We describe two methods to treat vortex sheets in a Lagrangian manner as a discontinuity, but to compute the rest of the flow using a fixed Eulerian grid. This way, we retain advantages of both schemes. The method is applied to the vortex sheet shed by an elliptically loaded wing, in the parabolized approximation. In this approximation, the vorticity is assumed to be normal to a two dimensional cross-stream computational plane. Thus the sheet is treated as a line across which the cross-stream velocity is discontinuous. The stream-wise variation of velocity is then neglected and time evolution of the line in the plane approximates the cross-stream variation as the sheet is followed downstream. The time-dependent problem is solved as follows: At each time step, the vortex line is first assumed to be fixed and a potential is computed on a grid such that the discontinuity across the line is maintained and Laplace's equation is satisfied everywhere else. Then, a velocity is computed along the line by interpolation from the grid. Finally, a forward Euler integration scheme is used to compute the new position of the line. The main approximation assumed is that of the radius of curvature of the line is much larger than the grid cell width. One method described is analogous to shock fitting and involves fitting the discontinuity. The other, presented previously, involves spreading the discontinuity over several grid cells, and is analogous to shock capturing. A numerical comparison of the two schemes is given.

"MODIFICATION OF THE EULER EQUATIONS FOR 'VORTICITY CONFINEMENT': APPLICATION TO THE COMPUTATION OF INTERACTING VORTEX RINGS"

Physics of Fluids, Vol. 6, No. 8, August 1994, 2738-274.

A new 'vorticity confinement' method is described which involves adding a term to the momentum conservation equations of fluid dynamics. This term depends only on local variables and is zero outside vortical regions. The partial differential equations with this extra term admit solutions that consist of Lagrangian-like confined vortical regions, or covons, in the shape of two-dimensional (2-D) vortex 'blobs' and three-dimensional (3-D) vortex filaments, which convect in a constant external velocity field with a fixed internal structure, without spreading, even if the equations contain diffusive terms. Solutions of the discretized equations on a fixed Eulerian grid show the same behavior, despite numerical diffusion. Effectively, the new term, together with diffusive terms, constitute a new type of regularization of the inviscid equations which appears to be very useful in the numerical solution of flow problems involving thin vortical regions. The discretized Euler equations with the extra term can be solved on fairly coarse, Eulerian computational grids with simple low-order (first- or second-)

accurate numerical methods, but will still yield concentrated vortices which convect without spreading due to numerical diffusion. Since only a fixed grid is used with local variables, the vorticity confinement method is quite general and can automatically accommodate changes in vortex topology, such as merging. Applications are presented for incompressible flow in 3D, where pairs of thin vortex rings interact and, in some cases, merge.

"SIMULATION OF AIRCRAFT WAKE VORTICES DURING LANDING WITH DECAY ENHANCING OBSTACLES"

ICAS 2014, September 2014, St. Petersburg, Russia.

Wake-vortex evolution during landing of a long-range aircraft is investigated in a turbulent environment. The simulations cover final approach, touchdown on the tarmac, and the evolution of the wake after touchdown. An ambient turbulent crosswind and headwind field is generated in a pre-simulation. The wake is initialized using a RANS-LES coupling approach. The aircraft in high-lift configuration with deployed flaps and slats is swept through a ground fixed domain. The fuselage turbulence is modeled as white noise. The further development of the vortical wake is investigated by large-eddy simulation until final decay. After touchdown wake vortices are subjected to strong three-dimensional deformations and linking with the ground. The down-wind vortex is strongly advected with the wind and decays quickly. End effects appear after touchdown and propagate along the wake vortices against the flight direction. They lead to a non-uniform circulation decay of the rolled-up wake vortices. Additionally, the effect of a plate line installed in front of the runway is studied with this method. The plates cause disturbances of the vortices propagating to either side and interacting with the end effects. The plate line further accelerates the vortex decay.

"AIRCRAFT WAKE VORTEX DECAY IN GROUND PROXIMITY -- PHYSICAL MECHANISMS AND ARTIFICIAL ENHANCEMENT"

AIAA Paper No. 2012-2672, June 2012, New Orleans, LA.

