical model of the far wake. The computed free-wake geometry of a single rotor in hover is represented by three wake regions: a well-defined tip vortex region, an intermediate region, and an initially generated wake bundle. The simulated wake geometries in the radial and axial directions agree well with the experimental data for a two-bladed rotor for the overall regions of the wake. This agreement can be obtained by slowly increasing the rotational speed of the rotor blade, instead of using an impulsively rotating blade. The unsteady generation process of the wake structure is calculated for a single rotor with two blades.

Lee, D. J. and Smith, C. A.

"EFFECT OF VORTEX CORE DISTORTION ON BLADE-VORTEX INTERACTION"

AIAA Journal, Vol. 29, No. 9, September, 1991, pp. 1355-1362.

The effect of vortex distortion on the flow arising from the interaction of a convecting vortex and an airfoil is analyzed for two-dimensional, incompressible, inviscid flow. Significant distortion of the vortex structure, owing to interaction with the airfoil, can occur, especially during close interactions. The vorticity field is represented by multiple vortex elements. Vortex instability and diffusion, resulting from discretization in space and time, are discussed. An integral-boundary-element method is used to represent the airfoil surface and its effect on the flowfield. The body panels are redistributed on the surface as the vortices are convected past the airfoil to calculate the effect of the vorticity field more accurately. The method is applied to several cases to examine effects of vortex strength, distribution, and initial separation position. The distortion, even splitting, of the vortex core is observed for the case of close interaction. However, the extent of distortion depends strongly on the initial size and strength of the vortex. Also, the unsteady pressure term contributes significantly to both the surface-pressure distribution and total lift in addition to the quasi-steady term. Circulation around the airfoil is also presented.

Lee, G. H.

"TRAILING VORTEX WAKES"

Aeronautical Journal, September 1975, pp. 377-388.

It is shown that the trailing vortex wakes generated by large airplanes can cause serious upsets (loss of control) to smaller following aircraft that may encounter them and may damage buildings near an airport. The increase in separation behind big aircraft imposed as a safety measure leads to a serious loss of runway capacity. After discussion of the nature of wake vortices, it is demonstrated that they may be attenuated, so avoiding unnecessary separation between aircraft at an airport and, at the same time, obviating ground damage. Discussion of alternative devices available for moderating the vortex wake indicates that practical solutions may be confidently expected.

Lee, H. and Schetz, J. A.

"COMPUTATIONAL AND EXPERIMENTAL STUDY OF TRAILING VORTICES"

AIAA Paper No. 1983-1868, Danvers, MA, July 1983

A coordinated computational and experimental study was undertaken to investigate the behavior of the vortices trailing from low aspect ratio lifting surfaces. Vortex formation in the near-wake was measured in a wind tunnel with yaw-head and hot-wire probes at three different Reynolds numbers, the highest of which was greater than most previous studies. These near-wake measurements provided initial conditions for the far-field computation with the parabolized Navier-Stokes equations written in terms of the vorticity and a stream function. Turbulent transport was modeled through the turbulent kinetic energy and the Prandtl-Kolmogorov hypothesis to give an eddy viscosity. The experimental results showed that the effects of Reynolds number are significant for vortex formation in the near-wake, and the computation adequately predicted these effects. However, the decay trend in the far-field is essentially unaffected by the Reynolds number. The predicted decay for maximum tangential velocity agreed very well with Iversen's data correlation.

Lee, H. and Schetz, J. A.

"EXPERIMENTAL RESULTS FOR REYNOLDS NUMBER EFFECTS ON TRAILING VORTICES"

Journal of Aircraft, Vol. 22, No. 2, February 1985, pp. 158-160

The simulation of vortices by small-scale model testing in wind tunnels and towing tanks presents a problem, since the history of vortices is known to be sensitive to Reynolds number. The near-wake behavior of the vortices trailing from low aspect ratio lifting surfaces mounted on either side of a larger, non-lifting, streamlined strut was investigated in a wind tunnel. The effect of Reynolds number was apparent; an increasing Reynolds number corresponded to a decreasing axial velocity defect and an increasing maximum swirl velocity. Furthermore, this Reynolds number effect was found to be greater than that of downstream distance.

Lee, H.-T. and Chatterji, G. B.

"CLOSED-FORM TAKEOFF WEIGHT ESTIMATION MODEL FOR AIR TRANSPORTATION SIMULATION"

AIAA Paper No. 2010-9156, September 2010, Fort Worth, TX.

Takeoff weight is an important parameter for computing accurate aircraft trajectories. Most systems used for simulating air traffic and for providing air traffic management decision support use takeoff weights that depend only on the aircraft type. This paper proposes a closed-form algorithm for estimating takeoff weights based on flight plan and aircraft performance data. The algorithm is derived by combining the constant-altitude-cruise range equation with the weight estimation procedure commonly used in aircraft design. The model first determines whether the payload is limited by payload capacity, maximum takeoff weight, or fuel tank capacity, and then calculates the takeoff weight accordingly. The model is verified against manufacturer provided payload range diagrams for a jet and a

turboprop aircraft. Accurate and fast takeoff weight estimation with negligible computational overhead will enhance large scale air traffic simulations by improving the accuracy of trajectories and fuel burn estimates. Improvement in trajectory and fuel burn estimates will benefit the assessment of noise and emissions as well as improve the accuracy of automated conflict detection and resolution algorithms.

Lee, J.

"AERODYNAMIC CHARACTERISTICS OF RECTANGULAR WING WITH SQUARE LATERAL TIP"

AIAA Paper 2013-0250, January 2013, Grapevine, TX.

A numerical study has been conducted to investigate aerodynamic characteristics and the behavior of wing-tip vortices of the three-dimensional symmetric wing (NACA0015) in the vicinity of the ground. Two distinct phenomena, ground effect and Venturi effect, can be observed when the wing is approaching the ground and change the aerodynamic characteristics significantly. The symmetric wing in the vicinity of the ground shows both phenomena according to the pitch angles. The ground effect increases the lift and decreases the drag, simultaneously, but the Venturi effect decreases the lift and decreases the drag, significantly. The high dynamic pressure, and positive wing tip vortex of the Venturi effect augment the friction drag and the induced drag dramatically, unlike the ground effect. The vortex core at the wing tip moves into the center of the wing when the Venturi effect is dominant whereas the vortex core moves outward when the ground effect is dominant.

Lee, J. H., Sevil, H. E., Dogan, A. and Hullender, D.

"ESTIMATION OF RECEIVER AIRCRAFT STATES AND WIND VECTORS IN AERIAL REFUELING"

Journal of Guidance, Control and Dynamics, Vol. 37, No. 1, January-February 2014, pp. 265-276.

A square root unscented Kalman filter is used to estimate the states of a receiver aircraft and the components of the wind the aircraft is exposed to as it flies behind the tanker aircraft. The wind is the superposition of time-varying prevailing wind, turbulence, and the tanker's wake-induced wind. The system update of the estimator uses the nonlinear aircraft model, augmented by a nonlinear wind model, obtained from the translational dynamics of the aircraft. The aircraft state estimates are successfully used in controlling the position of the receiver aircraft relative to the tanker flying straight level and making turns. Although the performance of the estimation and control is very dependent on the covariance and correlation time constants of the sensor measurement errors, the estimated state feedback performs better than measured state feedback with higher levels of measurement noise and turbulence intensity.

Lee, J., Birch, S. F. and Scovill, B. A.

"AIRPORT JET PLUME ZONE MAPPING"

Journal of Aircraft, Vol. 33, No. 4, July-August 1996, pp. 737-742.

A software package, which maps the jet plume zones for a jet aircraft during airport ground operation, has been developed. The method generates an airport plume zone map by predicting plume velocity contours (for a selected jet plume velocity level, e.g., 35 mph) as a function of the aircraft geometry and engine power setting. The velocity contours are then superimposed on a pre-digitized airport map. A standard normalized velocity contour plot, which is unique to each airplane configuration, is used to quickly determine the plume velocity contour for an engine power setting and a computer graphics program is used to display an airport plume zone map on the computer screen. The method is general and is applicable to any airplane configuration. The purpose of this article is to introduce an airport plume zone mapping tool to the airplane design and operation groups.

Lee, J., Han, C. and Bae, C.-H.

"INFLUENCE OF WING CONFIGURATIONS ON AERODYNAMIC CHARACTERISTICS OF WINGS IN GROUND EFFECT"

Journal of Aircraft, Vol. 47, No. 3, May-June 2010, pp. 1030-1040.

A numerical analysis is performed to investigate the aerodynamic characteristics and the static height stability of the endplate and the anhedral angle on an aspect-ratio-one wing-in-ground effect. The analysis shows that the ground effect increases the lift by the high pressure on the lower surface, reduces the drag, increases the suction on the upper surface, and considerably enhances the lift-drag ratio. The endplate, which prevents the high-pressure air from escaping out of the lower surface and reduces the influence of the wing-tip vortex, further augments the lift and the lift-drag ratio. Irodov's criteria are also numerically evaluated to investigate the static height stability. The comparison of Irodov's criteria shows that the endplate is not favorable for the static height stability. However, the anhedral angle improves the lift as well as Irodov's criteria at various angles of attack and heights. Interestingly, the stagnation point for the anhedral angle moves forward with decreasing height at the low angles of attack and leads an increase in the pressure drag. Thus, the lift-drag ratio of a wing is not improved as much with an anhedral angle as it is with an endplate.

"AN INVISCID ANALYSIS OF VORTEX-SURFACE COLLISIONS"

AIAA Paper 1995-2237, June 1995, San Diego, CA.

This work is part of a project designed to better understand the unsteady effects resulting from the close interaction of a rotor-wake tip-vortex with an airframe. The objective is to predict the unsteady air-loads associated with the rotor tip-vortex interaction with a helicopter airframe. In this paper we describe the results of a model developed to illustrate an inviscid mechanism for redistribution of vorticity concentrated initially in the vortex core as the vortex collides with a surface. Experiments

indicate that a strong suction peak generated as the tip-vortex approaches the airframe is rapidly reduced and the pressure soon returns to a locally quasi-steady distribution having a near-zero mean. The present model exhibits the same trends; in particular, it is shown that the vortex core bulges and the vorticity decays when the axial velocity in the core of the vortex is toward the surface. This is precisely what is seen in experiments on the advancing rotor side of the helicopter airframe.

"OSCILLATING-WING TIP VORTEX WITH PASSIVE SHORT-SPAN TRAILING-EDGE FLAPS"

Journal of Aircraft, Vol. 43, No. 3, May-June 2006, pp.723-731

Tip vortex flow behind an oscillating NACA 0015 wing with passive short-span trailing-edge flaps was investigated experimentally at $Re = 1.81 \times 100,000$. The spoiler was found to be very effective in diffusing the tip vortex, in terms of the reduction of peak tangential velocity and vortex strength, compared to a baseline wing; it also led to additional vertical upward displacement of the vortex center. No significant influence on the vortex size was observed, however. The spoiler-induced negative camber effects also translated into slightly reduced bound circulation, total lift, and lift-induced drag. For a tab, the dynamic increase-decrease in the vortex size and strength persisted and had values larger than for a baseline wing. No substantial change in the peak tangential velocity, compared to that for a baseline wing, was noticed. The axial core velocity was always wakelike, and the vortex center was shifted relatively outboard and vertically downward below the baseline wing. The tab also led to an increase in the lift and drag forces. The symmetric flap provided a compromise in the critical vortex-flow quantities between the spoiler and tab cases.

"EFFECT OF GURNEY FLAP ON UNSTEADY WAKE VORTEX"

J. Aircraft, Vol. 44, No. 4, July-August 2007, pp. 1398-1401

The influence of a Gurney flap, in both regular and inverted arrangements, on the critical vortex flow parameters of an oscillating NACA 0015 wing was investigated. The larger the Gurney flap height, the higher the core radius and circulation but the lower the peak tangential velocity. The core vorticity and axial velocity were significantly reduced by the presence of Gurney flaps. For an oscillating wing equipped with an inverted Gurney flap, the reduction in peak tangential velocity and core circulation was found to be most overwhelming and was accompanied by a considerable reduction in peak vorticity and mean axial core velocity throughout the entire oscillation cycle. The larger the inverted flap height, the smaller the peak tangential velocity, peak vorticity, and mean axial core velocity and the narrower the associated hysteresis.

Lee, S. and Bershader, D.

"HEAD-ON PARALLEL BLADE-VORTEX INTERACTION"

AIAA Journal, Vol. 32, No. 1, January 1994, pp. 16-22.

An experimental and computational study was carried out to investigate the parallel head-on blade-vortex interaction (BVI) and its noise generation mechanism. A shock tube, with an enlarged test section, was used to generate a compressible starting vortex which interacted with a target airfoil. The dual-pulsed holographic interferometry (DPHI) technique and airfoil surface pressure measurements were employed to obtain quantitative flowfield data during the BVI. A thin-layer Navier-Stokes code (BV12D), with a high-order upwind-biased scheme and a multizonal grid, was also used to simulate numerically the phenomena occurring in the head-on BVI. The detailed structure of a convecting vortex was studied through independent measurements of density and pressure distributions across the vortex center. Results indicate that, in a strong head-on BVI, the opposite pressure peaks are generated on both sides of the leading edge as the vortex approaches. Then, as soon as the vortex passes by the leading edge, the high-pressure peak suddenly moves toward the low-pressure peak - reducing in magnitude as it moves - simultaneously giving rise to the initial sound wave. In both experiment and computation, it is shown that the viscous effect plays a significant role in head-on BVIs.

Lee, S. and Bershader, D.

"THE STRUCTURE OF COMPRESSIBLE STARTING VORTICES"

Experiments in Fluids, Vol. 16, 1994, pp. 248-254.

The structures of highly two-dimensional shock-induced compressible starting vortices were investigated. Density distributions across the vortex were measured by dual-pulsed holographic interferometry. Pressure profiles of the vortex were measured by fast-response miniature Kulite transducers. From these two independent measurements the velocity profile was calculated using the radial momentum equation. The detailed vortex structure is like that from the tip of a wing and consists of four well-defined regions: a core region, a logarithmic region, a transition region, and an inviscid region. The distribution of circulation of the vortices can be expressed by a set of empirical formulae. The proportionality constants of the logarithmic region were found to be 0.43 ± 0.01 for three different two-dimensional vortices.

"AERODYNAMIC CHARACTERISTICS OF A RECTANGULAR WING IN GROUND PROXIMITY"

Journal of Aircraft, Vol. 51, No. 2, March-April 2014, pp. 688-692.

Depending on the heights and the angles of attack, the aerodynamic characteristics and the behavior of the wing-tip vortex are significantly changed. The flow characteristics can be clearly explained by the Venturi effect and the ground effect. When the angle of attack is less than 4 deg, the gap between the pressure side and the ground clearly shows the Venturi effect due to the convergence-divergence passage. When the Venturi effect is dominant, negative lift and the drag due to friction, flow separation, and induced vortex dramatically increase simultaneously. The wing-tip vortex sucked into the pressure side moves close to the center of the wing. The induced drag is increased as well as the

friction drag due to the high dynamic pressure on the pressure side. This high dynamic pressure increases the suction on the lower surface. Therefore, the negative vortices are generated and move in the negative spanwise direction. In contrast, when the ground effect (angle of attack greater than 4) is dominant, the lift is augmented, but the drag decreases as the height decreases. The induced drag and friction drag are diminished, and the aerodynamic characteristics improve as height decreases. The negative vortex is generated at the wing tip and drifts outward. At the intermediate angle of attack (4 deg), both effects are present simultaneously, and so the lift and the drag are not changed significantly as height changes. In this study, using a symmetric airfoil, we can show significant lift changes due to the Venturi effect and the ground effect, depending on the angle of attack. Despite the presence of a cambered or optimized airfoil, there is a severe lift decrease under the critical angle of attack. Thus, the critical angle of attack is critical for the safety and the efficiency of a vehicle operating in the ground effect.

"ATTENUATION OF THE TIP VORTEX FLOW USING A FLEXIBLE THREAD"

Experiments in Fluids, Vol. 59, 2018, pp. 23-2 to 23-12.

Tip vortex cavitation (TVC) is important in several practical engineering applications. The onset of TVC is a critical concern for navy surface ships and submarines that aim to increase capability to evade detection. A flexible thread attachment at blade tips was recently suggested as a new method to delay the onset of TVC. Although the occurrence of TVC can be reduced using a flexible thread, no scientific investigation focusing on its mechanisms has been undertaken. Thus, herein, we experimentally investigated the use of the flexible thread to suppress TVC from an elliptical wing. These investigations were performed in a cavitation tunnel and involved an observation of TVC using high-speed cameras, motion tracking of the thread using image-processing techniques, and near-field flow measurements performed using stereoscopic particle image velocimetry. The experimental data suggested that the flexible thread affects the axial velocity field more than the circumferential velocity field around the TVC axis. Furthermore, we observed no clear dependence of the vortex core size, circulation, and flow unsteadiness on TVC suppression. However, the presence of the thread at the wing tip led to a notable reduction in the streamwise velocity field, thereby alleviating TVC.

Lee, S.-Y.

"THE VORTEX AERODYNAMICS OF DELTA WINGS"

AIAA Paper 2016-4171, June 2016, Washington, DC.

Based on a proposed vortex/circulation model, this paper presents a set of equations representing the aerodynamic forces on a delta wing. In addition to the potential lift due to the bound circulation on the wing, a novel expression for the force due to the leading-edge separation vortex is established and is identified as the 'Linear Crossflow Vortex Force.' An empirical formula is also employed for the non-linear drag component. Since experimental data indicate that, at small to intermediate aspect ratios,

there is no contribution from the drag free pure potential lift and it can, thereby, be omitted. As a result, the sum of linear and non-linear normal forces from the current theory matches the experiments accurately, indicating that the aerodynamics is dominated by the crossflow vortex force. A function emulating the vortex breakdown behavior extend the data fit to post stall conditions. For larger aspect ratios, a much higher lift arises while the predicted vortex normal force begins to diminish, resulting in a transition to potential lift dominance. The current solution supports such a transition and converges to the classical infinite wing at very large aspect ratio. An examination of the right-angle apex planform, with aspect ratio of 4, demonstrates the shifting contribution from all lift components as the angle of attack increases, attributable to both leading edge separation and vortex breakdown phenomena.

Lee, S.-Y.

"THE VORTEX IMPULSE THEORY OF WING AERODYNAMICS"

AIAA Paper No. 2004-4733, Providence, RI, August 2004

A kinematic model of flow on an infinite flat plate is established, describing how the circulatory flow field is developed on the plate and how the circulation slips off to form wake vortices. The two-dimensional model is then extended to rectangular plates, proposing a circulation distribution relationship over the span that describes its dependency on the finite plate geometry. Built on these observations, a quasi-steady vortex impulse analysis method is developed and applied to calculate the linear, potential lift and drag forces on the plate. The results match remarkably well with experimental data. Several key findings are reported in the study: 1) the no-flow condition on the solid surface boundary is determined to be the sole cause for circulatory flows. More precisely, the circulation caused by the reactive flow at centerline yields the exact Kutta-Joukowski circulation expression. Shedding of the leeward circulation leaves the windward half attached to the wing, producing aerodynamic lift. 2) for wings of finite span, due to the presence of side edges, the circulatory flow must emanate in radial directions. As a result, the lifting capability is reduced due to this 'circulation diffusion effect'. The analytical expressions derived yield very accurate results compared to experiments but differ substantially in representation from the classical Prandtl 'Lifting-line Theory'.

Lee, T.

"EFFECTIVENESS OF DYNAMICALLY DEFLECTED TAB CONTROL OF A TIP VORTEX"

AIAA Journal, Vol. 45, December 2007, pp. 2994-3002

The control of the tip vortex generated by an oscillating NACA 0015 wing via a dynamically deflected trailing-edge tab, actuated at 29 different start times, amplitudes, and ramp-up rates, was investigated. The upward tab deflection was found to be more effective in weakening the peak tangential velocity and vortex strength than the downward deflection, regardless of the start time and ramp-up rate. A pair of corotating vortices was persistently noticed during pitch-up. An earlier and faster tab deflection (actuated during pitch-up) led to a larger reduction in the core vortex flow quantities. The downward

tab deflection was, however, more effective in displacing the vortex position and in diffusing the vortex. The later and slower the downward tab actuation, the larger the vortex displacement and diffusion that took place. The largest reduction in the vortex strength was obtained with a start time at the beginning of pitch-down. The effectiveness of the tab control was also evaluated via the hysteretic behavior of the vortex core flow quantity and the potential suppression of the blade-vortex-interaction noise.

Lee, T.

"PIV STUDY OF NEAR-FIELD TIP VORTEX BEHIND PERFORATED GURNEY FLAPS"

Experimental Fluids, Vol. 10, 2010.

The impact of Gurney flaps, of different heights and perforations, on the growth and development of a tip vortex, both along the tip and in the near field of a finite NACA 0012 wing, at $Re = 105000$ was investigated by using particle image velocimetry (PIV). Wind-tunnel force balance measurements were also made to supplement the PIV results. This study is a continuation of the work of Lee and Ko on the near-wake measurements behind perforated Gurney flaps. The present results show that along the tip, the overall behavior of the secondary vortices and their interaction with the primary, or tip, vortex remained basically unchanged, regardless of flap height and always exhibited a local maximum at $x/c = 0.8$ (from the leading edge). In the near field, the strength and structure of the near-field tip vortex were found to vary greatly with the flap height and perforation. The small flaps produced a more concentrated tip vortex with an increased circulation, while the large Gurney flaps caused a disruption of the tip vortex. The disrupted vortex can, however, be re-established by the addition of flap perforation. The larger the flap perforation the more organized the tip vortex. The Gurney flaps have the potential to serve as an alternative off-design wake vortex control device.

"INTERACTION OF A STREAMWISE VORTEX WITH A BLADE TIP VORTEX"

Journal of Aircraft, Vol. 43, No. 6, November-December 2006, pp. 1956-1958

The downstream development of a streamwise vortex interacted with a blade tip vortex was investigated. For separation distances $= 0$, the peak tangential velocity of the interaction vortex remained basically unchanged, whereas core circulation and core radius were increased approximately linearly with x/c . For separation distance < 0 , the generator vortex interacted constructively with the blade tip vortex of the same sign to create a single and stronger interaction vortex (i.e., a constructive mode). The values of core radius, core circulation and tangential velocity of the interaction vortex increased with reducing the absolute value of the separation distance and exhibited a local maximum at separation distance $= 0$. For separation distance > 0 , the passing generator vortex paired with the blade vortex of the same sign to create a field of a vortex pair (i.e., a pairing mode) with the generator vortex of larger core radius and core circulation but lower tangential velocity than the blade vortex.

"NAVIER-STOKES CALCULATION OF WING WAKE STRUCTURE"

AIAA Paper 1994-1882, June 1994, Colorado Springs, CO.

A 'flow embedding' method in Navier-Stokes calculation is developed to calculate a detailed wing wake structure. The method allows the calculation to be completed in two stages, first a global solution with a coarse grid and then the embedded solution in a small region of interest with a dense grid. The boundary condition for the latter is provided by the former. This embedded flow method is shown to produce a detailed and accurate wake structure for a 76-degree-delta wing by comparing the results with available data in the near wake. The computed results for the delta wing further downstream indicate that there are two concentrated vortices, one being the leading-edge vortex, and the other being the trailing vortex, rotating opposite to each other. These two vortices stay strong and well organized from feeding of wake shear layers. The total pressure and axial velocity of both vortices are increasing in the downstream direction. The leading-edge vortex tends to move down and outboard in the downstream direction; while the trailing vortex stays above the leading-edge vortex and moves inboard. For a rectangular wing of aspect ratio 6, the calculated results are also compared with the near-wake data. Again, two vortices are identified, one being the conventional tip vortex and the other being the trailing vortex. The tip vortex is formed at the wing tip and moves outboard and upward; while the trailing vortex is formed downstream of the trailing edge from the roll-up of shear layer and tends to move inboard and downward. The calculated results for the rectangular wing also indicate that the vorticity associated with the trailing vortex becomes more concentrated even though its magnitude decreases downstream. Calculated total velocity in the core and the maximum tangential velocity around the trailing vortex core are shown to agree reasonably well with experimental data.