Aircraft wake vortex evolution in ground proximity is investigated numerically with large eddy simulations (LES). The simulations are performed with different modifications of the ground surface to trigger rapid vortex decay or to simulate the landing of an aircraft. The impact of environmental turbulence in terms of turbulent winds is considered, where well-resolved and wall-modeled LES are performed for low and high Reynolds number cases, respectively. To understand wake vortex decay mechanisms in ground proximity the interaction of primary and secondary vortices is thoroughly investigated. The results show that vortex decay is initiated and accelerated with obstacles at the ground. To optimize obstacle shape and size we show that we can achieve a similar effect with relatively small plates as with large block-shaped barriers. Concerning large Reynolds number we show that turbulence effects triggered by the ground cannot be modeled by a simple wall model. As a first approximation of landing, we use a ramp at the ground and show that the flow disturbances are like

the result of flat ground with obstacles. In particular, two kinds of so-called end effects are superposed: pressure waves in the vortex core and the propagation of the secondary vortex structure.

"TOWARDS REALISTIC SIMULATION OF WAKE-VORTEX EVOLUTION DURING LANDING WITH FLAT AND COMPLEX TERRAIN"

International Symposium on Turbulence and Shear Flow Phenomena (TSFP-8), August 2013, Poitiers, France.

The complete landing phase of a long-range aircraft is studied including final approach, touchdown at the tarmac and the development of the wake. In particular, end effects appearing after touchdown and propagating along the wake vortices as well as their interaction with a plate line in front of the run way are investigated. An aircraft model in high lift configuration with deployed flaps and slats obtained from a high-fidelity Reynolds-averaged Navier-Stokes simulation is used to simulate the final approach until touchdown. After the wake initialization a large-eddy simulation of the vortical wake is performed until decay. The flow field is analyzed and the interaction with the ground is studied. End effects appear after touch down. They lead to a circulation decay combined with a growth of the core radius to 300 percent. That effect propagates downstream. The plate line further accelerates the vortex decay reducing rapidly the circulation by another 25 percent of the initial circulation.

"HYBRID SIMULATION OF WAKE-VORTEX EVOLUTION DURING LANDING ON FLAT TERRAIN AND WITH PLATE LINE"

International Journal of Heat and Fluid Flow, Vol. 49, 2014, pp. 18-27.

Wake-vortex evolution during approach and landing of a long-range aircraft is investigated. The simulations cover final approach, touchdown on the tarmac, and the evolution of the wake after touchdown. The wake is initialized using a high-fidelity Reynolds-averaged Navier-Stokes solution of the flow field around an aircraft model. The aircraft in high-lift configuration with deployed flaps and

slats is swept through a ground fixed domain. The further development of the vortical wake is investigated by large-eddy simulation until final decay. The results show the formation of a pronounced shear layer at the ground and an increase in circulation in ground proximity, caused by the wing in ground effect. Disturbances at disconnected vortex ends, so-called end effects, appear after touchdown and propagate along the wake vortices against the flight direction. They lead to a circulation decay of the rolled-up wake vortices, combined with a growth of the core radius to 300 percent of its initial value. After touchdown wake vortices are subjected to strong three-dimensional deformations and linking with the ground. The complete vortex evolution, including roll-up and decay, is accelerated in ground proximity. Additionally, the effect of a plate line installed in front of the runway is studied with this method. The plates cause disturbances of the vortices propagating to either side and interacting with the end effects. The plate line further accelerates the vortex decay, reducing the circulation rapidly by another 25 percent of its initial value.

"AIRCRAFT WAKE-VORTEX DECAY IN GROUND PROXIMITY -- PHYSICAL MECHANISMS AND ARTIFICIAL ENHANCEMENT"

Journal of Aircraft, Vol. 50, No. 4, July-/august 2013, pp. 1250-1260.

Aircraft wake-vortex evolution in ground proximity is investigated numerically by means of large-eddy simulations. The simulations are performed either with a flat ground or with different modifications to the ground surface to trigger rapid vortex decay. The impact of environmental turbulence in terms of turbulent wind is considered, where wall-resolved and wall-modeled large-eddy simulation are performed for low- and high-Reynolds-number cases, respectively. To understand wake-vortex decay mechanisms in ground proximity, the interaction of primary and secondary vortices is carefully investigated. We find that vortex decay can be initiated at an earlier time and substantially accelerated with obstacles at the ground. We explain the fundamental vortex dynamics describing five characteristics of the phenomenon and quantify the decay. We demonstrate that similar effects can be achieved, employing relatively small plates lines as opposed to the original large block-shaped barriers. The obstacles trigger two kinds of so-called end effects: pressure disturbances propagating within the vortex cores and secondary vortex structures propagating along the outside of the vortex cores.