Lee, T. and Nikolic, V.

"EFFECTS OF A MOVABLE TIP STRAKE ON WAKE VORTEX STRUCTURE"

Journal of Aircraft, Vol. 45, No. 4, July-August 2008, pp. 1305-1314.

The impact of a tip-mounted strake, set at different deflection angles relative to the main-wing chord plane on the near-field wake vortex structure, and the associated lift-induced drag were investigated experimentally at $Re=191,000$. Force-balance aerodynamic forces were also obtained to supplement the wake vortex measurements. The results show that in addition to its substantial influence on the aerodynamic performance, the presence of the strake also led to an earlier completion of the rolling up of the tip vortex, compared with the baseline wing. The tip vortex had a reduced peak tangential velocity and core axial velocity but an increased core radius, compared with the baseline wing. These vortex core flow quantities increased with increasing strake angle. The core and total circulation increased above and remained below the baseline-wing value for a strake angle greater than 5 deg and less than 5 deg, respectively. The lift-induced drag, computed by using the Maskell induced-drag model,

was found to increase nonlinearly with strake angle and became larger than the baseline wing for a strake angle greater than 5 deg.

Lee, T. and Pereira, J.

"PASSIVE CONTROL OF UNSTEADY-WING TIP VORTEX VIA A SLENDER HALF-DELTA WING IN BOTH REVERSE AND REGULAR CONFIGURATIONS"

Experimental Fluids, Vol. 55, 2013, pp. 1564-1 to 1564-10.

The passive control of the tip vortex generated by an oscillating NACA 0012 wing via a tip-mounted half-delta wing, in both regular and reverse configurations, was investigated experimentally at $Re = 245,000$. Velocity and vorticity measurements, performed using a miniature triple hot-wire probe, show that vortex breakdown occurred when the half-delta wing (HDW) was mounted, but not for the reverse half-delta wing (RHDW) configuration. The HDW vortex breakdown led to a rapidly diffused tip vortex, suggesting an enhanced wake-vortex decay. For the RHDW wing configuration, the tip vortex remained concentrated but had a smaller size and also a weaker strength and rotation compared to the oscillating baseline wing. In addition, the vortex center of the oscillating RHDW wing-generated tip vortex was also found to be greatly displaced, especially in the transverse direction, which could translate into an increased blade-vortex-impingement miss distance and, as a result, an alleviated blade-vortex interaction.

Lee, T. and Pereira, J.

"IMPACT OF SHORT-SPAN STRIP ON OSCILLATING-WING TIP VORTEX"

Experiments in Fluids, Vol. 43, 2007, pp. 617-626

The impact of 12 spoiler-tab configurations, of different heights and widths, on the tip vortex generated by an oscillating NACA 0015 wing was investigated experimentally. For an oscillating wing equipped with a spoiler, the peak tangential velocity and core and total circulation were greatly reduced compared to a tab, regardless of its width, while the core radius remained largely unaffected with its center displaced vertically above the baseline wing. The most noticeable impact of a spoiler with a reduced height was its potential in alleviating the blade vortex interaction (BVI) strength. Meanwhile, the largest favorable impact on the critical vortex flow parameters was achieved via a 25%-span spoiler-tab combination with a height of 5 and 2.5% chord, respectively. A contrary effect on the BVI suppression, especially during pitch-up, was, however, observed. The impact on the BVI can be improved by reducing the height of the spoiler at the expense of unfavorable change in the vortex strength and displacement.

Lee, T. and Pereira, J.

"NATURE OF WAKELIKE AND JETLIKE AXIAL TIP VORTEX FLOWS"

Journal of Aircraft, Vol. 47, No. 6, Nov.-Dec. 2010, pp. 1946-1954.

The mechanisms responsible for the wake like and jet like axial flows of a tip vortex were investigated experimentally at $Re = 307000$. Both square and round tips were tested. Along the wing tip, a pocket of a higher-than-freestream, or jet like, fluid was continually present, regardless of the tip condition and airfoil angle of attack. Its maximum velocity increased with angle of attack and always exhibited a peak value around the trailing edge. In the near field, this jet like fluid pocket was entrained by the shear layers and the wing wake, and it resulted in a wake like axial flow for smaller angles of attack. For higher angles of attack, the jet like fluid pocket was, however, surrounded by the shear layers that, in turn, protected it from the destructive effects of the wing wake and remained jet like. The switchover angle at which the axial flow switched from wake like to jet like appeared around 7 degrees regardless of the tip condition, which also coincided with the angle at which the lift-to-drag ratio was a maximum. Finally, the round-tip-produced vortex was more concentrated and had a higher peak tangential velocity and core circulation but a smaller core radius compared with those of the square tip.

Lee, T. and Su, Y. Y.

"WINGTIP VORTEX CONTROL VIA THE USE OF A REVERSE HALF-DELTA WING"

Experimental Fluids, Vol. 52, 2012, pp. 1593-1609.

The effect of a 65-degree-sweep reverse half-delta wing (RHDW), mounted at the squared tip of a rectangular NACA 0012 wing, on the tip vortex was investigated experimentally at $Re = 245,000$. The RHDW was found to produce a weaker tip vortex with a lower vorticity level and, more importantly, a reduced lift-induced drag compared to the baseline wing. In addition to the lift increment, the RHDW also produced a large separated wake flow and subsequently an increased profile drag. The reduction in lift-induced drag, however, outperformed the increase in profile drag and resulted in a virtually unchanged total drag in comparison with the baseline wing. Physical mechanisms responsible for the RHDW-induced appealing aerodynamics and vortex flow modifications were discussed.

Lee, T. E., Leishman, J. G. and Ramasamy, M.

"FLUID DYNAMICS OF INTERACTING BLADE TIP VORTICES WITH A GROUND PLANE"

Journal of the American Helicopter Society, Vol. 55, 2010, pp. 022005-1 to 022005-16.

Flow visualization and phase-resolved particle image velocimetry (PIV) experiments were conducted on a hovering rotor to help understand the fluid dynamics of its vortical wake as it interacted with a horizontal ground plane. Visualization was performed by illuminating submicron tracer particles using a strobed laser sheet that was phase locked to the rotational frequency of the rotor. Two-component PIV measurements of the flow in radial planes were obtained at four rotor heights off the ground. Measurements at several wake ages were obtained to examine the morphology of the wake-surface interaction process. The results showed that the rotor wake and its downwash flow are initially subjected to powerful curvature and straining effects as it is deflected into a radially outward direction at the ground plane. An unsteady outward flow comprising a wall jet then developed in the region

between the ground plane and the vortical remnants of the rotor wake. The viscous processes of diffusion, vorticity intensification by straining, as well as turbulence generation were all shown to be factors affecting the fluid dynamics of the resulting flow field. In general, the tip vortices were found to induce significantly unsteady flow velocities if they reached the ground plane without undergoing substantial diffusion, especially when they remained coherent enough for adjacent vortices to pair and possibly merge. Further away from the rotor, the turbulence and velocity gradients in the developing wall jet were noted to shear the tip vortices and accelerate the diffusion of vorticity. An intermediate rotor height off the ground was found where the diffusion of vorticity was countered by the straining effects in the flow, which in this case resulted in the highest flow velocities and shear stresses on the ground plane.

Lee, T., Birch, D. and Gerontakos, P.

"VORTEX SHEDDING AND SPACING OF A ROTATIONALLY OSCILLATING CYLINDER"

AIAA Journal, Vol. 42, No. 6, 2004, pp. 1268-1272

The vortex wake behind a rotationally oscillating circular cylinder at $Re = 1750$ was investigated. Depending on the forcing frequency and amplitude, different vortex-shedding modes, like those observed for a cylinder in transverse and sinusoidal motion were observed. The vortex wake expanded for oscillation frequencies less than the Karman frequency whereas it contracted for frequencies greater than the Karman frequency. The longitudinal spacing decreased significantly with increasing oscillation frequency and changed to a much lesser degree with an increase in the oscillation amplitude. In contrast, the lateral spacing of the shed vortices showed a relatively weaker dependence on the rotary oscillation. Further experiments on the vortex strength and formation are needed to better understand the characteristics of the various synchronized wake patterns.

Lee, T.-C.

"NAVIER-STOKES SOLUTION OF WING WAKE STRUCTURE AND ITS PERTURBATION"

Ph.D. Thesis, January 1993, Univ. of Kansas, Lawrence, KS.

A 'flow embedding' method based on Navier-Stokes solutions is developed to calculate detailed wing wake structures. The method allows the calculation to be completed in two stages, first a global solution with a coarse grid and then the embedded solution in a small region with a dense grid. The main advantages of this two-staged scheme are: (1) it provides a very fine grid resolution in the region of interest to capture flow details; and (2) it calculates efficiently without demanding huge computer memory space. This embedded flow method, when comparing the numerical results with available experimental data in the near wake, is shown to produce a detailed and accurate wake structure for a delta wing. The computed results further downstream indicate that there are two concentrated vortices, one being the leading-edge vortex, and the other being the trailing vortex, rotating opposite to each other. These two vortices stay strong and well organized from feeding of wake shear layers. Due to this effect, the total pressure and axial velocity of both vortices are increasing in the

downstream direction. For the rectangular wing of aspect ratio 6, the calculated results are also compared with near-wake experimental data. Again, two vortices are identified, one being the conventional tip vortex and the other being the trailing vortex. The tip vortex is formed at the wing tip and moves outboard and upward; while the trailing vortex is formed downstream from the roll-up of shear layer and tends to move inboard and downward. The calculated total velocity in the core and the maximum tangential velocity around the trailing vortex core are shown to agree reasonably well with experimental data. The steady-state Navier-Stokes solution of the local wake flow region further serves as a base flow for wake attenuation investigations. An oscillatory disturbance is imposed at the trailing edge of the wing to excite the instabilities of the wake flow. Results from the unsteady computations indicate that the current scheme can excite the wake flow with limited success.

Lee, Y. L. and Gursul, I.

"AN INVESTIGATION OF UNSTEADY INTERACTIONS OF A VORTEX PAIR OVER DELTA WINGS"

AIAA Paper No. 2003-0423, Reno, NV, January 2003

An investigation of unsteady interactions of a vortex pair over stationary delta wings was carried out. Two-point measurements of unsteady flow velocity were performed to detect the unsteady interactions in a wind tunnel investigation. Response of the vortex pair to controlled antisymmetric perturbations was studied. Results show that the vortex pair does not respond to antisymmetric perturbations at low angles of attack. As incidence is increased, even before vortex breakdown appears on the wing, the vortex pair becomes responsive to the antisymmetric perturbations over a range of excitation frequencies. This range of frequencies agree very well with the theoretical predictions for an idealized point vortex pair over slender delta wings. When vortex breakdown is near the trailing-edge, largest responses were observed, indicating a coupling with antisymmetric oscillations of vortex breakdown locations.

Leese, G. W.

"UH-1H DOWNWASH VELOCITY MEASUREMENTS"

Final Report, August 1972, US Army Engineer Waterways Experiment Station, Vicksburg, Mississippi (and Misc. Paper S-72-31).

Field measurements were made to determine the velocity of the horizontal and vertical downwash flow beneath the rotor of a UH-1H helicopter. Maximum downwash velocities measured during a 7-sec period were as follows: Horizontal, 41 feet from center of rotor rotation, hover height 10 feet and 59 mph maximum downwash velocity; Vertical, 29 feet from center of rotor rotation, hover height 30 feet and 30 mph maximum downwash velocity.

Leese, G. W. and Knight Jr, J. T.

"HELICOPTER DOWNWASH DATA"

Misc PAPER S-74-17, June 1974, US Army Engineer Waterways Experimental Station, Vicksburg, MS.

The report describes an investigation involving measurement of horizontal velocities, along and up to six feet above the ground surface, generated by the rotor systems of various Army helicopters during takeoff, hover, and fly-by operations. Measurements of ground-wash velocities during various operational modes were collected for OH-58A, OH-6A, AH-1G, UH-1H, UH-1M, CH-47, and CH-54 helicopters.

Lehman, A. F.

"MODEL STUDIES OF HELICOPTER TAIL ROTOR FLOW PATTERNS IN AND OUT OF GROUND EFFECT"

USAAVLABS TR-71-12, April 1971, Oceanics Inc., Plainview, NY

Water tunnel studies of a model helicopter which entailed a visualization of the main and tail rotor wakes, the inflow patterns, and their subsequent interactions as the wind velocity and wind reading were changed are presented. Of significant interest was the impingement of the main rotor wake with a ground plane.

Leibovich, S.

"WAVE PROPOGATION, INSTABILITY, AND BREAKDOWN OF VORTICES"

Vortex Motion: Proceedings of a Colloquium Held at Goettingen on the Occasion of the 75th Anniversary of the Aerodynamische Versuchsanstalt in November 1982, edited by Hornung, H. G. and E. A. Mülle.

The themes of wave propagation and hydrodynamic stability have played prominent roles in attempts to understand the phenomenon of vortex breakdown. Recent theoretical and experimental work provide evidence that waves and instabilities are important elements of the vortex breakdown process. Breakdown of vortex cores at high Reynolds numbers may occur in one of two forms: the apparently axisymmetric ('bubble') form or the 'spiral' form. The application of soliton theory and hydrodynamic stability theory to both forms is discussed, together with a new large amplitude theory for axisymmetric waves.

Leibovich, S.

"VORTEX STABILITY AND BREAKDOWN: SURVEY AND EXTENSION"

AIAA Journal, Vol. 22, No. 9, September 1984, pp. 1192-1206

Given a model describing the smooth streamwise evolution of a vortex core, the position of breakdown may be estimated by computing the Froude number N , the stability ratio q/q_c where q_c corresponds to the critical value of q . In the observations that can be documented, stationary vortex breakdown occurs in supercritical regions, N greater than 1. The location seems to correlate better

with the point at which the vortex reaches a marginally stable condition than it correlates with the point at which critical conditions are obtained. A new conceptual framework is suggested based upon information derived from experimental studies of vortex breakdown. In the picture put forward, growth of axisymmetric modes occurs as a result of propagation in a variable vortex waveguide, and this wave loses stability to three-dimensional disturbances when it reaches a critical amplitude. Energy drain from the axisymmetric wave to the non-axisymmetric modes serves to fix the possible equilibrium positions of the vortex breakdown, which is identified with a large amplitude axisymmetric wave and smaller amplitude superposed non-axisymmetric wave modes.

Leibovich, S.

"WAVE MOTION AND VORTEX BREAKDOWN"

AIAA Paper No. 1969-0645, San Francisco, CA, 1969

Vortex breakdown is a phenomenon occurring in rotating fluids when there is a component of velocity along the axis of rotation. It occurs in many flows including the conical vortex cores above delta wings on an angle of attack, leading to an abrupt deceleration of the flow and the consequent rapid expansion of stream surfaces. In the original theory, due to Squire, it was suggested that the phenomenon was related to wave motion along the rotation axis. Squire's theory was for infinitesimal perturbations, and Benjamin pointed out a serious inconsistency which discredited the wave idea. Here the wave theory is re-examined, by considering the effects of nonzero wave amplitude. It is found that a nonlinear wave theory is consistent, is easy to calculate, and is quite flexible, allowing treatment of both incompressible and compressible fluids, in either axially-symmetric or spiral wave modes.

Leibovich, S.

"THE STRUCTURE OF VORTEX BREAKDOWN"

Annual Review of Fluid Mechanics, Vol. 10, Ann. Rev. Inc., Palo Alto, 1978, pp. 221-246

A survey of experimental and theoretical work on vortex breakdown published since the 1972 review by Hall. All studies have been carried out at low speeds so only incompressible motions are considered.

"PAIRED APPROACH FLIGHT DEMONSTRATION: PLANNING AND DEVELOPMENT ACTIVITIES"

2018 Integrated Communications Navigation and Surveillance (ICNS) Conference, Paper 3G4, April 2018, Herndon, VA.

Simultaneous arrivals to closely spaced parallel runways (CSPR) are permissible when visual approaches can be conducted, and visual separation from the lead aircraft and its wake can be provided by the trail aircraft flight crew. During instrument meteorological conditions (IMC), CSPR

visual approaches cannot be conducted, and instrument approach procedures are used. These procedures reduce the airport capacity because of increased separation to compensate for surveillance uncertainty and larger collision avoidance response times associated with having a controller in the loop. To increase capacity during IMC, the Paired Approach procedure has been developed. The Paired Approach procedure is a part of Interval Management (IM), which leverages automatic dependent surveillance-broadcast (ADS-B) Out for the lead aircraft (referred to as the Target aircraft) and ADS-B In for the trail aircraft (referred to as the IM aircraft). During the Paired Approach procedure, the IM aircraft uses speed commands from the flight-deck IM (FIM) equipment to maintain precise spacing between itself and the Target aircraft. The IM flight crew is given a time-based spacing parameter referred to as the assigned spacing goal, which is the desired spacing behind the Target aircraft. The desired spacing between the IM and Target aircraft in a Paired Approach operation is the spacing that will keep the IM aircraft far enough behind the Target aircraft to avoid the risk of a collision while still being close enough to the Target aircraft to avoid an encounter with its wake. The FAA is conducting a Paired Approach Flight Demonstration at San Francisco International Airport in early 2019. Honeywell is developing the prototype avionics that will be used and Alaska Airlines, United Airlines, and Honeywell are providing aircraft. The FAA is choosing to scope the demonstration based on a limited part of the Paired Approach operational concept due to technology and concept maturity.

Leishman, J. G.

"MEASUREMENTS OF ROTOR TIP VORTICES USING LASER DOPPLER VELOCIMETRY"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany, pp. 449-458.

An experimental investigation has been made to study blade tip vortex structure in the wake of hovering rotors using three-component laser Doppler velocimetry. Several interesting conclusions have been drawn from the study. First, the swirl or tangential velocity profiles surrounding the tip vortices were found to be asymmetric. This is because of the curved nature of the vortices, which produces a self-induced effect. Second, for the one-bladed rotor the vortex core was found to diffuse approximately with the square-root of wake age up to the first blade passage. For the two-bladed rotor, the initial core size was somewhat larger and the tip vortices did not diffuse as quickly. However, in each case the core sizes after the first blade passage were approximately the same. Third, at the first blade passage event, a change was observed in the tip vortex diffusion because of an increase in tangential velocity and decrease in viscous core size. However, the net circulation about the vortex remained constant throughout. Fourth, the tip vortices from both rotors exhibited deficit type axial velocity profiles in their early stages, although of considerably different magnitude.

Leishman, J. G.

"SEED PARTICLE DYNAMICS IN TIP VORTEX FLOWS"

J. Aircraft, Vol. 33, No. 4, July-August 1996, pp. 823-825

Experiments and calculations have been conducted to explore issues associated with seeding of strong vortical flows for LDV measurements, such as flows induced by the tip vortices generated by rotors. Both velocity errors and statistical weighting of the seed distribution through the vortex have been examined. Radial velocity errors tend to be larger than swirl errors, and dominate up to two core radii from the vortex axis. The weighting of seed is such that the core (rotational) region suffers a scarcity of particles, with a peak in the density distribution well outside the viscous core. This distribution is very sensitive to particle mass and size. A nondimensional parameter has been developed to help quantify the likelihood of successfully seeding a typical vortex flow.

Leishman, J. G.

"UNSTEADY AERODYNAMICS OF AIRFOILS ENCOUNTERING TRAVELING GUSTS AND VORTICES"

J. Aircraft, Vol. 34, No. 6, November-December 1997, pp. 719-729

By means of the reverse flow theorems, results are obtained for the unsteady lift and pitching moment on two-dimensional airfoils penetrating sharp-edged traveling gusts. Both downstream and upstream traveling gusts are considered. For the incompressible case, exact results are given and are generalized numerically for any gust field by means of Duhamel superposition. Results are then given for the air loads and acoustics generated by a two-dimensional airfoil encountering a vortex convecting at different gust speed ratios. Numerical results for the traveling sharp-edged gust problem are also derived for subsonic flows by means of exact linear theory. Further results for the subsonic case are computed by means of an Euler finite difference method. It is found that the gust speed ratio has substantial effects on the unsteady air loads and will be an important parameter to represent in helicopter rotor aero acoustic problems.

Leishman, J. G.

"MEASUREMENTS OF THE APERIODIC WAKE OF A HOVERING ROTOR"

Experiments in Fluids, Vol. 25, 1998, pp. 352-361

An experimental investigation was made to study the aperiodic flow characteristics of the tip vortices generated by one-bladed and two-bladed hovering rotors. Measurements of the tip vortex locations and accompanying aperiodicity statistics were established as a function of vortex age. Velocity field measurements were made using three-component laser Doppler velocimetry. The average amplitude of the aperiodicity was found to be a fraction of the measured viscous core radius, this being approximately 5% of blade chord or about 50% of the core radius for wake ages of less than two rotor revolutions. The aperiodicity appeared isotropic. A numerical analysis of the aperiodicity problem based on convolution with an assumed displacement probability function showed that for this experiment the measured tangential velocities in the tip vortices were underestimated by approximately 20%. There was no evidence that the number of blades or the blade passage adversely influenced the aperiodicity of the rotor tip vortices.

Leishman, J. G.

"INTRODUCTION: ROTOR WAKES"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, p. 721.

This special issue of the Journal of Aircraft concerns the improved understanding and prediction of rotor wake aerodynamics of helicopters and tilt rotors. This task continues to be of fundamental importance in defining blade aerodynamics, and in evaluating new and improved rotor designs that are more efficient in hover and forward flight, show lower vibration levels, and are also acoustically quieter. As this special issue shows, the field of rotorcraft aerodynamics, particularly the subject of rotor wakes, will continue to challenge the rotorcraft analysts of the future with some of the most fascinating problems in fundamental fluid dynamics and applied aerodynamics.

"CHALLENGES IN UNDERSTANDING THE VORTEX DYNAMICS OF HELICOPTER ROTOR WAKES"

AIAA Journal, Vol. 36, No. 7, July 1998, pp. 1130-1140

Many experimental challenges are encountered when attempting to understand the complex vortical wakes generated by helicopter rotors. The problems are illustrated by means of several examples, including blade/vortex interactions, vortex perturbations, wake instabilities, and vortex/surface interaction phenomena. Specific emphasis is placed on flow visualization and quantitative measurements using laser Doppler velocimetry.

Leishman, J. G. and Martin, P. B.

"MEASUREMENTS OF THE TRAILED VORTEX WAKE FROM A HELICOPTER ROTOR"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Improved helicopter designs require a much better understanding of the flow physics produced by the intense wake vortex system generated by the main rotor. A helicopter rotor wake is known to be highly dynamic, vortical, and three-dimensional in nature, being comprised mostly of intertwining tip vortices generated by the blades. These tip vortices may remain close to the rotor plane as localized, coherent flow structures for several rotor revolutions after they are generated. The present work reports on high-resolution three-dimensional velocity-field measurements and flow visualization results that were acquired in the wake of a sub-scale helicopter rotor blade. Using three-component laser Doppler velocimetry (LDV), the measurements documented the trailing tip vortex formation, its initial structure, and the viscous evolution of the vortex core. The test conditions covered a range of wake-ages from as young as one-degree, up to about one rotor revolution. For each wake age, vortex core properties were estimated from the velocity-field measurements. The high spatial and temporal resolution of the measurements (obtained, in part, through a precise alignment of the LDV optics using a laser beam profiler) has shown that the tip vortex core radius can be less than 3% of chord just at

formation, but grows asymptotically as it ages. A significant axial velocity deficit was found in the vortex core, which was of the order of the peak swirl velocity at early wake-ages but quickly diminished as the tip vortex aged. Using a Richardson parameter combined with strobed laser light-sheet visualization of the tip vortex flow, the results suggest that the inner core of the tip vortex is mostly laminar at the vortex Reynolds numbers obtained in this experiment. It was found that bands of turbulent eddies, originating from an adjacent vortex sheet trailed by a blade, underwent a relaminarization process as they were entrained into the vortex core. The evidence suggests that the entire tip vortex structure is neither fully laminar or fully turbulent, but is instead in a continuous state of dynamic evolution with a region of relatively slow laminar diffusion and a region of accelerated turbulent diffusion. It is suggested that the variation of peak swirl velocity is the result of the competing influences of an inviscid roll-up process and viscous diffusion within the tip vortex.