"THE EFFECT OF GUSTS ON AIRCRAFT WAKE VORTICES"

Aircraft Engineering and Aerospace Technology, Vol. 89, Issue 5, 2017, pp. 692-702.

This study aims to investigate the effect of gusts on aircraft wake vortices. Aircraft wake vortices present a potential risk to following aircraft, particularly during final approach and landing, as wake vortices may remain in the flight corridor for a long time. Wind and turbulence are key factors that influence the wake vortex evolution and the wake vortex generation in the aircraft. Flying through a gust influences the wake vortex roll-up process and its evolution. Note that vertical and lateral gusts may affect counter-rotating wake vortices differently. Both vortices influence each other by inducing a downward velocity. Disturbances may therefore lead to local vortex tilting and later to a complex three-dimensional deformation. This work uses two different hybrid Reynolds-averaged Navier-Stokes/large-eddy simulation (RANS-LES) approaches to investigate the effect of gusts on wake vortex evolution. In a one-way coupling, a pre-calculated RANS velocity field of the aircraft's near-field is being swept through an LES domain. The effect of a sine gust on the turbulent wake is modeled by manipulating the RANS-field accordingly. As a more sophisticated approach, the concept of a two-way coupling is being presented. Here an LES solver is bi-directionally coupled with an unsteady RANS (URANS) solver, exchanging values at every physical time step of the simulation. A one-way coupling approach of the LES code MGLET and the RANS code TAU is presented to simulate the gust effect on aircraft wake vortices. Additionally, the concept of the two-way coupling of these two codes incorporating a coupling module. The gust effect of wake vortices subjected to a crosswind can be simulated. The vortex physics is analyzed. Unexpected behavior like fast upwind vortex decay is revealed.

"ENHANCEMENT OF AIRCRAFT WAKE VORTEX DECAY IN GROUND PROXIMITY - EXPERIMENT VERSUS SIMULATION"

CEAS Aeronautical Journal, Volume 5, Issue 2, 2014, pp. 109-125

Aircraft wake vortex evolution in ground proximity is investigated experimentally in a water towing tank as well as numerically with wall-resolved large eddy simulation (LES). With these complementary

instruments the enhancement of wake vortex decay by obstacles introduced at the ground surface is analyzed. The experimental methods include time-resolved stereo particle image velocimetry (PIV) and vortex core visualization. For comparison with the experiment, the LES considers the turbulent wake of the strut holding the towed aircraft model. Wake vortex trajectories and circulation decay are compared at different distances from the obstacle. Tracers are employed to visualize the obstacle's effects on the vortex core in LES and experiment.

"HYBRID NUMERICAL SIMULATION OF THE JET-WAKE-VORTEX INTERACTION OF A CRUISING AIRCRAFT"

AIAA Paper 2018-2865, June 2018, Atlanta, GA.

The aircraft wake of an A320 aircraft from roll-up until decay is investigated with hybrid Reynolds averaged Navier-Stokes/Large-eddy simulation methods. The turbulent jet as well as the heat emission is included. The dynamics of the wake vortices interacting with the jet exhaust is investigated as well as the heat evolution in the wake. The results show that the jet engines influence the near field as well as the far field. They disturb the coherency of the wake particularly the relatively strong engine vortex is getting turbulent very fast. This leads to a slower decay of the entire system, as the Crow-instabilities are suppressed and develop later. The heat dissipates very fast. The descending vortex system leaves a vertical heat plume, where the maximal temperature is in the turbulent jet first, but is captured inside the vortex core for later vortex ages.

"NUMERICAL OPTIMIZATION OF PLATE-LINE DESIGN FOR ENHANCED WAKE-VORTEX DECAY"

Journal of Aircraft, Vol. 54, No. 3, May-June 2017, pp. 995-1010.

The design of plate lines as a ground mounted device for wake-vortex decay enhancement is investigated in this work. The most important design parameters, the aspect ratio and plate distance, are analyzed for the wake vortices generated by two aircraft: the A340 as well as the A380. Large-eddy-simulations (LES) are used to simulate the wake-vortex evolution in ground proximity for different parameter combinations. Fully rolled-up wake vortices are initialized using a Lamb-Oseen vortex model resembling the characteristics of the two aircraft. With the stochastic, so-called kriging method, estimates of the performance and respective probabilistic envelopes are given for the design parameter region, spanned by the large-eddy-simulation. The vortex circulation averaged over the rapid decay phase is taken as the objective function. The large-eddy-simulation parameters are selected in the vicinity of the expected optimum. An optimal parameter combination can be localized in the A340 case, as well as in the A380 case. For both cases, statistical relevance is provided. Moreover, it can be deduced that the optimal parameters for the A380 are also well suited for smaller aircraft like an A340.

"A COMPARISON AT MACH NUMBERS UP TO 0.92 OF THE CALCULATED AND EXPERIMENTAL DOWNWASH AND WAKE CHARACTERISTICS AT VARIOUS HORIZONTAL TAIL HEIGHTS BEHIND A WING WITH 45 DEGREES OF SWEEPBACK"

NACA RM-A55D27a, June 1955, Langley Aeronautical Lab., Langley Field, VA

Wind-tunnel tests were conducted at Mach numbers from 0.25 to 0.92 to measure downwash and dynamic pressure in the region of the tail of a wing-fuselage-tail model having a wing with 45 degrees of sweepback, an aspect ratio of 5.5, and NACA 64A010 sections normal to the quarter-chord line. The data were analyzed to determine the origin and character of variations in the contribution of the horizontal tail to static longitudinal stability observed in tests of the model with the tail in various vertical positions. The spanwise distribution of downwash at the tail and the effect of tail height on downwash were not accurately predicted by a theory in which it is assumed that horseshoe vortices are distributed along the wing quarter-chord line and that there is no rolling-up of the vortex sheet. A somewhat improved prediction of the spanwise distribution of downwash was provided by an approximate theory based on the flow induced by a single swept vortex, but this theory still did not predict the large downwash at high angles of attack that were observed experimentally at the higher tail positions.

"FAR WAKE ROTORCRAFT VORTEX TUMBLING"

AIAA Paper No. 2012-0425, January 2012, Nashville, Tennessee.

The far wake trajectory of the tumbling tip vortex of a reduced-scale, 1 m diameter, four-bladed rotor during hover is studied using vortex methods combined with a center of mass analysis approach. Measurements of all three components of the velocity field are acquired using a stereo PIV system synchronized to capture up to 800 degrees wake age of the vortex with 10-degree offsets during hover conditions. The nominal operating condition of the rotor is at a rotational speed of 1520 RPM, corresponding to $RE = 248,000$ with a chord length of 58.5 mm. The rotor was operated with a pitch of 7.2 ± 0.5 degrees. The far wake vortex tumbling phenomenon is captured and described. It is shown that tip vortices from two blades tumble through approximately 180 degrees of rotation before they coalesce. It is seen that the parent vortices are stronger than the daughter vortex, but due to vortex stretching the daughter vortex has a smaller radius with greater swirl strength. An accurate characterization and prediction of the trajectory of the far wake vortex tumbling can enhance the ability to predict and alleviate the resuspension of particles during brownout as well as provide a database for far wake validation of CFD codes.

"STUDY OF ROTOR BLADE TIP VORTEX GEOMETRY FOR NOISE AND AIRFOIL APPLICATIONS"

D8-2464-1A, December 1969, Boeing-Vertol, Philadelphia, PA

The application of a technique for making helicopter tip vortices visible in order to study the effect of the separation between the vortex and a rotor blade on the noise generated by the rotor system was the primary purpose of this program. A secondary objective was to evaluate analytical prediction of the vortex path. Mathematical analyses were developed to obtain blade-vortex separation from the motion picture films taken during the tests.

Stewart, E. C.