Leishman, J. G., Bhagwat, M. J. and Ananthan, S.

"FREE-VORTEX WAKE PREDICTIONS OF THE VORTEX RING STATE FOR SINGLE-ROTOR AND MULTI-ROTOR CONFIGURATIONS"

58th Annual Forum, American Helicopter Society, June 2002, Montreal, Canada.

Results are shown that give a better understanding of factors that may influence the initiation and subsequent development of the vortex ring state (VRS) on single rotors, tandems, and laterally side-by-side (tiltrotor) configurations. This problem is approached from the perspective of vortex wake theory and a wake stability analysis. The results show that for all types of rotors operating in hover or at low rates of descent, the rotor wake is inherently unstable. Increasing the descent velocity makes the wake more susceptible to developing instabilities, which causes the regular helicoidal form of the wake to break down. Eventually, higher rates of descent take the rotor into the beginnings of the VRS, the onset of which occurs when wake instabilities reach the rotor disk. The low net velocity near the rotor at these higher rates of descent causes vorticity to accumulate near the rotor plane, forming tight bundles resembling vortex rings. This is an unstable flow condition, where the rings develop Kelvin waves and periodically break away from the rotor disk, leading to the aperiodic fluctuations of blade air loads and rotor thrust that is characteristic of the VRS. The results show that the wake breakdown and onset of VRS depends on several factors that are a consequence of rotor configuration, and as well as the rotor operating state. Maneuvering flight issues are also shown to be significant factors that can affect the conditions for wake breakdown. The vortex wake characteristics of the tiltrotor configuration is investigated in some detail because of the significant asymmetric interactions that can occur between the two rotor wakes when in descending flight.

Leishman, J. G., Bhagwat, M. J. and Ananthan, S.

"THE VORTEX RING STATE AS A SPATIALLY AND TEMPORALLY DEVELOPING WAKE INSTABILITY"

American Helicopter Society International Specialists Meeting on Aerodynamics, Acoustics and Test and Evaluation, San Francisco, CA, January 2002

It is shown that the onset and development of the vortex ring state (VRS) on a rotor can be viewed as a spatial and temporal wake instability. A linearized wake stability (eigenvalue) analysis and a second-order-time accurate free-vortex method are used to show that the flight conditions leading to the onset of wake instabilities are rotor configuration and operating state specific. In hovering flight the rotor wake is shown to be in unstable equilibrium, and the wake stability increases with climb rate. However, in descending flight the wake is shown to be more susceptible to the onset and persistence of instabilities because of the reduced helicoidal spacing between the individual vortex filaments. The results suggest that equilibrium descending flight conditions can be reached when wake instabilities are being formed as quickly as they are being convected away from the rotor. A slightly greater rate of descent then takes the rotor into the beginnings of the VRS, the onset of which occurs when disturbances produced by the wake instabilities reach the rotor disk. Under these conditions, the rotor wake may recirculate in the rotor plane as individual tip vortices form tight bundles of vorticity resembling vortex rings. These rings are spatially and temporally unstable, and break away from the rotor disk leading to the aperiodic fluctuations of blade air loads and rotor thrust that are characteristic of the VRS. The results suggest that subtle differences in the onset of VRS are a consequence of rotor configuration and operating state. Side-by-side rotor configurations are shown to have interesting asymmetric VRS characteristics resulting from mutual interactions between the two rotor wakes, the onset of which occurs at relatively low rates of descent.

"FREE-VORTEX FILAMENT METHODS FOR THE ANALYSIS OF HELICOPTER ROTOR WAKES"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 759-775

The theoretical basis and the numerical implementation of free-vortex filament methods are reviewed for application to the prediction and analysis of helicopter rotor wakes. The governing equations for the problem are described, with a discussion of finite difference approximations to these equations and various numerical solution techniques. Both relaxation and time-marching wake solution techniques are reviewed. It is emphasized how the careful consideration of stability and convergence (grid-independent behavior) are important to ensure a physically correct wake solution. The implementation of viscous diffusion and filament straining effects are also discussed. The need for boundary condition corrections to compensate for the inevitable wake truncation are described. Algorithms to accelerate the wake solution using velocity field interpolation are shown to reduce computational costs without a loss of accuracy. Several challenging examples of the application of free-vortex filament methods to helicopter rotor problems are shown, including multirotor configurations, flight near the ground, maneuvering flight conditions, and descending flight through the vortex ring state.

"SURFACE AND WAKE FLOW CHARACTERISTICS OF A HOVERING HELICOPTER ROTOR"

9th International Symposium on Flow Visualization, Paper No. 189, 2000, pp. 189-1-189-10

Surface flow visualization methods were examined for potential application to a hovering helicopter rotor blade. These techniques included liquid crystals, chemical sublimation, and fluorescent oil flow. Test cases involved both the identification of a laminar separation bubble and the effects of a serrated boundary layer trip strip. The results were used to understand some of the boundary layer physics associated with sub-scale helicopter rotor testing. In addition, the vortex system trailed into the wake behind the rotor blades was studied using laser sheet smoke flow visualization. The results were supported by quantitative measurements of the flow made using LDV and PIV.

Lele, S. K.

"VORTEX-WAKE POLLUTION: A PROBLEM IN FLUID MECHANICS"

Lecture Notes in Physics, Vol. 566, 2001, pp. 163-181.

The vortex-wake of an airplane contains a system of one or more pairs of trailing vortices. The vortex-wake interacts with the surrounding atmosphere and decays due to instabilities such as the Crow instability. The downwash associated with the wake constitutes a hazard to other airplanes since it may cause an appreciable loss of lift and/or induce a rolling-moment. This can be dangerous if the second airplane is near the ground such as during takeoffs and landings. In this paper we begin by drawing parallels between this problem of air-space pollution near airports due to vortex-wakes and other environmental pollution problems. Attention is focused on how fluid mechanical processes influence different elements of this problem and on fluid mechanical means with potential of alleviating the wake hazard.

"A FAST RESPONSE PROBE SYSTEM FOR IN-FLIGHT MEASUREMENTS OF ATMOSPHERIC TURBULENCE"

Aerospace Science and Technology, Vol. 6, 2002, pp. 233-243.

A fast response probe for in-flight, three-dimensional measurements of atmospheric turbulence is presented. The system comprises a commercial five-hole probe connected to miniature pressure transducers by extremely short pneumatic lines. This design yields high dynamic response with negligible transmission errors at least up to 10 Hz. The transducers are installed into a temperature-conditioned shell to eliminate thermal zero and sensitivity shifts during flight. The system has been tested on the Falcon D-CMET research aircraft of the German Aerospace Center (Deutsches Zentrum für Luft- und Raumfahrt, DLR) in Oberpfaffenhofen at flight altitudes up to 37000 ft (11278 m) and Mach numbers up to 0.75. Spectral analyses of the air-data obtained by the system confirm the predictions concerning its high frequency response capabilities. Simultaneous measurements with conventional air sensing devices installed in the aircraft provide evidence regarding the operational reliability and the accuracy of the system.

Lengendre, R.

"EFFECT OF WING TIP SHAPE ON VORTEX SHEET ROLLING UP"

Rech. Aerosp., No. 4, July-August 1971, pp. 227-228

Laws of separation over a whole wing are applied to study straight or moderately swept back wings. The effect of vortex sheet rolling up can be avoided by tailoring the profile of the trailing edge to the edge of a wing or blade, with constant or zero leading edge sweepback, in such a way as to make a clear distinction between the leading and trailing edges. Break phenomena are studied.

"APPLICATION OF THE LASER VELOCIMETER FOR TRAILING VORTEX MEASUREMENTS"

AEDC-TR-74-26, December 1974, ARO Inc., Arnold Air Force Station, TN

This report summarized a three-year analytical and experimental program to develop a dual-scatter laser velocimeter system to map the flow field of trailing vortices stemming from the wingtips of flying aircraft. The basic design parameters ascertaining feasibility of the LV-measuring technique are presented. Included is a discussion and evaluation of a newly developed two-dimensional Bragg cell for resolving directional ambiguity. The electronics instrumentation developed for the operation of the Bragg cell is evaluated in detail.

Leonard, A.

"VORTEX METHODS FOR FLOW SIMULATION"

Journal of Computational Physics, Vol. 37, 1980, pp. 289-335.

Recent progress in the development of vortex methods and their applications to the numerical simulation of incompressible fluid flows are reviewed. Emphasis is on recent results concerning the accuracy of these methods, improvements in computational efficiency, and the development of three-dimensional methods. Simulations of several example flows which display some of the strengths and weaknesses of vortex methods are presented.

Leopold, F., Jagusinski, F. and Demeautis, C.

"EXPERIMENTAL INVESTIGATION OF SHOCK/VORTEX INTERACTION FOR SLENDER CANARD CONFIGURATION AT SUPERSONIC SPEED"

Proceedings 20th International Congress on Instrumentation in Aerospace Simulation Facilities 2003, Gottingen, Germany, August 25-29, 2003, pp. 247-257

The interaction of a concentrated vortex and a shock wave may occur in many cases in the operational environment of supersonic aircraft and missiles. The interaction may be the result of vortices created by the forward components of a supersonic vehicle (for example canards, wings, etc.)

convecting downstream and interacting, for example, with shock waves present in front of air intakes or other wings. The objective of the present work is to conduct experimental studies simulating the interaction of streamwise wing-tip vortices with shock waves in supersonic flows. Flow-field visualizations show the different behavior (for example: unsteady vortex breakdown). To elucidate the complex flow containing shock waves, backflow and large-scale fluctuations, measurements using a laser Doppler velocimeter (LDV) were carried out.

Leopold, F., Richard, H., Raffel, M. and Christnacher, F.

"EXPERIMENTAL INVESTIGATIONS OF THE INTERACTION OF SUPERSONIC WING-TIP VORTICES WITH A NORMAL SHOCK"

11th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, July 2002

The interaction of a concentrated vortex with a shock wave may occur in many instances in the operational environment of supersonic aircraft and missiles. The interaction may be the result of vortices created by the forward components of a supersonic vehicle convecting downstream and interacting, for example, with shock waves present in front of air intakes or other wings. The objective of the present work was to conduct an experimental study simulating the interaction of streamwise wing-tip vortices with normal shock waves in a Mach 3 flow. Therefore, an experimental study was conducted to simulate the interaction of streamwise wing-tip vortices and normal shock waves. In this paper two recently developed visualization techniques are shown. The results of the Background Oriented Scattering (BOS), invented at DLR, are compared to the flow-field visualizations, obtained by using the ISL holographic filters. To elucidate the complex flow containing shock waves, backflow and large-scale fluctuations, measurements using a laser Doppler velocimeter (LDV) were carried out.

Leppington, F. G.

"THE FIELD DUE TO A PAIR OF LINE VORTICES IN A COMPRESSIBLE FLUID"

J. Fluid Mech., Vol. 559, 2006, pp. 45-55

The problem considered is that of a self-propagating pair of line vortices, of equal and opposite strengths, in a compressible inviscid fluid. An asymptotic solution is sought in the limit of small propagation speed compared with the sound speed in the medium. In most of the fluid region, the elementary incompressible flow solution limit is enhanced by a Rayleigh-Janzen approximation. This approximation fails at points that are either far from, or very close to, a vortex. For distant points, rescaled outer variables lead to an approximation that corresponds to the field induced by a moving dipole in compressible fluid. The main approximation also fails near each vortex line, where the analysis of Barsony-Nagy, Er-el & Yungster (J. Fluid Mech. Vol. 178, 1987, p. 367) is used to express the local flow field in terms of a hypergeometric function.

Leroy, A., Buron, F. and Devinant, P.

"UNSTEADY AERODYNAMIC MODEL FOR THIN WINGS WITH EVOLUTIVE VORTEX SHEETS"

RTO AVT Symposium on 'Advanced Flow Management: Part A - Vortex Flows and High Angle of Attack for Military Vehicles', Loen, Norway, May 2001.

This paper presents recent advances in a computing method for unsteady inviscid incompressible flows around thin lifting surfaces with arbitrary motion. This involves the velocity field, deriving from a potential, the pressure field, and the free vortex sheet characteristics (geometry and vortex strength). When considering high angles of attack, the separation lines along which the vortex sheets are shed are the trailing edge, as well as wing tips or parts of the leading edge. Compared to classical methods of singularity, such as panel methods, an improved vortex wake model was constructed. It consists in representing the wake by a vortex particle concept, particularly well-suited for the prediction of its unsteady deformations. This approach stems from the unsteady vortex sheet theory established by MUDRY, in which the vortex sheet is considered as a median layer, on which is founded the concept of continuous vortex particle. This ensures the computing method to compare favorably with the classical methods in terms of flexibility and computing costs. Computed unsteady flow-field simulations are presented for several cases and compared with some available experimental data.

Leroy, A., Molton, P., Carpels, Y. and Pons, J.

"EXPERIMENTAL STUDIES OF DBD ACTUATOR EFFECTS ON WING TIP VORTEX TOPOLOGY"

AIAA Paper No. 2012-2951, June 2012, New Orleans, LA.

Experiments studying the wing tip vortex, generated by a rectangular wing with a symmetric airfoil section and a straight tip, manipulated by surface plasma actuators are presented in this paper. Objectives are focused on modifying vortex development to alter streamwise vorticity downstream of the wing trailing edge. Actual limitation of the ionic wind magnitude obtained with DBD actuators leads to investigate vortex control by action on the transverse component of the freestream flow velocity. Different DBD arrangements installed near the wing tip were tested to examine effects of momentum addition, firstly on the pressure and suction side surfaces, and secondly, simultaneously located more precisely on the main vortex separation and attachment lines. Stereoscopic PIV measurements were performed in different planes orthogonal to the vortex development axis to visualize and characterize wing tip vortices. According to DBD arrangements, results of the actuation show a slight displacement of the wing tip vortex and a reduction of the mean streamwise vorticity level in its core.

Lesieutre, D. J. and Quijano, O.

"STUDIES OF VORTEX INTERFERENCE ASSOCIATED WITH MISSILE CONFIGURATION"

AIAA Paper 2014-0213, January 2014, National Harbor, MD.

Studies of vortex-induced aerodynamic nonlinearities associated with body and fin vortices for missile configurations have been performed. As part of this effort, the vortex and fin modeling methodologies in the engineering-level and intermediate-level aerodynamic predictions codes MISL3 and MISLDL have been reviewed and improved. The ability of the methods to predict detailed fin loads in the presence of external vortices is demonstrated. Both codes have been used extensively to predict missile performance including canard/wing vortex induced effects on tail fins. These effects often manifest themselves in pitching moments and most dramatically in induced rolling moments on tail fins which counter, and often times reverse, the direct roll control of canard fins. Both codes have shown the capability to capture these vortex-induced phenomena. For validation purposes, the methods were compared to detailed vortex-fin interaction studies, performed at Sandia National Laboratories, which measured fin loads influenced by a vortex generated by an upstream fin.

Leslie, F. W. and Justus, C. G.

"THE NASA MARSHALL SPACE FLIGHT CENTER EARTH GLOBAL REFERENCE ATMOSPHERIC MODEL-2010 VERSION"

NASA TM-2011-216467, June 2011, NASA Marshall Space Flight Center; Huntsville, AL.

Reference or standard atmospheric models have long been used for design and mission planning of various aerospace systems. The NASA Marshall Space Flight Center Global Reference Atmospheric Model was developed in response to the need for a design reference atmosphere that provides complete global geographical variability and complete altitude coverage (surface to orbital altitudes), as well as complete seasonal and monthly variability of the thermodynamic variables and wind components. In addition to providing the geographical, height, and monthly variation of the mean atmospheric state, it includes the ability to simulate spatial and temporal perturbations.

Lessen, M.

"METHOD AND APPARATUS FOR ELIMINATION OF AIRFOIL TRAILING VORTICES"

US Patent 3,881,669, May 1975

Herein are disclosed a method and apparatus for eliminating or substantially attenuating the dangerous vortices which typically trail the airfoils of heavier-than-air aircraft in flight. The disclosed method consists of injecting a fluid stream into the core of the vortex (a) in a direction such that the longitudinal axis of the injected fluid stream is substantially colinear and coaxial with the longitudinal axis of the vortex where the injected stream enters the vortex core, and (b) at a momentum flux of such magnitude relative to that of the free air stream that the vortex will be rendered hydrodynamically unstable. The criteria as to the direction and the magnitude of the momentum flux of the injected fluid stream are disclosed as critical to the successful practice of the invention. It is preferable that the departure from co-linearity be not more than 4 degrees. The apparatus of the invention comprises, in combination with an airfoil, a pair of nozzles adapted for injecting a fluid stream of the required orientation and of a momentum flux of such magnitude relative to the free air stream

into the trailing vortex that the trailing vortex will be rendered hydrodynamically unstable and apparatus for supplying a suitable fluid to the nozzles.

Lessen, M.

"THE HYDRODYNAMIC STABILITY OF A TRAILING VORTEX"

Proceedings of the AFFDL/NASA/FAA Wake Turbulence Work Shop, Air Force Flight Dynamics Laboratory, AFFDL-TM-75-16-FGC, 1974, pp. 37-41

The results of research being conducted at the University of Rochester on the hydrodynamic stability of swirling flows was presented. There are two basic aspects to the problem: the mathematical solution of the formalized stability theory as applied to wake vortex models, and the extension of results obtained in such investigations to the finite amplitude disturbances and fully turbulent flows encountered in real life.

Lessen, M.

"AMELIORATION OF TRAILING VORTICES VIA INJECTION"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 19-1 - 19-11

The assumptions underlying the calculation of the turbulent trailing line vortex and the principle of marginal instability are examined. The similarity solution for the turbulent trailing vortex is developed and the power laws derived. The inviscid stability of the vortex is studied and the maximum swirl ratio for instability is obtained analytically.

Lessen, M. and Paillet, F.

"THE STABILITY OF A TRAILING LINE VORTEX, PART 2: VISCOUS THEORY"

J. Fluid Mech., Vol. 65, Part 4, October 1974, pp. 769-77.

The viscous stability of the Lamb vortex and axisymmetric wake is explored. A locally constant eddy viscosity is used to formulate the full stability equations. Disturbance growth rates are then calculated as a function of Reynolds number, axial and azimuthal periodicity, and intensity of core rotation. It is shown that the initial destabilization by the superposition of stable rotation reduces the minimum critical Reynolds number to half that for the wake alone. All modes are stabilized when the rotation becomes strong, and the increase of minimum critical Reynolds number with increasing rotation is traced.

Lessen, M., DeShpande, N. V. and Hadji-Ohanes, B.

"STABILITY OF A POTENTIAL VORTEX WITH A NON-ROTATING AND RIGID-BODY ROTATING TOP-HAT JET CORE"

J. Fluid Mech., Vol. 60, Part 3, September 1973, pp. 459-466

The stability of a potential vortex with a rotating and a non-rotating jet core is analyzed. Eigenvalues are calculated numerically for different values of the ratio of the strength of the vortex to the axial velocity. These results show that the potential vortex becomes unstable in the presence of a jet.

Lessen, M., Singh, P. and Paillet, F.

"THE STABILITY OF A TRAILING LINE VORTEX, PART 1: INVISCID THEORY"

J. Fluid Mech., Vol. 63, Part 4, May 1974, pp. 753-76.

The hydrodynamic stability of a continuous velocity distribution (Lamb vortex and axisymmetric wake) resembling that in a wake vortex is examined, and stability is calculated as a function of the ratio of maximum velocity defect to maximum tangential flow. It is found that rotation can destabilize the axisymmetric wake, but that all instability modes appear stable when the rotation becomes strong enough.

Leuchter, O. and Solignac, J. L.

"EXPERIMENTAL INVESTIGATION OF THE TURBULENT STRUCTURE OF VORTEX WAKES"

4th Symposium sur les Ecoulements Cisailles Turbulents, University of Karlsruhe, September 1983

Two configurations of vertical wake flows are investigated. The first (flow A) corresponds to a double branched trailing vortex, the second (flow B) to the leading-edge vortex of a delta wing. Both flows are studied in the presence of a destabilizing adverse pressure gradient leading to vortex breakdown. For various degrees of destabilization, the flow field is explored by means of a two-color laser velocimeter that yields mean velocity and Reynolds stress distributions across the flow. Breakdown is characterized by a strong deceleration of the flow near the axis of the vortex, by a significant decrease of the rotation rate in the center and consequently by a large production of turbulence. When breakdown occurs, both types of flow reveal similar characteristics of the flow structure. However, there are also significant differences, the most important being the abruptness of the breakdown phenomenon and its instability character which is much more pronounced for vortex flow B.

Leung, R. C. K. and Ko, N. W. M.

"THE INTERACTION OF PERTURBED VORTEX RINGS AND ITS SOUND GENERATION"

Journal of Sound and Vibration, Vol. 202, Issue 1, April 1997, pp. 1-27

Interactions of two coaxial vortex rings of thin cores with and without azimuthal instability and the far field sound radiated have been studied numerically using the vortex blob method and acoustic analogy. The azimuthal instability waves of wavenumbers m less than or equal to 5 or greater than or equal to 1 are represented by weak axial and radial sinusoidal perturbations. It was found that the behavior and the far field sound radiated of two perturbed vortices during the three slip throughs of m less than or equal to 4 or greater than or equal to 3 and during the first slip through of m less than or equal to 5 or greater than or equal to 1 are the same as those of unperturbed case $m = 0$. Because of their mutual induction, an unstable mode of the trailing vortex is found during the third slip through at $m = 1$ and 5, significantly lower wavenumbers compared with those of a single vortex ring. The far field sound radiated and their directivity, though still quadrupole, are different from those of unperturbed cases, showing the effect of perturbation on the interaction of the two vortices. A criterion for the onset of unstable mode is also established.

"ON SOUND RADIATED FROM A PERTURBED VORTEX RING"

Acta Mechanica, Vol. 146, 2001, pp. 43-58.

An analysis of the evolution and sound radiation of a slender vortex ring with initial weak perturbation in free space has been done. Depending on the integer wavenumber of perturbation, the circulation and the core size of the vortex ring, the perturbation evolves in either stable or unstable modes. Both stable and unstable evolutions radiate sound in the far field, and the vortex acceleration of the vortex has been found to be a major sound radiation mechanism. A stably perturbed vortex ring radiates stronger sound than an unstable one. The finding of the present study explains some experimental observations of sound from an isolated vortex ring.

"IMPROVING AIRPORT CAPACITY USING VERTICAL FLIGHT"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

A new, innovative solution must be developed and implemented which makes use of the parts of the airspace system and airport infrastructure that are currently either not used or under-utilized. The use of vertical flight in the form of new generation advance technology rotorcraft, civil tiltrotor (CTR) aircraft offers this potential. These and other runway independent aircraft (RIA), using an ATC framework which allows simultaneous non-interfering (SNI) operations, would appear to be the only viable solution to the current problems if the needs of the traveling public and commerce are to be met. This is possible since significant portions of flights, particularly in the USA, are over ranges of 100 to 200 miles. These aircraft only carry a small portion of the total number of passengers but require the same airspace and runway slot as a large long-distance aircraft. These operations could easily be replaced by advanced technology rotorcraft. With the advent of CTR and other RIA ranges of up to 400

to 600 miles could similarly be handled. These have the advantage of not requiring a valuable 'slot' and could easily make use of the unused airspace (airspace 'voids') on the side of most major airports. High reliability, all weather operations including flights in icing conditions to achieve true IFR operations, is essential. Operating costs are inherently higher than today's civil flights and the need to offset such costs, together with important aspects such as flight safety (included perceived safety) environmental impact and passenger acceptance are important. Advance technology rotorcraft CTR's and RIA's offer a solution in the short term of overcoming the airport/airspace capacity limitations and providing the basis of a valuable integrated aviation system based on today's civil aviation fleet supplemented with a vertical flight segment.

"USER'S GUIDE: TIP VORTEX COMPUTER CODE SRATIP"

NASA-CR-172603, July 1985, Scientific Research Associates, Glastonbury, CT

The User Guide applies to the three-dimensional viscous flow forward marching analysis as used for the calculation of the helicopter tip vortex flow field. The Guide presents a discussion of the program flow and subroutines, as well as a list of input and output.