"A PARAMETRIC STUDY OF ACCELERATIONS OF AN AIRPLANE DUE TO A WAKE VORTEX SYSTEM"

NASA/TM-1999-208745, May 1999, NASA Langley Research Center, Hampton, VA

A study was conducted using strip theory to systematically investigate the effects of progressively more complete descriptions of the interaction of an airplane with a wake vortex system. The emphasis was in roll-dominant, parallel, vortex encounters. That is, the simulated airplane's longitudinal axis was nearly parallel to the rotation axis of the vortex system for most of the results presented. The study began with a drag-less rectangular wing in the flow field of a single vortex and progressed to a complete airplane with aerodynamic surfaces possessing taper, sweep, dihedral, and stalling and immersed in the flow field of a vortex pair in ground effect. The effects of the pitch, roll, and yaw attitudes of the airplane on the calculated accelerations were also investigated. The airplane had the nominal characteristics of a Boeing 757, and the vortex flow field had the nominal characteristics of the wake of a Boeing 767. The Burnham-Hallock model of a vortex flow field was used throughout the study. The data are presented mainly in terms of contours of equal acceleration in a two-dimensional area centered on the vortex pair and having dimensions of 300 feet by 300 feet.

Stewart, E. C.

"PILOTED SIMULATIONS STUDY OF WAKE ENCOUNTERS"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 351-370

Results from preliminary simulation work at the Langley Research Center using the Visual Motion Simulator are presented. The purpose of the work was to develop an experimental procedure for a more comprehensive follow-on study using airline pilots. This preliminary work utilized NASA research pilots and consultants to define a 'worst-case' vortex encounter scenario at a fixed wake vortex strength and to develop a subjective rating scale to be used in the follow-on study. The worst-case scenario that was developed was a manual approach in poor visibility conditions with repeated, random wake vortex encounters having rapid onset rates and reversals. The rating scale developed used references and comparisons to the more-common atmospheric turbulence. The preliminary results indicated that under these worst-case conditions, only low-level wake strengths could be tolerated.

Stewart, E. C.

"A PILOTED SIMULATION STUDY OF WAKE TURBULENCE ON FINAL APPROACH"

AIAA Paper 1998-4339, Boston, MA, August 1998

A piloted simulation study has been conducted in a research simulator to provide a means to estimate the effects of different levels of wake turbulence on final approach. A worst-case methodology was used to ensure conservative estimates. Fourteen airline pilots voluntarily participated in the study and flew almost 1000 approaches. The pilots rated the subjective severity of the disturbances using a special rating scale developed for this study. Several objective measures of the airplane/pilot response to the simulated wake turbulence were also made. All the data showed a large amount of variation between pilots and to a lesser extent for a given pilot. Therefore, the data were presented at 50, 70, 90 percentile levels as a function of vortex strength. The data allow estimates of the vortex strength for a given subjective or objective response and vice versa. The results of this study appear to be more conservative than the results of previous studies.

Stewart, E. C.

"A COMPARISON OF AIRBORNE WAKE VORTEX DETECTION MEASUREMENTS WITH VALUES PREDICTED FROM POTENTIAL THEORY"

NASA TP-3125, November 1991, Langley Research Center, Hampton, VA

An analysis of flight measurements made near a wake vortex was conducted to explore the feasibility of providing a pilot with useful wake-avoidance information. The measurements were made with relatively low-cost flow and motion sensors on a light airplane flying near the wake vortex of a

turboprop airplane weighing approximately 90000 lb. Algorithms were developed which removed the response of the airplane which were due solely to the flow field of the vortex. These parameters were compared with values predicted by potential theory. The results indicated that the presence of the vortex could be detected by a combination of parameters derived from the simple sensors. However, the location and strength of the vortex cannot be determined without additional and more accurate sensors.

Stewart, E. C.

"FLIGHT-TEST EVALUATION OF A DIRECT-MEASUREMENT AIRBORNE WAKE-VORTEX DETECTION CONCEPT"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 44-1 - 44-26

Flight measurements of the flow field in an airplane wake vortex have been analyzed to determine the feasibility of developing the sensor technology for an airborne wake-vortex detection and avoidance system. The measurements were made with relatively low-cost instrumentation on a light airplane flying at small angles to the path of a 90,000 lb turboprop airplane. Algorithms were developed to isolate the effects of the wake vortex on the measurements and produce candidate wake vortex detection parameters. Video recordings of the light airplane relative to a smoke trail in the wake vortex were used to determine the separation distance of the light airplane to the wake vortex. The measured wake vortex detection parameters are compared to values predicted using potential theory. The results indicate that the presence of the wake vortex can be detected with relatively simple instrumentation at a distance of about one wing span of the generating airplane for the flaps retracted configuration and about one-half to three-fourths wing span for the flaps extended configuration. The location and strength of the wake vortex, however, cannot be determined uniquely without more sophisticated instrumentation. A short discussion of the effects on an operational system of guidance constraints, turbulence, wake vortex irregularities, and ground effect is also presented.

Stewart, E. C.

"A STUDY OF THE INTERACTION BETWEEN A WAKE VORTEX AND AN ENCOUNTERING AIRPLANE"

AIAA Paper No. 1993-3642, Monterey, CA, August 1993

An analytical study of the mutual interaction between a wake vortex and an encountering airplane has been conducted. The interaction was calculated based on conservation of angular momentum of the wake vortex and the encountering airplane in the roll axis. For the nominal conditions assumed in the study, the interaction reduced the roll response in the first second by 20 percent compared to the classical method of calculating the response. However, depending on the conditions assumed, the reduction varied from 0 to 30 percent which could be highly significant in determining separation standards for airplanes.

"EXPERIMENTS WITH UNSTEADY, FREE SURFACE, THREE-DIMENSIONAL VORTICES IN A THERMALLY STABLE, STRATIFIED FLUID"

NRL Memorandum Report 6630, May 1990, Naval Research Laboratory, Washington, DC.

The unsteady characteristics of a vortex pair formed behind a delta wing airfoil at a negative angle of attack have been studied experimentally in a large towing tank with a stable density stratification. Measurements of the vortex pair's upward migration and visualizations of the vortex circulation were made using the hydrogen bubble technique with a laser sheet illumination in the transverse plane. Axial visualizations of the vortex migration and axial velocities at the vortex core were made using the hydrogen bubble technique with a diffuse light source. The effects of the rising vortices and their circulation on the free surface temperature field was recorded using an imaging infrared radiometer mounted over the free surface.

Stewartson, K. and Hall, M. G.

"THE INNER VISCOUS SOLUTION FOR THE CORE OF A LEADING-EDGE VORTEX"

J. Fluid Mech., Vol. 15, Part 2, February 1963, pp. 306-318

Hall proposed a simplified model for the vortex core formed over a slender delta wing at incidence by the rolling-up of the shear layer that separates from a leading edge. This model enabled an outer inviscid solution and an inner viscous solution for the core to be obtained from the equations of motion. However, the procedure used for the inner solution led to several defects: in particular, the matching of the inner and outer solutions seemed unsatisfactory. In the present paper the defects are avoided by using a different procedure. The first approximation, in the sense of boundary-layer theory, is sought. A solution, in special variables, is obtained which is in the form of an asymptotic expansion containing inverse powers of the logarithm of a Reynolds number. The leading terms of the expansion are computed, and the results confirm that the inner and outer solutions are properly matched.

"GROUND-BASED FACILITIES FOR EVALUATING VORTEX MINIMIZATION CONCEPTS"

Proceedings Wake Vortex Minimization Symposium, NASA, SP-409, 1977, pp. 129-156

To determine the feasibility of altering the formation and decay of aircraft trailing vortices through aerodynamic means, NASA used the test capabilities of two wind tunnels and two towing basins. This paper describes the facilities, common models, and measurement techniques that were employed in the evaluation of vortex minimization concepts.

Stifle, K. E. and Panton, R. L.

"EXPERIMENTS CONCERNING THE THEORIES OF VORTEX BREAKDOWN"

AIAA Paper No. 91-0736, Jan. 1991, Reno, NV.

An experimental project was undertaken to investigate the character of vortex breakdown with focus on the stagnation and wave guide theories of vortex breakdown. Three different wings were used to produce a trailing vortex which convected downstream without undergoing breakdown. Disturbances were then introduced onto the vortex using a moving wire to 'cut' the vortex. The development of upstream and downstream propagating disturbance waves was observed and the propagation velocities measured. A downstream traveling wave was observed to produce a structure similar in appearance to a vortex breakdown. An upstream traveling wave produced a moving turbulent region. The upstream disturbance moved into an axial velocity profile that had a wake-like defect while the downstream moving vortex breakdown moved against a jet-like overshoot. The longitudinal and swirl velocity profiles were documented by LDV measurement. Wave velocities, swirl angles, and swirl parameters are reported.