Leweke, T.

"EXPERIMENTS ON SHORT-WAVE INSTABILITIES IN VORTEX PAIRS"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Experimental results concerning the short-wavelength instability in pairs of counter-rotating or co-rotating vortices will be presented. The former is a simplified model of the far wake behind a transport aircraft, whereas the latter represents the vortex configuration in the near wake behind a single wing in high-lift configuration (lowered flap). Pairs of uniform parallel vortices were generated in water by the impulsive motion of two flat plates, and their evolution was followed in time, using dye visualizations and Particle Image Velocimetry. At sufficiently high Reynolds numbers, both flows, counter- and co-rotating pairs, were found to develop a three-dimensional instability, whose axial wavelength scales on the vortex diameter, and which is associated with internal deformations of the vortex cores. The spatial

structure of the amplified perturbations show characteristic features of elliptic instability occurring in strained vortical flows, and quantitative measurements of wavelength, radial structure, and instability growth rates are in good agreement with predictions from elliptic instability theory. In the case of counter-rotating vortices, the late stages of the instability are characterized by a strong interaction of the two vortices. Secondary structures develop and lead to a pronounced exchange of fluid between the two sides of the flow. Consequently, the average circulation in each half-plane is found to drop significantly in a short time interval, an effect which is still enhanced by the interaction with the long-wavelength Crow instability always developing simultaneously in this flow. In the co-rotating vortex pair, the short-wave instability interacts with and perturbs the process of merging into a single vortex, which is the basic (two-dimensional) phenomenon characterizing this flow. Measurements show that, in the presence of the instability, merging is initiated earlier (i.e. for smaller relative core sizes), and leads to a more turbulent final vortex than in the two-dimensional case.

"THE LONG AND SHORT OF VORTEX PAIR INSTABILITY"

Physics of Fluids, Vol. 8, No. 9, Sept. 1996, p. S5

Photographs show visualizations of different instabilities of a pair of straight counter-rotating vortices. The vortex pair is generated at the sharpened edges of two flat plates, hinged to a common base and moved in a prescribed symmetric way. Visualization is achieved using fluorescent dye.

Leweke, T. and Williamson, C. H. K.

"LONG-WAVELENGTH INSTABILITY AND RECONNECTION OF A VORTEX PAIR"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

We present new experimental results concerning the dynamics of a pair of parallel counterrotating vortices. This flow provides a prototype system for the study of elementary interactions of slender vortices. In addition, a strong link to engineering applications exists, since similar flow structures are found in the far wake of aircraft and play an important role in flight safety at airports. In this presentation we will concentrate on one of several different features we observed in this flow: a long-wavelength instability and the associated phenomenon of vortex reconnection occurring in the long-time development of this instability. Although analytical studies of vortex pairs have considered such an instability (e.g. Crow), it is surprising that neither detailed quantitative measurements nor even a clear demonstration of such structure in laboratory experiments can be found in the literature. The same applies to the study of vortex reconnection or cross-linking, which has mainly been investigated via numerical simulations.

"EXPERIMENTS ON THE SHORT-WAVE INSTABILITY OF TRAILING VORTICES"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

We present results from an experimental study of the dynamics of a pair of parallel counterrotating vortices at low Reynolds number. The flow is studied in water, where the initially two-dimensional vortices are generated by the controlled motion of two flat plates. We observe the existence of several three-dimensional instabilities with different axial wavelengths and symmetry properties. Here, we focus on a short-wave instability, which occurs above a threshold Reynolds number. It is associated with internal deformations of the vortex cores at wavelengths of less than one vortex spacing. Detailed analysis of the spatial structure of the instability mode, as well as measurements of its growth rate, show that this behavior is a consequence of a so-called elliptic instability of the vortex cores, which can be related to the short-wave instability predicted by Widnall et al. The late stages of this instability involve the inception of perpendicular secondary vortex pairs, which, in combination with the long-wavelength Crow instability, results in a very effective destruction of the large-scale vortex structures.

"THREE-DIMENSIONAL DYNAMICS OF A COUNTERROTATING VORTEX PAIR"

8th International Symposium on Flow Visualization, Sorrento, Italy, 1998, pp. 271.1-271.9

In this paper, we present results from an experimental study of the dynamics of a pair of parallel counterrotating vortices, which is uniform in the axial direction. We observe the existence of three-dimensional instabilities at different axial wavelengths, depending on the Reynolds number of the flow. Under the effect of a long-wavelength Crow instability, the vortices develop a growing waviness, leading eventually to the formation of periodic vortex rings. A short-wavelength instability, which occurs above a threshold Reynolds number and can be associated with an elliptic instability of the vortex cores, causes internal deformations of the vortices and, in combination with the Crow instability, leads to a faster decay of the large-scale vortical structures. Detailed visualizations of both phenomena are shown.

Leweke, T. and Williamson, C. H. K.

"THREE-DIMENSIONAL INSTABILITIES OF A COUNTERROTATING VORTEX PAIR"

Lecture Notes in Physics, Vol. 555, 2000, pp. 221-230

Results from an experimental investigation on the dynamics and persistence of instabilities in a counter-rotating vortex pair are presented. Two distinct three-dimensional instabilities in the flow have been observed in these tow-tank experiments, and they were visualized with laser-induced fluorescent dye and quantified with Particle Image Velocimetry. In the case of the long-wave length Crow instability, the vortices undergo a wavy deformation before they cut and reconnect into a series of large-scale vortex rings. At higher Reynolds numbers, a second short-wavelength instability appears, which leads to internal deformations of the vortices and can be explained by an elliptic instability of the vortex cores. In the presence of short waves, the long-term evolution of the pair is distinctly altered:

the average propagation speed of the vortex system decreases drastically, and the large-scale vortical structures are destroyed much more effectively than in the case of a pure Crow instability.

Leweke, T. and Williamson, C. H. K.

"COOPERATIVE ELLIPTIC INSTABILITY OF A VORTEX PAIR"

J. of Fluid Mech., Vol. 360, April 1998, pp. 85-119

In this paper, we investigate the three-dimensional instability of a counter-rotating vortex pair to short waves, which are of the order of the vortex core size, and less than the inter-vortex spacing. Our experiments involve detailed visualizations and velocimetry to reveal the spatial structure of the instability for a vortex pair, which is generated underwater by two rotating plates. We discover, in this work, a symmetry-breaking phase relationship between the two vortices, which we show to be consistent with a kinematic matching condition for the disturbances evolving on each vortex. In this sense, the instabilities in each vortex evolve in a coupled, or cooperative, manner. Further results demonstrate that this instability is a manifestation of an elliptic instability of the vortex cores, which is here identified clearly for the first time in a real open flow. We establish a relationship between elliptic instability and other theoretical instability studies involving Kelvin modes. We note that the perturbation shape near the vortex centers is unaffected by the finite size of the cores. We find that the long-term evolution of the flow involves the inception of secondary transverse vortex pairs, which develop near the leading stagnation point of the pair. The interaction of these short-wavelength structures with the long-wavelength Crow instability is studied, and we observe significant modifications in the longevity of large vortical structures.

Leweke, T. and Williamson, C. H. K.

"EXPERIMENTS ON LONG-WAVELENGTH INSTABILITY AND RECONNECTION OF A VORTEX PAIR"

Physics of Fluids, Vol. 23, 2011, pp. 024101-1 - 024101-14.

We present results from an experimental study of the long-wavelength 'Crow' instability of a counter-rotating vortex pair. Employing a vortex generator in a water tank, comprising rotating horizontal computer-controlled flaps, we follow the vortices, marked by laser-induced fluorescence, using dual simultaneous light-sheets to determine the growth rate of the Crow instability as a function of the perturbation wavelength. To make a meaningful comparison to theory, one requires, as input to the theory, the distribution of circumferential velocity and thereby the 'equivalent' core size of the vortices. These distributions are measured using particle image velocimetry. The resulting agreement of the growth rates, between theory and experiment, appears to be very good. Of relevance to this study, we compute a stability diagram using the exact expression for the self-induced rotation speed of the perturbation waves on the vortices. Measurement of the nondimensional reconnection time, when the

vortex pair evolves into a series of rings at later times, is compared to existing numerical simulations, and we find evidence to suggest it varies with the inverse curvature of the vortices where they approach each other. The major axes of the resulting elliptical vortex rings switch with their minor axes, as the rings descend in the fluid, leading to a surprising phenomenon where the rings reconnect for the second time. By considering the conservation of impulse, and a linear relationship between the major axis length and the vortex spacing, we find that the relative descent speed of the rings increases with Reynolds number. It is coincidentally only at our chosen value that the descent speed of the subsequent rings appears to be close to the initial speed of the vortex pairs. Finally, the paper presents clear visualizations of the Crow instability phenomenon.

"DYNAMICS AND INSTABILITIES OF VORTEX PAIRS"

Annual Review of Fluid Mechanics, Vol. 48, 2016, pp. 507-541.

This article reviews the characteristics and behavior of counter-rotating and corotating vortex pairs, which are seemingly simple flow configurations yet immensely rich in phenomena. Since the reviews in this journal by Widnall (1975) and Spalart (1998), who studied the fundamental structure and dynamics of vortices and airplane trailing vortices, respectively, there have been many analytical, computational, and experimental studies of vortex pair flows. We discuss two-dimensional dynamics, including the merging of same-sign vortices and the interaction with the mutually induced strain, as well as three-dimensional displacement and core instabilities resulting from this interaction. Flows subject to combined instabilities are also considered, in particular the impingement of opposite-sign vortices on a ground plane. We emphasize the physical mechanisms responsible for the flow phenomena and clearly present the key results that are useful to the reader for predicting the dynamics and instabilities of parallel vortices.

"CONTROLLED INTERACTION OF CO-ROTATING VORTICES"

Proceedings 3rd ONERA-DLR Aerospace Symposium (ODAS 2001), Paris, France, June 2001, pp. S2-3/1-10

The two- and three-dimensional interactions of a pair of co-rotating vortices, representing a simplified model of flows found in the extended near wake behind aircraft wings, are analyzed using water tank experiments and numerical simulations. At low Reynolds numbers (Re), the vortices undergo two-dimensional merging, when the core size exceeds a certain fraction of the vortex separation distance. The time it takes to reach this limit increases with Re . At higher Re , a three-dimensional instability is observed, showing the characteristics of an elliptic instability of the vortex cores. The spatial structure of the amplified unstable modes, as well as their growth rate as function of axial wavelength are given and compared to theoretical predictions, showing excellent agreement between the three approaches.

The instability is found to rapidly generate small-scale motion, initiating merging for smaller core sizes and producing a turbulent final vortex.

"VORTEX DYNAMICS ASSOCIATED WITH THE COLLISION OF A SPHERE WITH A WALL"

Physics of Fluids, Vol. 16, No. 9, September 2004, pp. L74-L77

For moderate Reynolds numbers, a sphere striking a wall in the normal direction leads to the trailing recirculating wake threading over the sphere and developing into a complex vortex ring system as it interacts with the wall. The primary vortex ring, which consists of vorticity from the wake, persists and convects slowly outwards away from the sphere due to the motion induced from its image. The structure and evolution of this vortex system is quantified through a combined experimental and numerical study. At higher Reynolds numbers a non-axisymmetric instability develops, which leads to rapid dispersion of the ring system. A comparison of the wavelength and growth rate, predicted from both linear stability theory and direct simulations, with idealized models indicates that the mechanism is dominated by a centrifugal instability at the edge of the primary vortex core.

"ROLE OF TURBULENCE IN CHEMICAL AND DYNAMICAL PROCESSES IN THE NEAR-FIELD WAKE OF SUBSONIC AIRCRAFT; FINAL REPORT"

USGRDR0216, West Virginia University, March 2002, Morgantown, WV

During this grant, covering the period from September 1998 to December 2001, we continued the investigation of the role of turbulent mixing in the wake of subsonic aircraft initiated in 1994 for NASA's Atmospheric Effects of Aviation Project. The goal of the research has been to provide sufficient understanding and quantitative analytical capability to assess the dynamical, chemical, and microphysical interactions in the near-field wake that have the greatest potential to influence the global atmospheric impact of the projected fleet of subsonic aircraft. Through large-eddy simulations we have shown that turbulence in the early wake dynamics can have a strong effect on both the ice microphysics of contrail evolution and on wake chemistry. The wake vortex dynamics are the primary determinant of the vertical extent of the contrail; this together with the local wind shear largely determines the horizontal extent. The fraction of the initial ice crystals surviving the wake vortex dynamics, their spatial distribution, and the ice mass distribution are all sensitive to the aircraft type, assumed initial ice crystal number, and ambient humidity and turbulence conditions. Our model indicates that there is a significant range of conditions for which a smaller aircraft such as a B737 produces as significant a persistent contrail as a larger aircraft such as a B747, even though the latter consumes almost five times as much fuel. Large-eddy simulations of the near wake of a B757 provided a fine-grained chemical-dynamical representation of simplified NO_x - HO_x chemistry in wakes of ages from a few seconds to several minutes. By sampling the simulated data in a manner like that of in situ aircraft measurements it was possible to provide a likely explanation for a puzzle uncovered in the 1996

SUCCESS flight measurements of OH and HO₂. The results illustrate the importance of considering fluid dynamics effects in interpreting chemistry results when mixing rates and species fluctuations are large, and demonstrate the feasibility of using 3D unsteady LES with coupled chemistry to study such phenomena.

"THE EFFECTS OF AIRCRAFT WAKE DYNAMICS ON CONTRAIL DEVELOPMENT"

Journal of the Atmospheric Sciences, Vol. 58, No. 4, February 2001, pp. 390-406

Results of large-eddy simulations of the development of young persistent ice contrails are presented, concentrating on the interactions between the aircraft wake dynamics and the ice cloud evolution over ages from a few seconds to ~30 min. The 3D unsteady evolution of the dispersing engine exhausts, trailing vortex pair interaction and breakup, and subsequent Brunt-Vaisala oscillations of the older wake plume are modeled in detail in high-resolution simulations, coupled with a bulk microphysics model for the contrail ice development. The simulations confirm that the early wake dynamics can have a strong influence on the properties of persistent contrails even at late times. The vortex dynamics are the primary determinant of the vertical extent of the contrail (until precipitation becomes significant); and this together with the local wind shear largely determines the horizontal extent. The ice density, ice crystal number density, and a conserved exhaust tracer all develop and disperse in different fashions from each other. The total ice crystal number can be significantly reduced due to adiabatic compression resulting from the downward motion of the vortex system, even for ambient conditions that are substantially supersaturated with respect to ice. The fraction of the initial ice crystals surviving, their spatial distribution, and the ice mass distribution are all sensitive to the aircraft-type, ambient humidity, assumed initial ice crystal number, and ambient turbulence conditions. There is a significant range of conditions for which a smaller transport such as a B737 produces as significant a persistent contrail as a larger transport such as a B747, even though the latter consumes almost five times as much fuel. The difficulties involved in trying to minimize persistent contrail production are discussed.

"LARGE-EDDY SIMULATIONS OF THE VORTEX-PAIR BREAKUP IN AIRCRAFT WAKES"

AIAA Journal, Vol. 34, No. 11, November 1996, pp. 2337-2345.

We have utilized large-eddy simulations to simulate the transition from an aircraft wake dominated by the interaction of vortex-pair dynamics and engine plume buoyancy to one dominated by atmospheric dispersion. Our investigation concentrates on the period from a few seconds to several minutes after the wake is generated, during which the essentially two-dimensional vortex-pair is broken up into a variety of three-dimensional eddies. Our initial conditions are taken from near-wake simulations for three aircraft, the B-737, the B-747, and the ER-2. Comparisons of our simulations, for conditions representatives of the atmosphere in the upper troposphere and the lower stratosphere, with wake

photographs taken from the ground show very similar features. In the absence of wind shear, the vortex pair go through a linking instability that is affected both by engine buoyancy and ambient turbulence. The resultant series of vortex rings continue to descend, leaving the wake with the appearance of a series of suspended puffs. When the mean atmospheric shear is sufficiently large, the ambient vorticity can erode one member of the vortex pair, leading to a breakup mode with a much shorter wavelength.

Lewellen, D. C. and Lewellen, W. S.

"EFFECTS OF AIRCRAFT WAKE DYNAMICS ON MEASURED AND SIMULATED NO_x AND HO_x WAKE CHEMISTRY"

Journal of Geophysical Research, Vol. 106, No. D21, November 2001, pp. 27,661-27,672.

High-resolution numerical large-eddy simulations of the near wake of a B757 including simplified NO_x and HO_x chemistry were performed to explore the effects of dynamics on chemistry in wakes of ages from a few seconds to several minutes. Dilution plays an important basic role in the NO_x - O₃ chemistry in the wake, while a more interesting interaction between the chemistry and dynamics occurs for the HO_x species. These simulation results are compared with published measurements of OH and HO₂ within a B757 wake under cruise conditions in the upper troposphere taken during the Subsonic Aircraft Contrail and Cloud Effects Special Survey (SUCCESS) mission in May 1996. The simulation provides a much finer grained representation of the chemistry and dynamics of the early wake than is possible from the 1 s samples taken in situ. The comparison suggests that the previously reported discrepancy of up to a factor of 20 - 50 between the SUCCESS measurements of the [HO₂]/[OH] ratio and that predicted by simplified theoretical computations is due to the combined effects of large mixing rates around the wake plume edges and averaging over volumes containing large species fluctuations. The results demonstrate the feasibility of using three-dimensional unsteady large-eddy simulations with coupled chemistry to study such phenomena.

"LARGE-EDDY SIMULATIONS AND LIDAR MEASUREMENTS OF VORTEX-PAIR BREAKUP IN AIRCRAFT WAKES"

AIAA Journal, Vol. 36, No. 8, August 1998, pp. 1439-1445

Results of large-eddy simulations of an aircraft wake are compared with results from ground-based lidar measurements made at NASA Langley Research Center during the Subsonic Assessment Near-Field Interaction Flight Experiment field tests. Brief reviews of the design of the field test for obtaining the evolution of wake dispersion behind a Boeing 737 and of the model developed for simulating such wakes are given. Both the measurements and the simulations concentrate on the period from a few seconds to a few minutes after the wake is generated, during which the essentially two-dimensional vortex pair is broken up into a variety of three-dimensional eddies. The model and experiment show

similar distinctive breakup eddies induced by the mutual interactions of the vortices, after perturbation by the atmospheric motions.

"FLIGHT DATA ANALYSIS AND SIMULATION OF WIND EFFECTS DURING AERIAL REFUELING"

MS Thesis, May 2008, University of Texas, Arlington, TX.

This thesis presents an analysis of data obtained in an automated aerial refueling test flight with a KC-135 as the tanker and a Learjet 25 as the surrogate receiver unmanned aerial vehicle (UAV). The purpose is to identify the wind induced by the tanker wake and its effect on the receiver aircraft. From the available flight data, a direct computation of the winds experienced by the tanker and receiver is carried out. The mean variation of the receiver wind is compared with the tanker wind when the receiver is at the observation and contact positions. This results in the identification of the wake-induced wind. A spectrum analysis is conducted to characterize the turbulence and to identify the pilot effects. The thesis also presents methods used to model (i) prevailing wind, (ii) wake vortex induced wind and (iii) turbulence as the three sources of wind that the aircraft are exposed to and the approach used for incorporating the wind effect into the dynamic simulation of the aircraft. The test flight is simulated in various cases with different turbulence models and flight controllers. The simulation results are analyzed and compared with the flight data in terms of the power spectral densities and mean variations to validate the wind and turbulence modeling techniques.

Lezius, D. K.

"WATER TANK STUDY OF THE DECAY OF TRAILING VORTICES"

AIAA Journal, Vol. 12, No. 8, August 1974, pp. 1065-1071

Underwater towing experiments were carried out with a rectangular airfoil of aspect ratio 5.3 at 4 degree and 8 degree angles of attack and at chord-based Reynolds numbers between 2.2×10^5 and 7.5×10^5 . Tangential velocity measurements in the downstream region between 100 and 1000 chord lengths indicate rates of vortex decay proportional to $t^{-7/8}$ at 8 degrees, whereas previous flight tests show that the decay rate approaches $t^{-1/2}$ far downstream. The observed behavior is explained in terms of an analytical solution that includes time dependence of the turbulent eddy viscosity, $\sim \nu_m$. It shows that, for $m > 0$, an isolated turbulent vortex decays faster than $t^{-1/2}$. In this case, the decay is accompanied by increasing turbulent eddy viscosity, or levels of turbulence, which corresponds to turbulent nonequilibrium flow. The special case of vortex decay with equilibrium flow ($m=0$) leads to the well-known decay rate $t^{-1/2}$. Since, in towing tank experiments at low Reynolds number, turbulent vortex decay may occur predominantly in non-equilibrium, it is doubtful that such tests correctly

predict the late stage of decay of aircraft trailing vortices, when turbulence is the only dissipating mechanism.

"ANALYTICAL SOLUTION FOR INVISCID VORTEX ROLLUP FROM ELLIPTICALLY LOADED WINGS"

Journal of Aircraft, Vol. 12, No. 11, November 1975, pp. 911-914

An explicit analytical perturbation solution is presented that is based upon the Betz rollup theory for the vortex circulation after rollup from wings with elliptically distributed span loading. Since the resulting series solution converges rapidly, accurate and uniformly valid results emerge for the complete rollup when only the first three terms of the expansion are retained.

Lezius, D. K.

"UNSTABLE WING VORTEX ROLLUP INDUCED BY LIFT TAILORING IN THE WING-TIP REGION"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 23-1 - 23-10

The effects of modifying the circulation distributions near the tips of lifting wings on the stability of vortex rollup are investigated. Analytical considerations indicate that maintaining a positive spanwise lift gradient near and at the wing tips should result in unstable rollup of the vorticity originating in the region of increased wing-tip lift loading. The instability of the rollup is predicted by the Rayleigh stability criterion for rotating fluids and results from the attempted rollup of the wing vorticity in the tip region into a circular flow with radially decreasing circulation. Preliminary experiments with a rectangular wing with lift loading increasing toward the tip have demonstrated that rollup is prevented by turbulent rotating motions that are generated in the unstable arrangement of vorticity layers. The resulting turbulent vortex wake presents the appearance of one usually observed at large distances downstream of the wing.

"EFFECTS OF ASPECT RATIO AND ANGLE OF ATTACK ON TIP VORTEX STRUCTURES AND AERODYNAMIC PERFORMANCE FOR ROTATING FLAT PLATES"

AIAA Paper 2017-3645, June 2017, Denver, CO.

Numerical simulations are used to investigate the effects of aspect ratio and angle of attack on the vortex structure, circulation, and aerodynamic performance of revolving wings at a low Reynolds number regime (200 ~ 1600). Rectangular wings with various aspect ratio (1 ~ 8) are considered and rotating from rest at angle of attack ranging from 15 to 90 degrees. Simulations are carried out using

an in-house immersed-boundary-method-based direct numerical simulation (DNS) solver. A detailed analysis of the vortex formation shows that the general wake pattern near the wingtip shift from a single vortex loop to a pair of counter-rotating vortex loops. This tip vortex evolution was found related to the strength of LEV. In general, the stronger LEV will enhance the counter-pair trailing-edge vorticity. As the TEV increased, a secondary tip vortex will be formed at the bottom corner of wingtip and generate a pair of counter-rotating tip vortex loops. With the increment of the Reynolds number, these vortex loops will interact with each other and form hairpin-like vortical structures in the tail of the arc-shaped vortex loops. In addition to the vortex structures, the aerodynamic loading and power consumption were also examined. The findings from this work could be used to further understand the vortex dynamics of finite-aspect-ratio revolving wings at high angle of attack.

"WAKE VORTEX EFFECT MODELING AND SIMULATION IN AUTOMATED AERIAL REFUELING"

Journal of Beijing University of Aeronautics and Astronautics, Vol. 36, No. 7, July 2010, pp. 776-780.

According to the request of automated aerial refueling, the formation and distribution of wake vortex behind a large aerial tanker was discussed. A modified horseshoe vortex model that includes the effect of vortex descent and diffusion over time was given. This model was linearized nearby the mass point of the receiver and an averaging technique was implemented to compute effective wind on the receiver. The effective wind components and gradients were introduced into the nonlinear aircraft equations through aerodynamic equivalent to determine the effect on the receiver's dynamics. Computer simulation of receiver/wake vortex encounters in aerial refueling was built by Matlab/Simulink. The results show that the wake vortex model can exactly describe the interference between the receiver and the tanker. This behavior is well matched with the feeling of the receiver's pilot. This model can also be used for the flight safety about large aircraft during taking off and interaction analysis in tight formation flight. [In Chinese.]

"BUOYANCY EFFECTS IN AN UNSTEADY STRATIFIED TURBULENT BOUNDARY LAYER FLOW"

Physics of Fluids, Vol. 29, 2017, pp. 015104-1 to 015104-17.

Direct numerical simulation has been performed to investigate the effect of buoyancy on an unstably stratified turbulent boundary layer with the Oberbeck-Boussinesq approximation. The simulation results show that the mean values of the streamwise velocity and scalar fields are increased in the near-wall region but decreased in the outer layer under the effect of buoyancy, which leads to significant increases in the skin-friction drag and heat transfer. In addition, it is found that the unstable thermal stratification results in large increases in the intensities of the near-wall streamwise vortices and high- and low-speed streaks, and a reduction in the mean diameter of the vortical structures. Moreover, the turbulent coherent structures become less organized due to the stratification effect.

With respect to the neutral boundary layer flow, the outer vortical structures tend to bias the direction of the principal extensional strain towards the vertical plane in the unstably stratified flow.

"FORMATION OF A ROTOR TIP VORTEX"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 739-749

The origin of the tip vortex is described and important properties, such as core radius and circulation, as a function of these parameters, are calculated. Even though a large amount of computational and experimental work on the rotor wake has been published, little of a quantitative nature is known about the origin of the main component of the rotor wake, the tip vortex, as a function of the rotor speed, rotor blade geometry, and angle of attack. Experimental data by several workers have revealed little dependence on the Reynolds number. This lack of dependence on Reynolds number will hold only if the flow remains substantially unseparated, although it may be noted that drag coefficients of bluff bodies are remarkably constant over a wide range of Reynolds number. The rotor blade is assumed to be of large aspect ratio, that is, to leading order in the blade aspect ratio, it appears infinite in length. In this limit case, the analytical solution for the bound circulation on a fixed wing is shown to be extendable to the rotary wing case when the blade is viewed as a lifting line. Lifting-surface results are obtained also, and these compare with the lifting-line results for the bound circulation.

Li, H., Burggraf, O. R. and Conlisk, A. T.

"ON THE FORMATION OF A TIP-VORTEX"

AIAA Paper No. 2000-0282, Reno, NV, January 2000

The helicopter-rotor wake is among the most complex flowfields in aerodynamics. Even though a large amount of computational and experimental work on the rotor wake has been published, little of a quantitative nature is known about the origin of the main component of the rotor wake, the tip-vortex, as a function of the rotor speed, rotor blade geometry, and angle of attack. The objective of this paper is to investigate whether classical inviscid lifting surface methods applied locally near the wing tip can describe the origin of the tip vortex. Correlation of experimental data by several workers has revealed little dependence on the Reynolds number. Of course, this lack of dependence on Reynolds number will hold only if the flow remains substantially unseparated, though it may be noted that drag coefficients of bluff bodies are remarkably constant over a wide range of Reynolds number. The rotor blade is assumed to be of large aspect ratio and the method of Matched Asymptotic Expansions is used to calculate the bound circulation near the wing tip. The primary objective of this work is to predict the formation of the rotor tip vortex as a function of physical parameters such as angle of attack, rotor speed, and blade aspect ratio. While the rotor-blade tip-vortex is of primary interest here, the techniques developed are applied first to the simple problem of the aircraft wing. Results for the bound circulation on a rotary wing are presented subsequently.

"THE FORMATION OF ROTOR TIP-VORTICES"

53rd Annual Meeting of the Division of Fluid Dynamics, American Physical Society, November 2000, Washington, DC.

The helicopter rotor wake is composed of a strong tip-vortex and the relatively weak inboard sheet and the tip-vortex is the dominant component. The objective of this paper is to investigate whether classical inviscid lifting-line and lifting-surface methods applied locally near the rotor-tip can describe the origin of the tip-vortex. The rotor blade is assumed to be of large aspect ratio and the computations for the bound circulation are modeled on the method of matched asymptotic expansions. It is shown that in the tip region, an analytical solution for the bound circulation on the rotary wing may be obtained based on lifting-line theory whose form is like that of the fixed wing which is given by Stewartson except that there is an additional parameter which is dependent on the angle of attack, the aspect ratio and the number of blades. The formation of the rotor tip-vortex has been computed also. It is shown that the tip-vortex does not roll up completely at the trailing edge of the rotor blade as assumed in many rotor wake models; instead, the circulation of the tip-vortex develops downstream and approaches a constant asymptotically. The experiments on the rotor near wake show that the wake geometry is not a perfect helix. Two types of wake models (vortex-cylinder and discrete vortex-ring model) are used to consider the influence of rotor-wake contraction and the numerical results compare well with experimental data.

"CIRCULATION RETRIEVAL OF SIMULATED WAKE VORTICES UNDER RAINY CONDITION WITH A SIDE-LOOKING SCANNING RADAR"

IEEE Transactions on Aerospace and Electronic Systems, Vol. 54, No. 2, April 2018, pp. 569-584.

The strength of a wake vortex can be well described by vortex circulation. In the area of aviation safety, it serves as a crucial parameter for assessing hazards caused by wake vortices, and its retrieval has attracted much attention in the past decades. Generally, radar is a very promising detection sensor for wake vortices generated under rainy condition where the scattering is mainly caused by the raindrops driven by wake vortices. This makes it possible to retrieve the circulation of wake vortices by sensing and quantifying the motion of these raindrops. This paper proposes the use of a side-looking radar, whose beam scans up and down alternately, for detecting wake vortices. In this method, raindrops that make major contribution to the total scattering are identified as characteristic-size raindrops, and their motion equation is established to connect their motion to the dynamics of wake vortices. When the velocity and acceleration of characteristic-size raindrops are well estimated from the Doppler spectra, the motion equation can be well solved by the nonlinear least squares method to yield the target parameter, circulation. At the same time, two other important parameters (vortex spacing and vortex-core height) can be retrieved as well. Numerical simulation results verify good performance of the retrieval method.

"RADAR SCATTERING ANALYSIS OF WAKE VORTEX UNDER DIFFERENT WEATHER CONDITIONS"

2016 Progress in Electromagnet Research Symposium (PIERS), August 2016, Shanghai, China.

Wake vortex is a kind of largely-scaled distributed complex objects, and its radar scattering characteristics are very difficult to analysis. Generally, wake vortex can be classified into two categories in terms of weather conditions: clear air condition and precipitation condition (fog, rain, snow). Different wake vortices have different scattering mechanisms and characteristics. This paper presents some preliminary research results of wake vortex scattering, and some scattering mechanisms are briefly depicted.

Li, J., Wang, T., Qu, L., Wang, H. and Wang, X.

"CIRCULATION RETRIEVAL OF WAKE VORTEX IN FOG WITH AN UPWARD-LOOKING MONOSTATIC RADAR"

IEEE Transactions on Aerospace and Electronic Systems, Vol. 52, No. 1, February 2016, pp. 169-180.

Detection and parameter retrieval of aircraft wake vortices have attracted much attention in air traffic management and related fields. In foggy weather conditions, the scattering of a wake vortex is mainly determined by the fog drops carried by the velocity field of the wake. By taking the fog drops' property of weak inertia into account, a new theoretical method to retrieve the circulation of a wake vortex generated in fog is proposed in this paper. In the method, an upward-looking monostatic radar is employed to obtain the Doppler velocities of radar cells along the symmetric line of the wake vortex, and then the circulation can be obtained through a very simple expression with respect to the Doppler velocities and the length of the radar cells. Numerical simulation results verify the good performance of the method.

"RAPID MODELING OF DISTRIBUTION OF AIRCRAFT WAKE DIELECTRIC CONSTANT BASED ON HORSE-SHOE VORTEX MODEL"

Acta Aeronautica et Astronautica Sinica, Vol. 30, No. 7, July 2009, pp. 1214-1218.

For the convenience of the study of aircraft wake vortex scattering characteristics, a rapid modeling method for the wake dielectric constant distribution is put forward. In this article, the induced velocity field of an aircraft wake is obtained based on the horse-shoe vortex model. From the velocity field, the Euler equation and isentropic flow method are used to work out the thermodynamic parameter distribution of the wake vortex, and then the dielectric constant distribution is obtained. At the same time, a method to extrapolate the result from one wake to another is proposed to avoid duplicate computation. This method has the advantage of requiring less computation with few parameters. Therefore, it is a rapid and efficient method to simulate the aircraft wake dielectric constant distribution. [In Chinese.]

"SCATTERING MECHANISM OF AIRCRAFT WAKE VORTICES GENERATED IN CLEAR AIR"

IEEE Radar Conference, May 2010, Washington, DC, pp. 117-122.

To provide help to the development of radar detection technology on wake vortices, the scattering mechanism of a wake vortex is studied. The dielectric constant of wake vortices is divided into two terms regarding the density variation and water vapor variation, respectively. The effects of these two variations on the RCS of wake vortices are investigated to find the scattering mechanism. Research findings show that in the low frequency band, the density variation is the dominant factor to the total RCS of wake vortex; while in the frequency band, the dominant factor turns out to be the water vapor variation.

Li, J., Wang, X. and Wang, T.

"MODELING THE DIELECTRIC CONSTANT DISTRIBUTION OF WAKE VORTICES"

IEEE Transactions on Aerospace and Electronic Systems, Vol. 47, No. 2, April 2011, pp. 820-831.

The study of scattering characteristics of a wake vortex is very important for hazard avoidance, especially near airports. Obtaining the dielectric constant distribution is one of the basic issues in the scattering study for radar detection. The present work proposes a modeling method for the dielectric constant distribution. In the method the dielectric constant variation (also the radar cross section) due to the density variation and water vapor variation are studied. Research findings show that the density variation and water vapor variation serve as dominant factors to the radar cross section of a wake vortex in low frequency band and high frequency band, respectively.

"STUDY ON THE SCATTERING CHARACTERISTICS OF STABLE-STAGE WAKE VORTICES"

Radar Conf. - Surveillance for a Safer World, Oct. 2009, Bordeaux, France, pp. 1-5.

The present paper decomposes the study of wake vortex's scattering characteristics into three key problems. Based on the study of these three problems in detail, we obtained the scattering characteristics of the wake vortex, which include the frequency characteristic of RCS, the radiation pattern, the relation between RCS and the detection range, and the time evolution characteristic of RCS. Research findings can provide supports for the development of radar detection technology on wake vortex.

"HIGH RANGE RESOLUTION PROFILE OF SIMULATED AIRCRAFT WAKE VORTICES"

IEEE Transactions on Aerospace and Electronic Systems, Vol. 48, No. 1, January 2012, pp. 116-129.

Knowledge of radar scattering characteristics is very important to the development of radar detection technology on aircraft wake vortices. In this paper, the high range resolution (HRR) profile of the wake vortex is investigated. The HRR profile is observed to have a particular structure, from which the wingspan of the aircraft can be easily identified. This characteristic could be very useful to identify the wake vortex from the ambient air. At the same time, the Bragg scattering, whose characteristic and applicability are further explored, is used to explain the mechanism of such HRR profiles.

Li, W.

"FLOW/ACOUSTICS MECHANISMS IN TWO- AND THREE-DIMENSIONAL WAKE VORTICES"

Ph.D. Thesis, 2007, Kansas State University, Manhattan, KS

In this study, a vortex particle method is used to simulate incompressible vortical flows, specifically aircraft wake vortices. This is particularly suitable for a wake vortex system that is slowly varying in the axial direction and has a high Reynolds number and low Mach number. The flow field, in the form of vorticity, is employed as the source in the far-field acoustic calculation using a vortex sound formula that enables computation of acoustic signals radiated from an approximated incompressible flow field. In a two-dimensional vortex system, the stretching effect in the axial direction is neglected. The purpose of this study is to focus on vortex core behaviors. A numerical simulation is performed in a more realistic wake consisting of a counter-rotating vortex pair with inviscid ground effects and shear flows. A Kirchhoff spinning-core vortex model is thus used as a starting point. In a vortex system with multiple vortices, such as complicated aircraft vortex wake vortices, the sound emission frequency of the unsteady vortex core is subjected to change because of interactions between multiple vortices. The behaviors of the influence, indicated by the ratio between the core size and the distance of the vortices, are investigated as well as the underlining vortex core dynamic mechanisms. Cases of co-rotating vortices and a multiple-vortex system composed of two counter-rotating vortex pairs are studied for applications to aircraft wake vortex sound.

"FLOW/ACOUSTIC MECHANISMS IN THREE-DIMENSIONAL VORTICES UNDERGOING SINUSOIDAL-WAVE INSTABILITIES"

Proceedings of the ASME International Mechanical Engineering Congress and Exposition, IMECE-2007-43163, November 2007, Seattle, Washington

It has been identified that vorticity in a vortex core directly relates to the frequency of a significant sound peak from an aircraft wake vortex pair where each of the vortices is modeled as an elliptic core Kirchhoff vortex. In three-dimensional vortices, sinusoidal instabilities at various length scales result in

significant flow structure changes in these vortices, and thus influence their radiated acoustic signals. In this study, a three-dimensional vortex particle method is used to simulate the incompressible vortical flow. The flow field, in the form of vorticity, is employed as the source in the far-field acoustic calculation using a vortex sound formula that enables computation of acoustic signals radiated from an approximated incompressible flow field. Cases of vortex rings and a pair of counter-rotating vortices are studied when they are undergoing both long- and short-wave instabilities. Both inviscid and viscous interactions are considered and effects of turbulence are simulated using sub-grid-scale models.

"INITIAL SPACING EFFECTS ON CO-ROTATING TIP VORTEX FORMATION AND MERGER"

AIAA Paper No. 2000-2219, Denver, CO, June 2000

Preliminary results are presented from a study on the evolution, interaction, and merger of multiple trailing vortices in a towing tank and wind tunnel. The current study is limited to two corotating (like-signed) vortices of nearly equal magnitude. Various configurations of symmetric semispan airfoils are used to generate the vortex pair. The initial separation distance of the vortices is varied to investigate the effect on merger characteristics. In the wind tunnel, a seven-hole probe is used to extract the 3D average velocity in the vortex wake. In the tow tank, a laser sheet illuminates tracer particles in the flow and a digital camera is used to capture a sequence of PIV images. Planar velocity and vorticity fields are derived from these images using an adaptive Lagrangian parcel tracking algorithm. Merger of the corotating vortex pairs is observed at all Reynolds numbers and separation distances for all tow tank experiments and for the wind tunnel experiments with small initial separation.

"EMISSION OF SOUND BY LOCALIZED VORTICES IN A WEAKLY COMPRESSIBLE MEDIUM (REVIEW)"

Akusticheskii Zhurnal (ISSN 0320-7919), Vol. 34, Sept.-Oct. 1988, p. 769-790. [In Russian]

Results of recent theoretical studies of some of the most characteristic phenomena associated with sound emission by vortices are discussed with particular reference to localized vortices. The theoretical analysis is carried out for the simple case of a homogeneous isotropic fluid, facilitating the quantitative description of the principal physical characteristics of the excitation of acoustic oscillations by vortices. The general methods of analysis and specific examples presented here can be useful in obtaining rough estimates of similar effects in more complex hydrodynamic systems, such as the atmosphere, the ocean, plasma, and super fluids.

"VISUALIZATION OF THE WING-TIP VORTEX IN TEMPORAL AND SPATIAL PRESSURE GRADIENTS"

Journal of Fluids Engineering, Vol. 113, September 1991, pp. 511-515.

The evolution of the longitudinal vortex in the near field of a rectangular wing has been visualized using smoke and laser light sheet. The smoke photographs have been used to obtain qualitative and some quantitative information on the effect of small temporal and spatial pressure gradients on the evolution of the vortex in this region. The experiments indicate that even small temporal retardation of the flow produce a significant increase in the vortex size. This effect becomes larger with increase in retardation, angle of incidence and distance downstream from the trailing edge. Also, vortex 'breakdown' was found to occur in many temporal-deceleration experiments. The vortex evolution was, however, found to be relatively insensitive to the presence of small spatial adverse pressure gradients along the flow direction. The study is preliminary in nature and needs to be supported by more extensive quantitative measurements.

"WAKE VORTEX AND HOVER DOWNWASH MEASUREMENTS OF THE V-22 AND XV-15 TILTROTOR AIRCRAFT"

Military Sensing Systems Active Electrooptic Systems Conf., Redstone Arsenal, Huntsville, AL, April 2001

Lincoln Laboratory, in coordination with Bell Helicopter Textron, has conducted measurements of the wake vortex and hover downwash characteristics of the V-22 and XV-15 tiltrotor aircraft. Vortices generated in different forward flight configurations were detected and tracked by our mobile continuous-wave coherent CO₂ laser radar. The same lidar system was used to rapidly acquire downwash velocity profiles from the hovering aircraft. This is the first time the wake of a tiltrotor aircraft has been measured using laser radar. It is also the first time that a laser radar system has been used to record hover downwash data. Measurements made in August 2000 at the Bell Helicopter Test Flight Facility in Arlington, Texas are presented here, along with an analysis of the vortex and hover data.

"MITIGATION OF AIRCRAFT WAKE VORTICES"

UCB-ITS-RR-94-14, December 1994, Institute of Transportation Studies, University of California, Berkeley, CA

Airport capacity, hence the ground transportation around it is coupled to landing and take-off frequency of the aircraft. This frequency is determined by the longevity of the wake vortex pair. The research program is aimed at first understanding the issues determining the life span of the wake, then to destabilize it and hasten its demise to allow more aircraft in the queue. We have now completed velocity vector field measurements in the wake of rectangular wing. In this phase, we used rectangular planform of aspect ratio of 8 to study the behavior of a clean vortex wake. The wake system is extremely stable. The second phase will investigate the effect of broken symmetry on the longevity of the wake vortices. For this phase, a dynamic model will be constructed where there will be provisions

for modifying the vorticity distribution in the wake. These experiments will be guided by numerical studies which are concurrent.

"TIP VORTEX GEOMETRY OF A HOVERING HELICOPTER ROTOR IN GROUND EFFECT"

Journal of the American Helicopter Society, Vol. 38, April 1993, pp. 34-42.

The wide-field shadowgraph method has been used to photograph the tip vortices of a hovering helicopter rotor in ground effects. The shadowgraphs were used to obtain quantitative measurements of the rotor tip vortex geometry both in and out of ground effect. Many important phenomena are visible in the rotor wake using this method. These include the variation in descent and contraction rates of the tip vortices in ground effect, and the interaction between tip vortices in the far wake. The tip vortex geometry from the shadowgraphs is compared with the tip vortex geometry predicted using a free wake hover performance analysis. The free wake analysis accurately predicts the tip vortex geometry both in and out of ground effect. Performance data from the test is compared with the performance predicted using several methods, including the free wake analysis. All methods provided reasonable predictions of the helicopter performance in ground effect.

Light, J. S.

"TIP VORTEX GEOMETRY OF A HOVERING HELICOPTER ROTOR IN GROUND EFFECT"

45th Annual Forum of the American Helicopter Society, May 1989, Boston, MA.

The wide-field shadowgraph method has been used to photograph the tip vortices of a hovering helicopter rotor in ground effects. The shadowgraphs were used to obtain quantitative measurements of the rotor tip vortex geometry both in and out of ground effect. Many important phenomena are visible in the rotor wake using this method. These include the variation in descent and contraction rates of the tip vortices in ground effect, and the interaction between tip vortices in the far wake. The tip vortex geometry from the shadowgraphs is compared with the tip vortex geometry predicted using a free wake hover performance analysis. The free wake analysis accurately predicts the tip vortex geometry both in and out of ground effect. Performance data from the test is compared with the performance predicted using several methods, including the free wake analysis. All methods provided reasonable predictions of the helicopter performance in ground effect.

"ANALYSIS OF INDUCED VELOCITIES IN THE WAKE OF A HOVERING HELICOPTER ROTOR"

AIAA Paper 1987-2283, Monterey, CA, August 1987

A simple analytical method has been developed to predict the induced velocities at the tip vortex in the wake of a hovering helicopter rotor. The wake model in the analysis includes the blade bound

vortex as well as a tip vortex and vortex sheet trailed from each blade. Standard, prescribed wake models were used to describe the geometry of the tip vortex and the vortex sheet. Curved vortex elements were used to model the tip vortices and the vortex sheets. The analysis was used to study the contribution from each wake component to the axial-induced velocity of the tip vortex. Results show a highly variable induced velocity at the tip vortex both before and after the first blade passage. However, the prescribed tip vortex models require a constant axial velocity of the tip vortex. This inconsistency between the prescribed axial velocity of the tip vortex and the velocity that the wake geometry induces on the tip vortex points to a limitation of the current prescribed tip vortex geometry models.

"VALIDATION OF FOUR LES AND A VORTEX MODEL AGAINST STEREO-PIV MEASUREMENTS IN THE NEAR WAKE OF AN ACTUATOR DISC AND A WIND TURBINE"

Renewable Energy, Vol. 94, 2016, pp. 510-523.

In this paper we report the results of a workshop organized by the Delft University of Technology in 2014, aiming at the comparison between different state-of-the-art numerical models for the simulation of wind turbine wakes. The chosen benchmark case is a wind tunnel measurement, where stereoscopic Particle Image Velocimetry was employed to obtain the velocity field and turbulence statistics in the near wake of a two-bladed wind turbine model and of a porous disc, which mimics the numerical actuator used in the simulations. Researchers have been invited to simulate the experimental case based on the disc drag coefficient and the inflow characteristics. Four large eddy simulation (LES) codes from different institutions and a vortex model are part of the comparison. The purpose of this benchmark is to validate the numerical predictions of the flow field statistics in the near wake of an actuator disc, a case that is highly relevant for full wind farm applications. The comparison has shown that, despite its extreme simplicity, the vortex model can reproduce the wake expansion and the centerline velocity with very high accuracy. Also, all tested LES models can predict the velocity deficit in the very near wake well, contrary to what was expected from previous literature. However, the resolved velocity fluctuations in the LES are below the experimentally measured values.

"EXPERIMENTAL QUANTIFICATION OF THE ENTRAINMENT OF KINETIC ENERGY AND PRODUCTION OF TURBULENCE IN THE WAKE OF A WIND TURBINE WITH PARTICLE IMAGE VELOCIMETRY"

AIAA Paper 2014-0706, January 2014, National Harbor, MD.

The rule of the tip-vortex pairwise instability ('leapfrogging') is investigated in relation to the process of kinetic energy transport and turbulence production within the shear layer of a horizontal-axis wind-turbine wake. Experiments are conducted in an open-jet wind-tunnel on a wind turbine model. Stereoscopic particle image velocimetry is employed to obtain the velocity field in a meridian plane encompassing a large portion of the wake past the rotor model. Measurements with both phase-

locked and unconditioned sampling techniques allow for a triple decomposition of the flow fields. The levels of turbulence intensity show a dominant role of random fluctuations after the location of the pairwise instability. Computation of the kinetic energy fluxes across the wake shear layer shows the presence of three main zones. Prior to the onset of the instability, vortices shed from the blade inhibit the turbulent mixing of the wake during its expansion. The region affected by leapfrogging exhibits a sudden increase of the net entrainment of kinetic energy. Downstream, the energy exchange is characterized by a pronounced turbulent mixing, only due to random turbulent motions. Leapfrogging determines the end of the wake expansion and with the onset of a more pronounced turbulent mixing, coincident with the beginning of the wake re-energizing process.

"STUDY OF NUCLEI DISTRIBUTION AND VORTEX DIFFUSION INFLUENCE ON NUCLEI CAPTURE BY A TIP VORTEX AND NUCLEI CAPTURE NOISE"

Transactions of the ASME, Vol. 115, Sept. 1993, pp. 504-507.

Earlier studies of cavitation nuclei behavior in the presence of a Rankine tip vortex have shown that the nuclei are attracted or captured by the vortex pressure field and during this process noise is produced by the rapid growth. The present paper extends the study of Ligneul and Latorre (1989). The capture of nuclei by the tip vortex was characterized by an index M which depends on the nuclei radius, initial location, and the vortex circulation. To clarify the nuclei distribution effected by this capture process, the frequency of nuclei capture is derived in terms of the nuclei distribution $N(R)$. The influence of the tip vortex axial diffusion on the nuclei capture process is formulated and number results presented to show how vortex diffusion delays the nuclei capture. The paper closes with a discussion of the numerical simulation of the nuclei capture and noise generation by the tip vortex.

Likhachev, O. A.

"EQUILIBRIUM STATE OF TRAILING VORTICES: TWO-DIMENSIONAL MODEL OF A FAR-FIELD VORTEX WAKE"

Aerospace Science and Technology, Vol. 5, July 2001, pp. 329-338

The equilibrium statistical mechanics of a system composed of a large number of two-dimensional point vortices is employed to describe the vortex system shed from aircraft wings. According to this theory, these higher energy states of the vortex system can only be achieved by segregating the point vortices of like kind into two clusters that descend with a constant velocity. The solution is given in terms of the integral constraints for each cluster: total circulation, center of inertia, and kinetic energy. The negative non-dimensional inverse temperature of the system and the length scale related to angular momentum of a single trailing vortex are obtained versus initial interaction energy of the vortex system. Comparison of the theoretical results with available experimental data shows good agreement between the calculated tangential velocity distribution in the trailing vortex and the data.

The flow characteristics for three different wing loads are also compared to emphasize the effect of initial circulation distribution along a lifting wing on the vorticity distribution in the equilibrium trailing vortices.

Lim, C. C.

"RECENT ADVANCES IN 2D AND 2.5D VORTEX STATISTICS AND DYNAMICS"

AIAA Paper No. 2005-5158, Toronto, Canada, June 2005

This review paper offers both an overview of the recent developments in vortex statistics, and a detailed critical review of some of the advances as well as open problems in the area. A fruitful new direction in vortex dynamics concerns vortical systems with very large numbers of vortices in which statistical methods play a pivotal role. After a review of some of the older equilibrium statistical mechanics approaches, such as Onsager's Vortex gas theory, we survey the recent burst of interest and papers on the application of statistical mechanics to a wide range of problems. They include many interesting problems such as rotating stratified flows with natural applications to atmospheric and oceanic sciences. Special models that will be discussed include point vortex as well as vortex blob models in axisymmetric flows, in the plane, and in geophysical flows involving multi-layer baroclinic effects. A recent reverse application of a quantum path-integral Monte-Carlo algorithm to the Lions-Majda model for nearly parallel vortex filaments will be reviewed with numerical results. A connection between these statistical theories and the classical numerical method known as the vortex method will also be made. Many of these noteworthy advances are made possible by good Monte-Carlo algorithms, providing a cross-disciplinary aspect to the field. An important open problem in the field of the vortex gas is the exact partition function for any finite number of particles N and any finite temperature.

Lim, H.-B.

"NUMERICAL STUDY OF THE TRAILING VORTEX OF A WING WITH WING-TIP BLOWING"

PhD Thesis, March 1994, Stanford University, Stanford, CA.

Trailing vortices generated by lifting surfaces such as helicopter rotor blades, ship propellers, fixed wings, and canard control surfaces are known to be the source of noise, vibration, cavitation, degradation of performance, and other hazardous problems. Controlling these vortices is therefore of practical interest. The formation and behavior of the trailing vortices are studied in the present research. In addition, wing-tip blowing concepts employing axial blowing and spanwise blowing are studied to determine their effectiveness in controlling these vortices and their effects on the performance of the wing. The three-dimensional, unsteady, thin-layer compressible Navier-Stokes equations are solved using a time-accurate, implicit, finite difference scheme that employs LU-ADI factorization. The wing-tip blowing is simulated using the actuator plane concept, thereby not requiring resolution of the jet slot geometry. Furthermore, the solution blanking feature of the chimera scheme is used to simplify the parametric study procedure for the wing-tip blowing. Computed results

are shown to compare favorably with experimental measurements. It is found that axial wing-tip blowing, although delaying the rolling-up of the trailing vortices and the near-field behavior of the flowfield, does not dissipate the circulation strength of the trailing vortex farther downstream. Spanwise wing-tip blowing has the effect of displacing the trailing vortices outboard and upward. The increased 'wing-span' due to the spanwise wing-tip blowing has the effect of lift augmentation on the wing and the strengthening of the trailing vortices. Secondary trailing vortices are created at high spanwise wing-tip blowing intensities.

"COMPUTATIONAL MODELING OF HART II BLADE-VORTEX INTERACTION LOADING AND WAKE SYSTEM"

J. Aircraft, Vol. 45, No. 3, May-June 2008, pp. 923-933

Correlations using a loosely coupled trim methodology of the CFD (OVERFLOW-2) and CSD (CAMRAD-II) codes are presented in order to calculate the helicopter rotor blade-vortex interaction (BVI) airloads and wake system for the HART II rotor at an advance ratio of 0.15. Five different grid models are studied in order to quantify the effects of grid refinement on rotor wake resolution. The fine grid model (fine near-body/fine off-body) has a total of 113 million grid points and it gives very good air loads predictions for the HART II baseline, minimum noise and minimum vibration cases. The rotor wake positions are also very well predicted by this fine grid model. The computed vorticity field for a young vortex using the fine grid model is compared with the measured PIV data and the results are surprisingly good. The fine grid model underpredicts the experimental value for maximum vorticity by only 29%. In addition, the predicted vortex core radius is 15% chord for the fine grid calculation while the measured data shows about 5% chord length. The predicted swirl velocity is, however, higher than the measured data for this vortex. The results in this paper provide the first quantitative comparisons of a measured flow field and CFD/CSD computed solutions for a helicopter rotor-wake system.

Lim, J. W. and van der Wall, B. G.

"AN ASSESSMENT OF 3-C PIV ANALYSIS METHODOLOGY FOR HART II MEASURED DATA"

NASA/TM-2010-216024 and TR-RDMR-AF-10-03, July 2010, US Army Research, Development and Engineering Command, Redstone Arsenal, AL.

Since the completion of the DNW test, HART II partners have put forth significant efforts to derive vortex properties from the measured data. These properties include vortex center, rotation angles of the vortex axis in the PIV measurement plane, maximum vorticity, core radius, and swirl velocity. Differences among the partners' results were found for some of these vortex properties, which required more effort to assess the physical significance of the differences. This was because the derived vortex properties were an integral of all the sub-processes in the complex PIV data analysis procedure, and more information was needed to resolve the differences in vortex properties. The objectives of this report are to discuss and summarize the parameters and techniques that could contribute to these

differences. The detailed comparisons in this report have helped establish a strong foundation for a PIV data analysis methodology in determining vortex properties.

"CALCULATION OF ROTOR BLADE-VORTEX INTERACTION AIRLOADS USING A MULTIPLE-TRAILER FREE-WAKE MODEL"

Journal of Aircraft, Vol. 40, No. 6, November-December 2003, pp. 1123-1130.

Analytical results of rotor blade-vortex interaction air loads are presented with two different wake models in the comprehensive analysis CAMRAD II, and these calculated results are compared with the experimental data obtained from the higher-harmonic-control aero acoustic rotor test (HART-I) program. The HART rotor was a 40 percent, Mach-scaled model of the hinge less BO-105 main rotor. Two wake models used in the comprehensive analysis are the single-trailer and the multiple-trailer free-wake models. The multiple-trailer wake model shows good prediction of lift distribution as a function of azimuth for baseline, minimum noise, and minimum vibration cases, and shows significant improvement relative to the single-trailer model in prediction of the tip vortex wake geometry.

Lim, T. T.

"AN EXPERIMENTAL STUDY OF A VORTEX RING INTERACTING WITH AN INCLINED WALL"

Experiments in Fluids, Vol. 7, 1989, pp. 453-463

An experimental study has been made on the interaction of a vortex ring with a plane solid boundary which is inclined to the axis of the ring. Dye visualizations of the ring during the interaction revealed (i) the formation of bi-helical vortex lines around the circumferential axis of the ring, and (ii) that these vortex lines were constantly being displaced along the circumferential axis on either side of the plane of symmetry and towards the region of the ring furthest away from the wall. Key factors which may be responsible for this phenomenon have been identified and are discussed in this paper.

"ON THE GENERATION OF A SPIRAL-TYPE VORTEX BREAKDOWN IN AN ENCLOSED CYLINDRICAL CONTAINER"

Physics of Fluids, Vol. 17, April 2005, pp. 044105-1-044105-9

Earlier experimental studies [see H. U. Vogel, 'Experimentelle Ergebnisse uber die Laminare Stromung in einem zylindrischen Gehause mit darin roterender Scheibe' Max-Planck-Inst. Bericht 6 (1968) and M. P. Escudier, 'Observations of the flow produced in cylindrical container by a rotating endwall,' Exp. Fluids 2, 189 (1984)] showed that vortex breakdown in an enclosed cylindrical container with one rotating end wall could exhibit either one, two, or three recirculating bubbles depending on the combination of Reynolds number Re and aspect ratio H/R , at least for H/R less than 3.5. However, a

recent numerical study by Serre and Bontoux ['Vortex breakdown in a three-dimensional swirling flow,' J. Fluid Mech. 459, 347 (2002)] at $H/R = 4.0$ showed that under some conditions, an S-shape vortex structure follows by a spiral-type vortex breakdown could also be produced. This finding is most interesting because, to the best of our knowledge, a spiral-type vortex breakdown in an enclosed cylindrical container has not been produced previously in experiments. The aim of the present investigation is to verify if these vortex structures can be produced under laboratory conditions. Experiments conducted using dye visualization techniques confirm their existence, even for H/R as low as 3.65. However, attempts to produce similar vortex structures in low aspect ratio cases (H/R less than 2.5) by 'artificially' introducing three dimensionality into the flow was less successful. Here, the confined environment makes a bubble-type vortex breakdown extremely robust, and the imposed asymmetry merely distorts the bubble geometry. The present study also reveals that the formation of a bubble-type vortex breakdown is associated with helical instability of decreasing wavelength, and the S-shape structure is linked with a similar instability of increasing wavelength.

Lim, TT., Nickels, T. B. and Chong, M. S.

"A NOTE ON THE CAUSE OF REBOUND IN THE HEAD-ON COLLISION OF A VORTEX RING WITH A WALL"

Experiments in Fluids, Vol. 12, 1991, pp. 41-48

It is well documented that a trailing vortex pair approaching the ground, and a vortex ring colliding head-on with a rigid plane, experience a reversal in axial velocity which is commonly referred to as 'rebound'. One explanation of this phenomenon suggests that it is essentially an inviscid process because of the finite core-size, whereas another and more widely accepted explanation attributes it to the influence of a secondary vortex which is generated at the surface by viscous effects. The aim of this paper is to assess experimentally the validity of these competing explanations. To achieve this, flow visualization studies of the collision of a vortex ring with a wall are compared with those of the head-on collision of two identical rings. The head-on collision is designed to mimic the inviscid, free-slip case of a ring/wall interaction. This paper describes the experimental findings.

"A NEW VORTEX SHEET MODEL FOR SIMULATING AIRCRAFT WAKE VORTEX EVOLUTION"

Chinese Journal of Aeronautics, Vol. 30, No. 4, 2017, pp. 1315-1326.

A new vortex sheet model was proposed for simulating aircraft wake vortex evolution. Rather than beginning with a pair of counter-rotating cylindrical vortices as in the traditional models, a lift-drag method is used to initialize a vortex sheet so that the roll-up phase is considered. The results of this model report a better approximation to a real situation when compared to the measurement data. The roll-up induced structures are proved to influence the far-field decay. On one hand, they lead to an early decay in the diffusion phase. On the other hand, the growth of linear instability such as elliptical instability is suppressed, resulting in a slower decay in the rapid decay phase. This work provides a simple and practicable model for simulating wake vortex evolution, which combines the roll-up process

and the far-field phase in simulation. It is also proved that the roll-up phase should not be ignored when simulating the far-field evolution of an aircraft wake vortex pair, which indicates the necessity of this new model.

"LARGE EDDY SIMULATION OF AIRCRAFT WAKE VORTEX WITH SELF-ADAPTIVE GRID METHOD"

Applied Mathematics and Mechanics, Vol. 37, No. 10, 2016, pp. 1289-1304.

A self-adaptive-grid method is applied to numerical simulation of the evolution of aircraft wake vortex with the large eddy simulation (LES). The Idaho Falls (IDF) measurement of run 9 case is simulated numerically and compared with that of the field experimental data. The comparison shows that the method is reliable in the complex atmospheric environment with crosswind and ground effect. In addition, six cases with different ambient atmospheric turbulences and Brunt Vaisala (BV) frequencies are compared with the LES. The main characteristics of vortex are appropriately simulated by the current method. The onset time of rapid decay and the descending of vortices agree with the previous measurements and the numerical prediction. Also, secondary structures such as baroclinic vorticity and helical structures are also simulated. Only approximately 6 million grid points are needed in computation with the present method, while the number can be as large as 34 million when using a uniform mesh with the same core resolution. The self-adaptive-grid method is proved to be practical in the numerical research of aircraft wake vortex.

"NUMERICAL STUDY OF AIRCRAFT WAKE VORTEX EVOLUTION NEAR GROUND IN STABLE ATMOSPHERIC BOUNDARY LAYER"

Chinese Journal of Aeronautics, Vol. 30, No. 6, 2017, pp. 1866-1876.

The evolution of aircraft wake vortices near the ground in stable atmospheric boundary layer are studied by Large Eddy Simulation (LES). The sensitivity of vortex evolution to the Monin-Obukhov (M-O) scale is studied for the first time. The results indicate that increasing stability leads to longer lifetimes of upwind vortices, while downwind vortices will decay faster due to a stronger crosswind shear under stable conditions. Based on these results, an empirical model of the vortex lifetime as a function of 10-m-high crosswind and the M-O scale is summarized. This model can provide an estimate of the upper boundary of the vortex lifetime according to the real-time crosswind and atmospheric stability. In addition, the lateral translation of vortices is also inspected. The results show that vortices can travel a furthest distance of 722 m in the currently-studied parameter range. This result is meaningful to safety analysis of airports that have parallel runways.

Lin, Y.-L.

"INSTABILITIES CONDUCIVE TO AVIATION TURBULENCE"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 3, 2016, Springer International Publishing Switzerland, pp. 59-82.

Atmospheric instabilities, including static, Kelvin-Helmholtz (KHL), inertial, conditional, potential (convective), symmetric, conditional symmetric, and potential symmetric instabilities, might trigger aviation-scale turbulence such as the clear-air turbulence (CAT), mountain wave turbulence (MWT), and near-cloud turbulence (NCT) that are reviewed in this chapter. Energy conversion associated with several atmospheric instabilities is reviewed through an equation governing energy transfer in an inviscid, stably stratified shear flow, and the Taylor-Goldstein equation is used to prove a corollary of Howard's semicircle theorem and the Miles-Howard Theorem. The criteria for static (gravitational) instability, conditional instability, potential instability, inertial instability, symmetric instability, conditional symmetric instability, and potential symmetric instability are discussed and summarized in a table. Their implications for the development of turbulence diagnostics or indices for aviation turbulence forecasting are also discussed.

"NUMERICAL MODELING STUDIES OF WAKE VORTEX TRANSPORT AND EVOLUTION WITHIN THE PLANETARY BOUNDARY LAYER"

NASA-CR-196078, January 1994, North Carolina State University, Raleigh, NC

The proposed research involves four tasks. The first of these is to simulate accurately the turbulent processes in the atmospheric boundary layer. TASS was originally developed to study meso-gamma scale phenomena, such as tornadic storms, microbursts, and windshear effects in terminal areas. Simulation of wake vortex evolution, however, will rely on appropriate representation of the physical processes in the surface layer and mixed layer. This involves two parts. First, a specified heat flux boundary condition must be implemented at the surface. Using this boundary condition, simulation results will be compared to experimental data and to other model results for validation. At this point, any necessary changes to the model will be implemented. Next, a surface energy budget parameterization will be added to the model. This will enable calculation of the surface fluxes by accounting for the radiative heat transfer to and from the ground and heat loss to the soil rather than simple specification of the fluxes. The second task involves running TASS with prescribed wake vortices in the initial condition. The vortex models will be supplied by NASA Langley Research Center. Sensitivity tests will be performed on different meteorological environments in the atmospheric boundary layer, which include stable, neutral, and unstable stratifications, calm and severe wind conditions, and dry and wet conditions. Vortex strength may be varied as well. Relevant non-dimensional parameters will include the following: Richardson number or Froude number, Bowen ratio, and height to length scale ratios. The model output will be analyzed and visualized to better understand the transport, decay, and growth rates of the wake vortices. The third task involves running simulations using observed data. MIT Lincoln Labs is currently planning field experiments at the Memphis airport to measure both meteorological conditions and wake vortex characteristics. Once this data becomes available, it can be used to validate the model for vortex behavior under different atmospheric conditions. The fourth task will be to simulate the wake in a more realistic environment covering a wider area. This will involve grid nesting, since high resolution will be required in the wake

region but a larger total domain will be used. During the first allocation year, most of the first task will be accomplished.

Lin, Y.-L., Arya, S. P., Kaplan, M. L. and Shen, S.

"NUMERICAL MODELING STUDIES OF WAKE VORTEX TRANSPORT AND EVOLUTION WITHIN THE PLANETARY BOUNDARY LAYER"

NASA/CR-1998-207826, April 1, 1998, North Carolina State University, Raleigh, NC

In support of the wake vortex effect of the Terminal Area Productivity program, we have put forward four tasks to be accomplished in our proposal. The first task is validation of two-dimensional wake vortex-turbulence interaction. The second task is investigation of three-dimensional interaction between wake vortices and atmospheric boundary layer (ABL) turbulence. The third task is ABL studies. The fourth task is addition of a Klemp-Durran condition at the top boundary for TASS model. The accomplishment of these tasks will increase our understanding of the dynamics of wake vortex and improve forecasting systems responsible for air safety and efficiency. The first two tasks include following three parts: (a) Determine significant length scale for vortex decay and transport, especially the length scales associated with the onset of Crow instability; (b) Study the effects of atmospheric turbulence on the decay of the wake vortices; and (c) Determine the relationships between decay rate, transport properties and atmospheric parameters based on large eddy simulation (LES) results and the observational data. These parameters may include turbulence kinetic energy, dissipation rate, wind shear and atmospheric stratification. The ABL studies cover LES modeling of turbulence structure within planetary boundary layer under transition and stable stratification conditions. Evidences have shown that the turbulence in the stable boundary layer can be highly intermittent and the length scales of eddies are very small compared to those in convective case. We proposed to develop a nesting grid mesh scheme and a modified Klemp-Durran condition at the top boundary for TASS model to simulate planetary boundary layer under stable stratification conditions.

Lin, Y.-L., Han, J., Zhang, J, Ding, F. and Arya, S. P.

"LARGE EDDY SIMULATION OF WAKE VORTICES IN THE CONVECTIVE BOUNDARY LAYER"

AIAA Paper No. 2000-0753, Reno, NV, January 2000

The behavior of wake vortices in a convective boundary layer is investigated using a validated large eddy simulation model. Our results show that the vortices are largely deformed due to strong turbulent eddy motion while a sinusoidal Crow instability develops. Vortex rising is found to be caused by the updrafts (thermals) during daytime convective conditions and increases with increasing nondimensional turbulence intensity n . In the downdraft region of the convective boundary layer, vortex sinking is found to be accelerated proportional to increasing n , with faster speed than that in an ideal line vortex pair in an inviscid fluid. Wake vortices are also shown to be laterally transported over a significant distance due to large turbulent eddy motion. On the other hand, the decay rate of the

vortices in the convective boundary layer that increases with increasing n , is larger in the updraft region than in the downdraft region because of stronger turbulence in the updraft region.

Lindelow, P.

"FIBER BASED COHERENT LIDARS FOR REMOTE WIND SENSING"

PhD Thesis, November 2007, University of Denmark, Lyngby, Denmark.

In this thesis a study of coherent lidars for remote wind sensing is undertaken. Remote wind sensing is important when mast mounted anemometers cannot be used due to economical or practical reasons. One such important field is within the wind energy sector where accurate wind sensing at distances of up to a few hundred meters from the ground is important for site evaluation, turbine power verification and for future applications such as active blade pitch and load control for an optimized output. The thesis covers a wide field; the state-of-the-art coherent lidar wind sensors is reviewed, the signal model is expanded upon and results of applied research on commercially available lidars, as well as the development and evaluation of a frequency modulated prototype, are presented. The standard model for coherent lidars sensing dispersed targets was expanded upon by considering the range dependent correlated contribution duration of range gated systems, which significantly affects the narrowband signal to noise description and the weighting of the sample volume. A model of the range dependent collection efficiency obtained by focused fiber based lidars has been developed and verified. These advancements are important for predicting the lidar performance and optimizing the signal processing. A novel frequency modulation concept, which is promising for the remote sensing of wind, was invented in this study. The technique is based on equidistantly frequency stepped pulse trains and a frequency pursuing local oscillator. It operates at high pulse repetition but will despite this avoid the customary disadvantages, range ambiguity and a limitation of the sensing range. This novel concept could provide more accurate systems while avoiding the use of high peak powers which introduces stimulated Brillouin scattering and non-linear effects as well as higher demands on other components in the transmitter. A frequency sweeper, appropriate for the invented frequency modulation technique, was constructed and evaluated. This sweeper was subsequently used to modify a continuous wave lidar into a frequency modulated prototype and a proof of principle campaign, demonstrated the merits and limitations of the novel technique.

Line, A. J. and Brown, R. E.

"HIGH RESOLUTION WAKE MODELLING USING A SEMI-LAGRANGIAN ADAPTIVE GRID FORMULATION"

European Rotorcraft Forum, Friedrichshafen, Germany, September 2003

Current interest in improving numerical predictions of helicopter rotor vibration and acoustic signature has driven a requirement to model blade aerodynamic loadings to extremely high resolution. The problem is complicated by the complexity of the flow in the rotor wake and the difficulty in conserving vortical structures in the wake for long enough so that all important vibration- or noise-producing blade vortex interactions are represented properly. The Vorticity Transport Model,

developed by Brown, can preserve vortical structures over sufficiently long timescales, but, up to now, has been prohibitively expensive when run at the resolutions required for accurate vibration or acoustic prediction. In this paper we present a new computational grid system which, using adaptive cell management and nested grids, allows significant increases in grid resolution with minimal impact on computational cost. The new grid system is effectively boundary-free, thus eliminating the need for numerical boundary conditions. In addition, the velocity field is optimally evaluated on the new grid using an extremely efficient technique based on the Cartesian Fast Multipole Method. The implementation of both the grid system and the velocity calculation within a new version of the Vorticity Transport Model is described. The performance of the new model is validated against experimental data and some properties of the model, when used to predict rotor loads to a resolution that approaches that required for calculations of rotor vibration or acoustic signature, are illustrated.

"VELOCITY FIELD OF A CYLINDER IN THE WAKE OF A ROTOR IN FORWARD FLIGHT"

J. Aircraft, Vol. 27, No. 9, September 1990, pp. 804-809

The rotor and the airframe of a rotorcraft can have severe effects on each other because of flowfield interactions. Data on flowfield characteristics have been obtained using laser velocimetry to identify and interpret the features of such interactions. This paper summarizes previous results on the flowfield of the rotor and then describes the effects of the rotor wake on the flowfield around an airframe model. A circular cylinder with a hemispherical nose is used as the airframe model and is instrumented with static pressure taps and flush-mounted microphones. A two-bladed teetering rotor is suspended above it in a wind tunnel. The periodic and time-averaged velocity fields are measured along lines parallel to the airframe axis at a rotor advance ratio of 0.1 and a rotor tip Mach number of 0.29. The dominant features in the velocity distribution over the airframe are seen to be linked to vortex interactions with the airframe surface. The tip vortex and the trailing vortex sheet are seen to be displaced in opposite directions by the airframe. Secondary vortex generation phenomena are observed near the airframe surface during vortex interaction.

"SOUND GENERATED BY A PAIR OF AXISYMMETRIC COAXIAL VORTEX RINGS"

AIAA Journal, Vol. 43, No. 2, February 2005, pp. 326-336

The time-dependent acoustic field generated by the mutual interaction of a pair of coaxial viscous vortex rings advecting along a common axis of symmetry is simulated using a two-step numerical procedure. In the first step, the flowfield is predicted by solving the incompressible Navier-Stokes equations. In the second step, Powell's vortex sound theory is used to predict the far-field acoustic field associated with the flow unsteadiness. This study considers the effect of the initial toroidal ring radii on the sound radiation. The acoustic predictions are compared with those obtained using the method of matched asymptotic expansions. Our results indicate that the acoustic signature for the

Mach-number range simulated shows an axisymmetric lateral quadrupole pattern. In addition, the time variation of the far-field acoustic signal displays significant effects caused by vortex dynamics associated with the finite-sized cores and viscous diffusion. These effects are more pronounced for rings with a smaller initial toroidal radius. The influence of Mach number on the far-field directivity (e.g., location of polar extinction angles) and the multipole content of the acoustic signal is examined through a multiple decomposition of the predicted acoustic fields.

"AIRCRAFT VORTEX WAKE DESCENT AND DECAY UNDER REAL ATMOSPHERIC EFFECTS"

FAA-RD-73-120, October 1973, AeroVironment Inc., Pasadena, CA

Aircraft vortex wake descent and decay in a real atmosphere is studied analytically. Factors relating to encounter hazard, wake generation, wake descent and stability, and atmospheric dynamics are considered. A new analysis for Crow instability in ambient turbulence is given, expressing time-to-linkage as an explicit function of the turbulent dissipation. Wake descent in a stratified inviscid fluid is studied analytically providing new results. According to the new theory, the vortex span reduces upon descent into a stably stratified flow, causing the rate of descent to increase. Exact solutions are derived for vortex cell shapes in a uniformly sheared crosswind, showing that the upwind cell is greatly increased in size. It is believed that this may partly account for the observed unsymmetrical behavior (banking, etc.) in crosswinds.

Liu, B., Byon, E. and Plumlee, M.

"DATA-DRIVEN PARAMETER CALIBRATION IN WAKE MODELS"

AIAA Paper 2018-2017, January 2018, Kissimmee, FL.

Physical interactions among wind turbines, called wake effects, are known to be one of the significant factors that affect power generation performance in wind power systems. Among several wake modeling approaches, physics-based engineering models, such as Jensen's model, have been widely used due to their computational tractability. Although substantial efforts have been made to improve the accuracy of engineering wake models, few studies suggest calibrating the model parameters in the literature. We propose a new data-driven calibration approach for adjusting the model parameters using real operational data.

Liu, C.

"WAKE VORTEX ENCOUNTER ANALYSIS WITH DIFFERENT WAKE VORTEX MODELS USING VORTEX-LATTICE METHOD"

MS Thesis, Delft University of Technology, Delft, The Netherlands, Dec. 2007

The objective of the present study is to program a reliable MathCAD code based on the Vortex Lattice Method (VLM) to calculate the induced rolling moment on an aircraft during wake vortex encounters (WVEs). The code is named Chaos because of the complexity of WVEs. As part of the present work, nine different vortex profiles are compared throughout their properties. The maximum induced rolling moment depends on the vortex model, the core radius and the vortex spacing. A short distance behind the wing of an aircraft the cross-flow kinetic energy of the vortex pair is directly related to the induced drag of the wing and this provides a condition for the initial vortex core size. Starting from this point, the decay of the vortex core radius can be calculated with an effective viscosity turbulence model (Owen 1970). Moreover, the decay of the wake vortex circulation and decay of induced rolling moment (an empirical equation from Winckelmans (2004) can be obtained. For different vortex models, all the different decays are compared numerically in this report. It was found that the nine different vortex profiles do not cause very big differences for the induced rolling moment coefficient analysis, especially for bigger follower aircraft.

Liu, C. H.

"A THREE-DIMENSIONAL VORTEX PARTICLE-IN-CELL METHOD FOR VORTEX MOTIONS IN THE VICINITY OF A WALL"

International J. for Numerical Methods in Fluids, Vol. 37, November 2001, pp. 501-523

A new vortex particle-in-cell method for the simulation of three-dimensional unsteady incompressible viscous flow is presented. The projection of the vortex strengths onto the mesh is based on volume interpolation. The convection of vorticity is treated as a Lagrangian move operation but one where the velocity of each particle is interpolated from an Eulerian mesh solution of velocity-Poisson equations. The change in vorticity due to diffusion is also computed on the Eulerian mesh and projected back to the particles. Where diffusive fluxes cause vorticity to enter a cell not already containing any particles new particles are created. The surface vorticity and the cancellation of tangential velocity at the plate are related by the Neumann conditions. The basic framework for implementation of the procedure is also introduced where the solution update comprises a sequence of two fractional steps. The method is applied to a problem where an unsteady boundary layer develops under the impact of a vortex ring and comparison is made with the experimental and numerical literature.

"INTERACTION OF DECAYING TRAILING VORTICES IN SPANWISE SHEAR FLOW"

Computers & Fluids, Vol. 15, No. 4, 1987, pp. 77-92.

The drift of trailing vortices in a cross wind near the ground is modeled by an unsteady two-dimensional, rotational flowfield where there are concentrations of large vorticity in spots having small effective sizes and finite total strengths. The problem is analyzed by combining the matched asymptotic solution of the decaying vortical spots and the Euler solution of the background unsteady rotational flow. Using the method of averaging, we develop a numerical scheme in which the grid size

and time step depend only on the length and velocity scales of the background flow and not on the effective core size of vertical spots. Numerical results are presented to illustrate the interaction between the trajectories of the vertical spots and the convection of vorticity in the background flowfield.

Liu, C. H. and Ting, L.

"MOTION, DECAY AND MERGING OF VORTEX FILAMENTS"

Southeastern Conference on Theoretical and Applied Mechanics, April 1988, Biloxi, MS.

The asymptotic solutions of Navier-Stokes equations for vortex filaments of finite strength with small effective vortical cores are summarized. Emphases are placed on the physical meaning and the practical limit to the applicability of the asymptotic solution. Finite-difference solutions of Navier-Stokes equations for the merging of the filament(s) are described. It is focused on the development of the approximate boundary conditions for the computational domain.

Liu, C. H., Kandil, O. A. and Kandil, H. A.

"NUMERICAL SIMULATION AND PHYSICAL ASPECTS OF SUPERSONIC VORTEX BREAKDOWN"

Computers Fluids, Vol. 22, No. 4/5, 1993, pp. 607-622.

Existing numerical simulations and physical aspects of subsonic and supersonic vortex-breakdown modes are reviewed. The solution to the problem of supersonic vortex breakdown is emphasized in this paper and carried out with the full Navier-Stokes equations for compressible flows. Numerical simulations of vortex-breakdown modes are presented in bounded and unbounded domains. The effects of different types of downstream-exit boundary conditions are studied and discussed.

Liu, C. H., Krause, E. and Menne, S.

"ADMISSIBLE UPSTREAM CONDITIONS FOR SLENDER COMPRESSIBLE VORTICES"

AIAA Paper No. 1986-1093, May 1986, Atlanta, GA.

The influence of the compressibility on the flow in slender vortices is being studied. The dependence of the breakdown of the slender-vortex approximation on the upstream conditions is demonstrated for various Reynolds numbers and Mach numbers. Compatibility conditions, which have to be satisfied if the vortex is to remain slender, are discussed in detail. The general discussions are supplemented by several sample calculations.

Liu, C. H., Tavantzis, J. and Ting, L.

"NUMERICAL STUDIES OF MOTION AND DECAY OF VORTEX FILAMENTS"

AIAA Journal, Vol. 24, No. 8, August 1986, pp. 1290-1297.

A computational code is developed for the integro-differential equations governing the motion of the centerlines of vortex filaments submerged in a background potential flow. These equations, which are derived from the method of matched asymptotic analysis, include the effect of decaying large-magnitude circumferential and axial velocity components in the vortical cores. Numerical examples are presented to assess the effect of large axial velocity and of non-similar initial profiles in vortical cores. The initial configurations of the filaments are chosen so as to fulfill the basic assumptions of asymptotic analysis, which is the effective vortical core size is much smaller than all other length scales in the flowfield, e.g., the radius of curvature and interfilament distance. The computations are continued until the basic assumption is no longer valid, that is, when the merging or interaction of filaments have begun. Various types of local or global merging or interaction of filaments are classified and demonstrated by numerical examples.

Liu, C. H., Thomas, J. L. and Tung, C.

"NAVIER-STOKES CALCULATIONS FOR THE VORTEX WAKE OF A ROTOR IN HOVER"

AIAA Paper No. 1983-1676, Danvers, MA, July 1983

An efficient finite-difference scheme for the solution of the incompressible Navier-Stokes equation is used to study the vortex wake of a rotor in hover. The solution procedure uses a vorticity-stream function formulation and incorporates an asymptotic far-field boundary condition enabling the size of the computational domain to be reduced in comparison to other methods. The results from the present method are compared with experimental data obtained by smoke flow visualization and hot-wire measurements for several rotor blade configurations.

Liu, C.-H. and Ting, L.

"MOTION AND INTERACTION OF DECAYING TRAILING VORTICES IN SPANWISE SHEAR WIND"

NASA TP-2599, September 1986, NASA Langley Research Center, Hampton, VA.

This paper presents a simulation of the drift of trailing vortices in a cross-wind near the ground by an unsteady, two-dimensional, rotational flow field with a concentration of large vorticity in 'vortical spots' (having a finite but small effective size and finite total strength). The problem is analyzed by a combination of the method of matched asymptotic analyses for the decay of the vortical spots and the Euler solution for the unsteady rotational flow. Using the method of averaging, a special numerical method is developed in which the grid size and time step depend only on the length and velocity scales of the background flow and independent of the effective core size of a vortical spot. The core size can be much smaller than the grid size, whereas the peak velocity in the core is inversely proportional to the spot size. Numerical results are presented to demonstrate the strong interaction between the trajectories of the vortical spots and the change of the vorticity distribution in the background flow field.

Liu, G. C. and Ting, L.

"NUMERICAL STUDIES OF THE MARGIN OF VORTICES WITH DECAYING CORES"

AIAA Paper No. 1986-1072, Atlanta, GA, May 1986

The merging of vortices to one vortex is a canonical incompressible viscous flow problem. The merging process begins when the core sizes or the vortices are comparable to their distances and ends when the contour lines of constant vorticity lines are circularized around one center. Approximate solutions to this problem are constructed by adapting the asymptotic solutions for distinct vortices. For the early stage of merging, the next-order terms in the asymptotic solutions are added to the leading term. For the later stage of merging, the vorticity distribution is reinitialized by vortices with overlapping core structures guided by the 'rule of merging' and the velocity of the 'vortex centers' are then defined by a minimum principle. To show the accuracy of the approximate solution, it is compared with the finite-difference solution.

Liu, H.

"INTERFACING COMPREHENSIVE ROTORCRAFT ANALYSIS WITH ADVANCED AEROMECHANICS AND VORTEX WAKE MODELS"

MS Thesis, Dec. 2007, Georgia Institute of Technology, Atlanta, GA.

This dissertation describes three aspects of the comprehensive rotorcraft analysis. First, a physics-based methodology for the modeling of hydraulic devices within multibody-based comprehensive models of rotorcraft systems is developed. This newly proposed approach can predict the fully nonlinear behavior of hydraulic devices, and pressure levels in the hydraulic chambers are coupled with the dynamic response of the system. The second part of this research is in computational aeroelasticity, in which an interface between computational fluid dynamics (CFD) and computational structural dynamics (CSD) is established. This interface enables data exchange between CFD and CSD with the goal of achieving accurate air loads predictions. The ability to accurately capture the wake structure around a helicopter rotor is crucial for rotorcraft performance analysis. In the third part of this thesis, a new representation of the wake vortex structure based on Non-Uniform Rational B-Spline curves and surfaces is proposed to develop an efficient model for prescribed and free wakes. The proposed formulation has the potential to reduce the computational cost associated with the use of the Helmholtz law and the Biot-Savart law when calculating the induced flow field around the rotor. An efficient free wake analysis will considerably decrease the computational cost of comprehensive rotorcraft analysis, making the approach more attractive to routine use in industrial settings.

Liu, H.

"INTERFACING COMPREHENSIVE ROTORCRAFT ANALYSIS WITH ADVANCED AEROMECHANICS AND VORTEX WAKE MODELS"

Ph.D. Thesis, April 2008, Georgia Institute of Technology, Atlanta, GA.

This dissertation describes three aspects of the comprehensive rotorcraft analysis. First, a physics-based methodology for the modeling of hydraulic devices within multibody-based comprehensive models of rotorcraft systems is developed. This newly proposed approach can predict the fully nonlinear behavior of hydraulic devices, and pressure levels in the hydraulic chambers are coupled with the dynamic response of the system. The second part of this research is in the area of computational aeroelasticity, in which an interface between computational fluid dynamics (CFD) and computational structural dynamics (CSD) is established. This interface enables data exchange between CFD and CSD with the goal of achieving accurate air loads predictions. The ability to accurately capture the wake structure around a helicopter rotor is crucial for rotorcraft performance analysis. In the third part of this thesis, a new representation of the wake vortex structure based on Non-Uniform Rational B-Spline curves and surfaces is proposed to develop an efficient model for prescribed and free wakes. The proposed formulation has the potential to reduce the computational cost associated with the use of the Helmholtz law and the Biot-Savart law when calculating the induced flow field around the rotor. An efficient free wake analysis will considerably decrease the computational cost of comprehensive rotorcraft analysis, making the approach more attractive to routine use in industrial settings.

"LABORATORY INVESTIGATION OF ATMOSPHERIC EFFECTS ON VORTEX WAKES"

Report DTRS-57-87-C-00109, February 1990, Flow Research, Inc., Kent, WA.

Tow tank experiments were conducted to investigate atmospheric effects on the evolution of trailing vortex wakes. The atmospheric effects simulated in the tank included stable stratification, ambient turbulence, and wind shear. The rebound phenomenon of a vortex wake approaching the ground surface was also investigated. Two methods were used to generate vortex wakes: a towed NACA 0012 wing and a 2-D vortex generator.

Liu, H.-T.

"LABORATORY INVESTIGATION OF DETRAINMENT IN VORTEX WAKES"

AIAA Journal, Vol. 44, No. 8, August 2006, pp. 1872-1882

Detrainment in vortex wakes is a delicate phenomenon that has been predicted to occur only at high Froude numbers in stratified fluids, because of imbalance of buoyancy between fluids inside and outside the vortex wakes. Such a phenomenon rarely manifests in full-scale flights because the required high-Froude-number conditions are seldom met. Physical modeling of the phenomenon using small-scale wings must be conducted in a fluid with a very weak stratification, which is difficult to prepare and maintain in the laboratory. Furthermore, the detrainment flow is so weak that its observation relies on the generation of very clean vortex wakes. Consequently, only limited laboratory results are available and the phenomenon is by no means well understood. Detrainment in vortex wakes has not been observed directly but inferred from their kinematics, that is, acceleration and

deceleration. The first ever visual evidence of the detrainment phenomenon is provided. The stringent requirements were met by 1) conducting towing-tank experiments using a two-dimensional vortex generator and a clean wing model suspended on fine wires and 2) preparing weakly stratified fluids using brine and/or heat. Based on visual results effects of detrainment on the vortex wakes were studied qualitatively and quantitatively.

"LABORATORY INVESTIGATION OF ATMOSPHERIC EFFECTS ON VORTEX WAKES -A FEASIBILITY INVESTIGATION"

TR 394, March 1987, Flow Research, Inc., Kent, WA

Tow tank experiments were successfully conducted to demonstrate the feasibility of investigating atmospheric effects on the evolution of a trailing vortex wake. Atmospheric disturbances simulated in the tank included stable stratification, ambient turbulence, and wind shear. Visualizations of the vortex wakes from several perspectives were conducted using fluorescent dye illuminated by bands of ultraviolet lights and a sheet of laser light. In a quiescent environment, we have established the upper bound of the lifespan of a trailing vortex wake due to essentially self-induced sinusoidal instability. Ambient turbulence reduces the lifespan. Vortex linking is the dominant mode of vortex instability in weak turbulence. As the turbulence intensity or dissipation rate increases, vortex bursting begins to appear and eventually replaces linking as the dominant mode of instability. The wind shear affects the behavior of the vortex wake in two ways. In a longitudinal shear, the inclined trailing vortex pair is stretched, resulting in vortex contraction and leading to speed up of vortex descent and possibly to vortex annihilation prior to the onset of linking or bursting. In a cross shear, the vortex wake is forced to rotate about its axis.

Liu, H.-T.

"EFFECTS OF AMBIENT TURBULENCE ON THE DECAY OF A TRAILING VORTEX WAKE"

Journal of Aircraft, Vol. 29, No. 2, Mar.-Apr. 1992, pp. 255-263

Experiments were conducted to investigate the effects of ambient turbulence on the evolution of a trailing vortex wake. The wake was generated by towing an NACA 0012 wing, with a span of 10.2 cm and a chord of 5.1 cm, at an incidence of -10 deg and a speed of 40 cm/s in a tow tank. The chord Reynolds number was 20,400. The ambient turbulence was generated by towing three grids, with square meshes of 1.45, 10.2, and 20.3 cm, upstream of the wing. Turbulence parameters were measured with crossed hot-film probes. The trailing vortex wake, tagged with a fluorescent dye, was visualized from different perspectives and its decay was derived from 16-mm movie records. For weak turbulence with large integral scales compared with the vortex separation, vortex linking is the dominant mode of instability. The dominant wavelength of the linking decreases with increasing turbulence intensity or dissipation rate. As the turbulence intensity increases, vortex bursting appears and eventually replaces linking as the dominant mode of instability. For turbulence with a small

integral scale as compared with the vortex separation, vortex instability is predominantly of the bursting type.

Liu, H.-T.

"TOW-TANK SIMULATION OF VORTEX WAKE DYNAMICS"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 32-1 - 32-26

Towing tank experiments were conducted to investigate ambient and ground effects on vortex wakes. Two methods were used to generate the vortex wakes: a towed NACA 0012 wing with a chord Reynolds number of 20,400 and a slotted-jet vortex generator. The ambient turbulence was generated by towing upstream of the wing three grids of different meshes. Turbulence parameters were measured with crossed hot-film probes. The trailing vortex wake, tagged with a fluorescent dye, was visualized and its evolution was derived from 16-mm movie records. For weak turbulence with large integral scales compared with the vortex separation, vortex linking is the dominant mode of instability. The dominant wavelength of the linking decreases with increasing turbulence intensity or dissipation rate. As the turbulence intensity increases, vortex bursting appears and eventually replaces linking as the dominant mode of instability. For turbulence with a small integral scale as compared with the vortex separation, vortex instability is predominantly of the bursting type. Trajectories derived from trailing vortex wakes near a simulated ground surface have confirmed the inadequacy of the two-dimensional inviscid solution. The generation of a relatively weak secondary vortex causes the primary vortex to rebound from the surface as a result of unsteady separation. For the slotted-jet vortex generator, the introduction of a rigid surface close to the jet exit results in the formation of relatively strong and persistent secondary vortices at the ground outboard of the primary vortices. A simple modification of the two-dimensional inviscid theory -- namely, adding a secondary vortex to the system -- recreates the rebound phenomenon, which agrees qualitatively with the trend seen in the experiments.

Liu, H.-T. and Srnsky, R. A.

"LABORATORY INVESTIGATION OF ATMOSPHERIC EFFECTS ON VORTEX WAKES"

TR 497, February 1990, Flow Research, Inc., Kent, WA

Tow tank experiments were conducted to investigate atmospheric effects on the evolution of trailing vortex wakes. The atmospheric effects simulated in the tank included stable stratification, ambient turbulence, and wind shear. In a quiescent fluid, self-induced sinusoidal instability limits the lifespan of a trailing vortex wake in a neutral or weakly stratified environment. Ambient turbulence reduces the lifespan. For weak turbulence with a large integral scale compared with the vortex separation, vortex linking is the dominant mode of vortex instability. As the turbulence intensity or dissipation rate increases, however, vortex bursting begins to appear and eventually replaces linking as the dominant mode of instability. Existing theory tends to underpredict, by a factor of about 2, the lifespan of the vortex wake in a turbulent environment. For turbulence with a small integral scale compared with the

vortex separation, vortex instability is predominantly of the bursting type. In a longitudinal shear, the inclined trailing vortex pair tends to be stretched, resulting in an increase in the dominant wavelength of the linking instability. In a cross shear, one side of the vortex pair is stabilized and the other destabilized by the shear, the formation of a solitary vortex at large times is often observed. Tipping of the vortex wake is observed just below the exit of the 2-D vortex pair due to the presence of a crossflow. The tipping is attributed to the asymmetries of the initial rollup and of the flow generated as the vortex pair is carried by the crossflow across the exit plate. There is no correlation between the orientation of the tipping and the sign of the shear flow. With respect to ground effects, a vortex wake rebounds after it moves close to the ground. By introducing a solid surface close to the exit of the 2-D vortex pair, the formation of secondary vortices outboard of the main vortices that cause the latter to rebound is evident from the visual results. Trajectories derived from the trailing vortex wake released in the proximity of a simulated ground surface have confirmed that the hyperbolic inviscid solution is incorrect.

Liu, H.-T., Hwang, P. A. and Srnsky, R. A.

"PHYSICAL MODELING OF GROUND EFFECTS ON VORTEX WAKES"

Journal of Aircraft, Vol. 29, No. 6, November-December 1992, pp. 1027-1034.

Towing-tank experiments were conducted to investigate ground effects on vortex wakes. Two methods were used to generate the vortex wakes: 1) a towed NACA 0012 wing and 2) a slotted-jet vortex generator. Trajectories derived from trailing vortex wakes, tagged with a fluorescent dye and released near the simulated ground surface, have confirmed the inadequacy of the two-dimensional inviscid solution. The generation of a relatively weak secondary vortex causes the primary vortex to rebound from the surface because of unsteady separation. There is no significant difference between the trajectories, whether the ground is simulated by a rigid surface or a free surface. The introduction of a rigid surface close to the exit of the slotted-jet vortex generator results in the formation of secondary vortices at the ground outboard of the primary vortices. The secondary vortices generated by the slotted-jet vortex pair are more coherent and persistent than those generated by the trailing vortex pair. A simple modification of the two-dimensional inviscid theory -namely, adding a secondary vortex to the system - recreates the rebound phenomenon, which agrees qualitatively with the trend seen in the experiments.

"INTERACTION BETWEEN A SPATIALLY GROWING TURBULENT BOUNDARY LAYER AND EMBEDDED STREAMWISE VORTICES"

Journal of Fluid Mechanics, Vol. 326, 1996, pp. 151-179.

The interaction between a zero-pressure-gradient turbulent boundary layer and a pair of strong, common-flow-down, streamwise vortices with a sizable velocity deficit is studied by large-eddy simulation. The sub-grid-scale stresses are modelled by a localized dynamic eddy-viscosity model. The

results agree well with experimental data. The vortices drastically distort the boundary layer, and produce large spanwise variations of the skin friction. The Reynolds stresses are highly three-dimensional. High levels of kinetic energy are found both in the upwash region and in the vortex core. The two secondary shear stresses are significant in the vortex region, with magnitudes comparable to the primary one. Turbulent transport from the immediate upwash region is partly responsible for the high levels of turbulent kinetic energy in the vortex core; its effect on the primary stress ($u'v'$) is less significant. The mean velocity gradients play an important role in the generation of ($u'v'$) in all regions, while they are negligible in the generation of turbulent kinetic energy in the vortex core. The pressure-strain correlations are generally of opposite sign to the production terms except in the vortex core, where they have the same sign as the production term in the budget of ($u'v'$). The results highlight the limitations of the eddy-viscosity assumption (in a Reynolds-averaged context) for flows of this type, as well as the excessive diffusion predicted by typical turbulence models.

Liu, P.-Q., Wen, R.-Y. and Zhang, G.-W.

"EFFECTS OF CANARD SWEEP AND CANARD-SPANWISE BLOWING MAGNITUDE ON LIFT INCREMENT"

Journal of Aircraft, Vol. 43, No. 5, September-October 2006, pp. 1369-1371.

The effects of different canard's swept angles and jet momentum coefficients on the lift increment of simple close-coupled canard configurations with a 40-deg swept delta wing were investigated in a low-speed wind tunnel by force measurement. The experimental results show that at a certain range of attack angles (16-50 deg), on the condition of no blowing, with the increasing of the canard's swept angles, the lift increment and critical stall angles increase, which shows that the canard can be used as a controlling element for aerodynamic forces. On the condition of blowing, when the jet momentum coefficient exceeds a certain value, the more the jet momentum coefficient is, the more the lift increment is, which suggests that indirectly controlling the wing vortex is possible by canard-spanwise blowing for close-coupled canard configurations.

"BLADE PENETRATION INTO A VORTEX CORE WITH AND WITHOUT AXIAL CORE FLOW"

J. Fluid Mech., Vol. 519, 2004, pp. 81-103

A computational study of the penetration of a blade into the core of an initially columnar vortex in an incompressible viscous fluid and the subsequent cutting of the vortex is reported for the case where the blade axis is initially orthogonal to the vortex axis. The vortex is advected toward the fixed blade by a free-stream velocity-oriented tangent to the blade chord, where the free-stream speed is sufficiently large that the vortex does not induce ejection of vorticity from the blade boundary layer prior to impact of the vortex core with the blade leading edge. A range of computations are performed for cases both with and without ambient axial flow in the vortex core. As the blade leading edge penetrates the vortex core, cross-diffusion between the columnar vortex and the blade boundary layer causes vortex lines originating in the columnar vortex to rapidly reconnect to those in the blade

boundary layer. This cutting process is found to be always incomplete however, due to a change in sign of the spanwise vortex-induced velocity along the leading edge as the vortex is cut, leaving a thin vortex sheet that wraps around the blade leading edge. Cutting of a vortex with non-zero axial flow causes an asymmetry that results in an impulsive lift force on the blade. This lift force has maximum magnitude during the time period where the blade leading edge penetrates the vortex core. Both the vortex cutting process and the unsteady lift force on the blade are found to be approximately independent of Reynolds number for the various cases examined.

"AMPLIFICATION OF THREE-DIMENSIONAL PERTURBATIONS DURING PARALLEL VORTEX-CYLINDER INTERACTION"

J. Fluid Mech., Vol. 573, 2007, pp. 457-478

A computational study has been performed to examine the amplification of three-dimensional flow features as a vortex with small-amplitude helical perturbations impinges on a circular cylinder whose axis is parallel to the nominal vortex axis. For sufficiently weak vortices with sufficiently small core radius in an inviscid flow, three-dimensional perturbations on the vortex core are indefinitely amplified as the vortex wraps around the cylinder front surface. The paper focuses on the effect of viscosity in regulating amplification of three-dimensional disturbances and on assessing the ability of two-dimensional computations to accurately model parallel vortex-cylinder interaction problems. The computations are performed using a multi-block structured finite-volume method for an incompressible flow, with periodic boundary conditions along the cylinder axis. Growth of three-dimensional flow features is examined using a proper-orthogonal decomposition of the Fourier-transformed vorticity field in the azimuthal and axial directions. The interaction is examined for different axial wavelengths and amplitudes of the initial helical vortex waves and for three different Reynolds numbers.

"COMPARISON OF WIND MEASUREMENTS BETWEEN VIRTUAL TOWER AND VAD METHODS WITH DIFFERENT ELEVATION ANGLES"

19th Coherent Laser Radar Conference (CLRC), Paper P32, June 2018, Okinawa, Japan.

This paper compares wind retrieval methods of VT (Virtual Tower) mode and VAD (Velocity-Azimuth Display) with different scanning elevation angles. The field experiment was performed from September 23 to October 13 2017 at the campus of Ocean University of China under various weather conditions. A total of seven lidars were involved in the experiment. Three lidars carried out the staring mode to constitute the VT. The other four lidars were concurrently operating PPI scanning at different elevation angles, corresponding to different spatial average volume. The results of wind speed and direction from VT and VAD shows good correlation when lidars are well synchronized. The influence of spatial homogeneity on wind retrieval is also described in this paper.

"COMPUTATIONAL EVALUATION OF CONTROLLING FLAP EDGE VORTEX AND TIP VORTEX EFFECTS WITH CIRCULATION CONTROL TECHNIQUE"

AIAA Paper No. 2007-473, Reno, NV, January 2007

This paper extends our previous work on the two-dimensional Circulation Control (CC) airfoil studies to three-dimensional applications so that the potential benefits of CC techniques on controlling vortex and reducing noise can be evaluated. Two numerical simulations have been done to identify the effects of CC techniques on controlling the flap edge vortex and the tip vortex. The first is a stream-wise tangential blowing on a wing-flap configuration. It is demonstrated that a gradually varied CC blowing can eliminate flap-edge vortex, thus reducing flap-edge noise. The second case involves a span-wise tangential blowing over a rectangular wing with a rounded wing tip. It is found that CC blowing cannot eliminate the tip vortex. However, it can control and modify the location of the tip vortex to increase the vertical clearances between the wing and the tip vortex, thus reducing the blade vortex interaction (BVI) and the BVI noise.

"ESTIMATION OF VEHICLE-LEVEL FUEL BURN BENEFITS OF AIRCRAFT FORMATION FLIGHT"

Journal of Aircraft, Vol. 55, No. 2, March-April 2018, pp. 853-861.

The present paper investigates the overall aircraft-level impact of formation flight in terms of total drag savings and fuel consumption reductions. The current work is carried out because of an in-house multidisciplinary integrated conceptual aircraft design optimization framework. An aerodynamic method based on potential flow theory is first adapted for the induced drag estimation of aircraft in formation flight. By integrating the formation flight aerodynamic methodology into the in-house aircraft design and optimization platform, the potential drag reduction for arbitrary aircraft configurations in formation can be assessed. For specific flight missions, the fuel burn reduction can be further determined. Through comparing with other simulation and experimental results, the proposed formation flight aerodynamic methods in the present work show very good agreement. A case study on two medium-range passenger aircraft indicates that the trailing aircraft could achieve up to 60 percent induced drag reduction with optimal longitudinal, lateral, and vertical aircraft separations within formation. The fuel burn savings of the trailing aircraft are calculated to be up to 16 percent for specific payload and flight range combinations. A reserve fuel study shows that around 2 percent fuel burn savings would be eroded due to conservative fuel planning in formation flight.

"LDA: AN EXPERIMENTAL WHOLE FIELD INVESTIGATION ON CONFINED ROTATING FLOW WITH AND WITHOUT VORTEX BREAKDOWN"

10th International Symposium on Applications of Laser Techniques in Fluid Mechanics, July 2000, Lisbon, Portugal.

Rich complicated flow problems present in rotating flow inside cylindrical container, secondary flows, vortex breakdown, to name a few. The experimental research on vortex breakdown in rotating flows has been limited to visualizations up to now, and there are few quantitative measurement results. For the rotating flow with vortex breakdown, there are sharp changes of velocity distribution, especially direction of the fluid motion. Therefore, large number of measurement points is necessary to make clear the flow. With high measurement precision and broad dynamics band, LDA is suitable for whole field investigation on complicated recirculating flow with and without breakdown. However, it is unfortunately a point-by-point method, which makes duration of experimental whole field investigation much long. For the confined rotating flow inside cylindrical container with a rotating top lid, the method of adjusting the rotating rate dependent on measured temperature to keep Reynolds number is presented here, as a solution to the appreciable viscosity dependence of the working fluid on temperature. It is experimentally testified that the method is convenient to be used, and can keep the flow pattern at the same Reynolds number with high precision for long time. An experimental whole field investigation on confined rotating flow inside cylindrical container via LDA is presented in the paper. For $H/R=1.51$, $Re=330, 520, 610, 790, 990, 1290$ and 2180 , the whole field velocity distribution in the meridional plane is obtained. The flow patterns with existence and disappearance of vortex breakdown are made clear.

Liu, Y., Wang, J., Liu, Z. and Bao, F.

"EXPERIMENTAL INVESTIGATION OF WAKE VORTEX IN A WATER TOWING TANK"

Proceedings of the SPIE, Vol. 8417, article 84172Y, October 2012.

Wake vortex behind an aircraft would introduce great hazard to the following aircraft and threaten to the flight safety. Generic model using two rectangular airfoils was employed for generating wake vortex system to investigate the method of wake vortex alleviation. The investigation was carried out in a water towing tank equipped with a Particle Image Velocimetry system. Characteristics of double-vortex flow were analyzed for selected cases, proving that the intensity of the vortex is reduced with respect to the interaction between the wake vortices. The study exhibited that the R-L instability was most effectively triggered with parameter combinations of $\alpha-1 = 10$ deg, $\alpha-2 = 8$ deg and $b = 50$ mm respectively. As a result, the circulation of the wake vortices was alleviated by nearly 40 percent accordingly.

Liu, Y., Wu, M., Zhu, J. J., Lawrence, D. A., Gutmark, E. J., Myatt, J. H. and May, C. A.

"REACTIVE FLOW CONTROL OF DELTA-WING VORTEX"

Journal of Aircraft, Vol. 45, No. 3, May-June 2008, pp. 880-892.

In this paper, the reactive flow control of delta-wing trailing-edge vortices using along-core pulse-width-modulation flow injection is presented. Leading-edge vortices on the upper surface of a delta

wing can augment lift. Manipulating breakdown points of leading-edge vortices can effectively change the delta wing's lift and drag and generate attitude-control torque. In this paper, a black-box dynamic model for active flow control of vortex breakdown points is identified from wind-tunnel data using a model scheduling method. Based on the identified model, a closed-loop active flow controller is developed. Simulation and real-time wind-tunnel test show that the closed-loop controller can effectively manipulate the upper surface pressure of the delta wing, which indicates that the closed-loop controller can effectively control vortex breakdown points.

Liu, Z.

"MODELING THE RADAR SIGNATURE OF RAINDROPS IN AIRCRAFT WAKE VORTICES"

PhD Thesis, May 2013, University of Toulouse, Toulouse, France.

In recent years, wake vortex monitoring in real time has emerged as one of the key challenges in air traffic control at landing and taking-off. In clear air, several experimental tests have demonstrated that Lidar is an effective sensor for wake vortex monitoring. In rainy weather, Lidar becomes blind and Radar is a candidate sensor to detect the motion of raindrops in wake vortices. Thus, investigation on radar monitoring of wake vortices in rainy weather is of both scientific and practical interests. This topic has been tackled through three successive steps. Firstly, the motion of raindrops in wake vortices has been modeled and simulated. The equation of motion has been derived and the methodology to compute the raindrops' trajectory and distribution in the flow induced by the wake vortices has been proposed. Secondly, two simulators have been developed for evaluating the radar signatures of raindrops in wake vortices. One simulator is based on the simulation of radar signal time series, by superposing the radar backscattered signal from each raindrop in the wake vortex region. The other one is based on the raindrops' number concentration and velocity distribution in wake vortices, enabling the computation of radar signatures much more efficiently. Those simulators have been used to reproduce experimental configurations and the comparison between measured and simulated signature has shown an interesting agreement at X and W band. Lastly, the interpretation of radar signatures of raindrops in wake vortices has been presented. Based on the computation of three spectral moments, the dependence of radar signatures on rain rate, vortex circulation and radar parameters has been studied for vortices generated by different aircraft types. A wake vortex detection method based on the analysis of Doppler spectrum width of raindrops has been proposed. Considering radar scanning under flight path, a methodology to estimate the wake vortex characteristics has been proposed. Preliminary simulation results have shown its effectiveness.

"DOPPLER INFORMATION GEOMETRY FOR WAKE TURBULENCE MONITORING"

Matrix Information Geometry, edited by F. Nielsen and R. Bhatia, 2013, Springer-Verlag Berlin Heidelberg, pp. 277-290.

A wake vortex detector based on Doppler entropy was described in this paper using the methods of information geometry, which bridges the gap between the probability distribution and geometric quantities. The radar statistical signal models are parameterized as points on a manifold of covariance matrices. The Doppler information geometry provides a quantitative assessment of Doppler spectrum of radar signals by introducing the definition of Doppler entropy. The radar experimental results of monitoring wake turbulence close to the airport were used to illustrate the effectiveness of the wake vortex detector based on Doppler entropy and the new developed algorithm based on GPU parallel computation have been proved to be much more efficient regarding the computation time. The radar detection technology of wake turbulence is a very challenging work which is quite different from the radar detection of other objects, the future work on the detection performance of wake turbulence based on Doppler entropy will be of great interest for radar community. On the other hand, as a kind of powerful computational tools, GPU computation will be largely applied to radar real time signal processing due to its relative low cost and high efficiency. Besides the work described in this paper, in the framework of information geometry, the future efforts and insights into geometric properties of radar statistical signals will surely bring forth results on the new trend of radar detection technology.

Liu, Z., Jeannin, N., Vincent, F. and Wang, X.

"MODELING THE RADAR SIGNATURE OF RAINDROPS IN AIRCRAFT WAKE VORTICES"

Journal of Atmospheric and Oceanic Technology, Vol. 30, 2013, pp. 470-484.

The present work is dedicated to the modeling and simulation of the radar signature of raindrops within wake vortices. This is achieved through the computation of the equation of raindrop motion within the wake vortex flow. Based on the inhomogeneous distribution of raindrops within wake vortices, the radar echo model is computed for raindrops in a given resolution cell. Simulated Doppler radar signatures of raindrops within wake vortices are shown to be a potential criterion for identifying wake vortex hazards in air traffic control. The dependence of the radar signature on various parameters, including the radial resolution and antenna elevation angle, is also analyzed.

Liu, Z., Jeannin, N., Vincent, F. and Wang, X.

"DEVELOPMENT OF A RADAR SIMULATOR FOR MONITORING WAKE VORTICES IN RAINY WEATHER"

Proceedings of 2011 IEEE CIE International Conf. on Radar, October 2011, Chengdu, China, pp. 284-287.

A simulator for the evaluation of the radar signature of raindrops within wake vortices is presented. Simulated Doppler spectrum of raindrops within vortices led to think that it could be a potential criterion for identifying wake vortex hazard in rainy weather.

Liu, Z., Russell, J. W., Sankar, L. N. and Hassan, A. A.

"A STUDY OF ROTOR TIP VORTEX STRUCTURE ALTERATION TECHNIQUES"

Journal of Aircraft, Vol. 38, No. 3, May-June 2001, pp. 473-477.

Numerical studies of the tip-vortex structure from a hovering rotor with blowing are presented, and compared with the tip-vortex structure from a clean rotor, and from a rotor using a passive trailing-edge tip device. A hybrid, Navier-Stokes potential flow method is used to model the flowfield. A scheme that is fifth-order accurate in space is used to accurately capture the tip vortices. Velocity and vorticity data in the core of the vortex are studied at various planes behind the blade leading edge. These data for the clean rotor are first compared with experimental results obtained for the same rotor. Previously published results for the tip-vortex structure from the same rotor employing a passive tip device are discussed next. Finally, results for a rotor blade with upper and lower surface blowing are presented. It is concluded that the tip-vortex strength may be modified through blowing. Blowing is found to be just as effective as a spoiler in altering the tip-vortex strength, but does not have the high drag and torque penalty associated with spoilers.

Liver, P. A.

"ROLL-UP OF A VORTEX SHEET TRAILING FROM A VORTEX GENERATOR"

Ph.D. Thesis, January 1987, Tennessee University, Knoxville, TN

The roll-up of a vortex sheet trailing from an airfoil type vortex generator was investigated through various analytical models. The effects of a finite size vortex sheet and the effects of viscosity on the vortex trajectory are included as important factors. The problem is treated as two-dimensional with the streamwise direction being replaced by the time coordinate assuming that the streamwise gradients are small compared to the development in the crossflow plane. The strength and the distribution of vorticity in the wake sheet trailing from the vortex generator are determined using a modified vortex lattice approach. The influence of the airfoil represented by its camber distribution and the effects of the velocity profile of the oncoming boundary layer are investigated. The effects of finite size of the initial vortex sheet and the associated finite formation rate of the trailing vortex are isolated by employing an inviscid vortex sheet roll-up calculation. Viscous effects on the vortex strength and on the trajectory are included by the application of the vorticity-stream function form of the Navier-Stokes equations.

"MONITORING WAKE VORTICES WITH A SCANNING DOPPLER LIDAR"

9th International Symposium on Tropospheric Profiling (ISTP), September 2012, University of L'Aquila, L'Aquila, Italy.

Measuring and foreseeing wind conditions near airports are crucial issues for air traffic safety. Since aircraft maneuverability is the worst during takeoff and landing phases, strong air movements near airports such as wake vortices can have dramatic consequences on aircrafts. Wake vortices are created by all the aircrafts. Size and intensity of wake vortices are directly linked to the flight speed and also by plane characteristics, such as weight and wingspan. Even if strong efforts have been done to study and

model wake vortices, onsite measurements remain the best way to detect them as they depend a lot on meteorological conditions near airports especially wind and turbulence. Coherent laser radars or LIDARs can be very useful devices for monitoring wake vortices on airports. A WINDCUBE 200S developed by LEOSPHERE has been deployed at Charles De Gaulle airport near Paris in the framework of the European project SESAR and the subpackage 12.2.2 dedicated to wake vortices detection in cooperation with THALES AIR SYSTEMS. With specific swept scenarios, the WINDCUBE 200S has been able to detect the wake vortices of heavy, medium, and small aircrafts during takeoff and landing. Wake vortices have been monitored for a significant period. A dedicated post-treatment has been developed by the French Aerospace Lab ONERA for computing the cores position of wake vortices and for calculating their circulations. Thanks to that post-treatment the evolution of wake vortices trajectories and circulations can be determined. Several analyses have been achieved in order to determine the influence of the wind conditions on the trajectories of wake vortices. A variety of trajectories have been put in front.

Lobanova, M. A.

"A STUDY OF FLOW AND INITIAL STAGE OF WATER CONDENSATION IN THE TWO-PHASE JET-VORTEX WAKE BEHIND A CRUISE AIRCRAFT"

ICAS 2014, September 2014, St. Petersburg, Russia.

The paper describes the results of numerical investigation of large-scale flow structure in the near aircraft wake based on Reynolds Averaged Navier-Stokes equations. Influence of computational domain decomposition, grid refinement and the flow model on the jet flow field is analyzed. Initial growth of water clusters in the exhaust jet and the cluster distribution in size are studied at different distance from the nozzle outlet.

Lock, C. N. H., Hilton, W. F. and Goldstein, S.

"DETERMINATION OF PROFILE DRAG AT HIGH SPEEDS BY A PITOT TRAVERSE METHOD"

ARC-RM-1971, Ministry of Aircraft Production, Aeronautical Research Committee Reports and Memoranda, London, UK, September 1940.

At speeds at which the compressibility of the air can be neglected it is known that the profile drag of an airfoil section can be determined with sufficient accuracy from measurements of total head and static pressure across a section of the wake. For compressible flow, it appears that it is sufficiently accurate to assume that the total energy per unit mass of the air is constant, along with the measurements of total and static pressures. It is shown that the assumption of constant total energy is equivalent to assuming constant total stagnation temperature, and experimental evidence of this equivalence (up to Mach number 0.9, the available dataset used herein) has been obtained.

Lockard, D. P. and Morris, P. J.

"WING-TIP VORTEX CALCULATIONS USING A HIGH-ACCURACY SCHEME"

Journal of Aircraft, Vol. 35, No. 5, September-October 1998, pp. 728-738

The objective of the research described in this paper is to investigate the use of computational aero-acoustics methodology and parallel computers to simulate the development of a tip vortex. A three-dimensional Euler code, implemented using the message passing library and Fortran 90 on the IBM SP2, is used to perform calculations of the steady flow. Results are presented for low-speed flow over a finite span NACA 0012 wing. Comparisons with experimental data show that the tip vortex is predicted to diffuse too rapidly, but the high-accuracy scheme does reduce numerical errors. It is argued that Navier-Stokes calculations on a much finer mesh would improve the solutions, but they would be prohibitively expensive for unsteady calculations.

"CFD MODELING OF B-52 AND KC-135 IN AERIAL REFUELING FORMATION"

AIAA Paper 2017-4236, June 2017, Denver, CO.

This project investigated the potential for full-aircraft Computational Fluid Dynamics (CFD) simulation to replace flight testing to generate aerodynamic coefficients for use in a 6-Degree-of-Freedom ground-based flight simulator aerodynamics model. CFD was used to generate a dataset of aerodynamic coefficients for a B-52 in aerial refueling formation with a KC-135 tanker. Overset meshes were used for dynamic control surface deflections, and to place the B-52 and KC-135 at any angle-of-attack or angle-of-sideslip, with respect to each other, without requiring additional mesh generation. Results were largely in line with expectations; the greatest effect of the KC-135 was on the B-52 lift coefficient, due to the tanker downwash. No significant changes in control surface effectiveness were observed between the B-52 only and the B-52 / KC-135 formation. Simulations were also performed using near-body unstructured meshes overset on an off-body cartesian mesh to better resolve the tanker wake. While the project shows that it is feasible to simulate multiple aircraft in formation to extract the appropriate force and moment information for a flight simulator, further studies are required to determine if the tanker wake is fully resolved; to include tanker engine effects; and to determine changes in forces and moments as the relative position of the B-52 behind the KC-135 is changed.

"VORTEX VELOCITY DISTRIBUTIONS AT LARGE DOWNSTREAM DISTANCES"

J. Aircraft, Vol. 8, No. 11, November 1971, pp. 930-932

This paper extends the available data on the velocity structure within a trailing line vortex to large distances downstream of the generating wing. Data are presented to show the variation of both axial and tangential velocity with tunnel speed and trailing vortex strength. Specifically, data are presented at downstream distances of 10 and 26 chord lengths behind a semispan wing at 4- and 12-degree angles of attack for tunnel speeds of 50 and 70 mph.

"A SOLUTION TO THE VORTEX BREAKDOWN PHENOMENON IN A TRAILING LINE VORTEX"

M.S. Thesis, December 1966, Penn. State University, University Park, PA

A theoretical analysis of the vortex burst phenomenon in a trailing line vortex is carried out with the result being the development of a numerical solution to the line vortex behind a lifting surface. The acceleration or retardation of the axial velocity in a vortex in general was also predicted and supported by previous investigations and the present experimental work. Finally, both criteria for predicting vortex breakdown and a numerical program predicting the axial velocity deficit in the wake are developed theoretically and supported by experimental investigation.

"INTERACTION OF WAKE TURBULENCE WITH A FREE SURFACE"

Physics of Fluids, Vol. 8, Issue 3, 1996, pp. 805-815.

The turbulent wake of a flat plate aligned with a uniform water flow and extending through the free surface was investigated experimentally. Laser-Doppler velocimetry (LDV) measurements show good agreement with published data for a two-dimensional wake, except in a shallow layer near the free surface. In this surface layer, the wake width is observed to double while the wake centerline velocity remains essentially unchanged from its value at depth, resulting in a wake momentum deficit that is twice that at depth. Instantaneous, full-field measurements of the velocity were made using digital particle image velocimetry (DPIV) to elucidate the role of vortical structures in the development of the surface layer. DPIV measurements reveal that in the deep wake, vortex structures predominantly of opposite sign exist on opposite sides of the wake centerline and contribute to a velocity and vorticity field that is two-dimensional in the mean. However, near the surface, vortex structures tend to become either surface-normal or surface-parallel and contribute to a velocity and vorticity field that is highly three-dimensional in the mean. The resulting surface layer is characterized by surface-parallel structures interacting with their images above the surface to retard and widen the surface flow to a depth comparable to the size of the vortex structures. Histograms taken from many independent DPIV realizations of the flow characterize the distribution of vorticity in the wake and verify a mean flow consistent with the LDV measurements. The existence of these structures in the surface layer is further confirmed by flow visualization using laser-induced fluorescence.