"INITIAL CFD-SURVEY OF TIPTURBINE-EFFECTS ON THE NEAR-FIELD DEVELOPMENT OF A WINGTIP VORTEX"

AIAA Paper No. 2000-3199, Denver, CO, August 2000

The behavior of the wingtip vortex under the influence of several different perturbations, introduced by a wingtip mounted turbine positioned in the vortex, is investigated in this paper. The research was conducted on the tip area of a wing with a NACA 0012 profile, using a Navier-Stokes solver with a second-order numerical scheme. The domain contained approximately 1,000,000 points, the wing was set at a 6-degree angle of incidence and a freestream Mach number of 0.25. The perturbations were prescribed in the numerical domain on a plane, positioned in the vortex, 0.25 chords behind the wing. Three different types of perturbations have been applied, including a shear layer, a static pressure jump, and a tangential velocity distribution, contra-rotating with respect to the wingtip vortex. The impact of a change of the radius of the turbine has also been evaluated. The impact of the tangential velocity perturbations has shown to be the largest, even more so when the turbine radius exceeds the vortex core radius. The application of the tangential velocities is responsible for a decrease of the crossflow energy level and will cause the vortex to break up into several distinct regions of concentrated vorticity. This effect will enhance the vortex decay and it is recommended that future research will focus on the optimization of the tangential velocity perturbations and its effects on the breakup of the vortex.

"THE STRUCTURE OF A THREE-DIMENSIONAL TIP VORTEX AT HIGH REYNOLDS NUMBERS"

Journal of Fluids Engineering, Vol. 113, Sept. 1991, pp. 496-503.

The tip vortex structure of a three-dimensional hydrofoil at high Reynolds number was measured experimentally in both the 48 in. (1.22 m) diameter water tunnel and the 48 in. (1.22 m) wind tunnel at the Applied Physics Laboratory, Penn State. The flow on and near the hydrofoil was measured in both facilities using several flow visualization techniques and laser velocimetry. The downstream tip vortex was measured with a three-component laser velocimeter at several streamwise positions. A detailed planar mapping of the flow in the water tunnel was completed near the region of cavitation inception. The effect of roughness on the downstream tip vortex was investigated. In this paper, these measurements are presented with discussion relative to the occurrence of cavitation.

"MODELING ROTOR WAKES WITH A HYBRID OVERFLOW-VORTEX METHOD ON A GPU CLUSTER"

AIAA Paper 2010-4553, July 2010, Chicago, IL.

The vortex core shed from rotorcraft blades maintains coherency -- and thus dynamic relevance -- many blade turns after its creation. This presents a challenge to traditional Eulerian computational methods, as fine grids are required to suppress numerical diffusion which would weaken the vortex cores after a small number of revolutions. Vortex methods have been used in the past to overcome these problems, as they require computational elements only in vorticity-containing regions, but suffer from greater computational cost per element. In the present work, we will solve these problems with a hybrid Eulerian-Lagrangian method for modeling rotor wakes. An Eulerian OVERFLOW overset grid method computes the near-body flow, while a Lagrangian particle vortex method tracks the wake. The vortex method uses an anisotropic LES model to handle subgrid-scale dissipation explicitly. The computational cost of vortex methods is alleviated by using a parallel adaptive tree code on a cluster of machines each with multi-core CPU's and multiple cost-efficient graphics processing units (GPUs). Simulations of a low-Re sphere, finite wing, and 4-bladed rotor model are presented and are validated by comparisons with computational and experimental data.

"WAKE VORTICES AND THEIR AERODYNAMIC ALLEVIATION: A REVIEW OF THE LITERATURE"

DFVLR-MITT-83-07, April 1983, DFVLR, Braunschweig, Germany

Wake vortex minimization and remedial measures to be taken at the vortex generating aircraft were investigated. Boeing 747, DC 10 and L 1011 aircraft were equipped with spoilers, winglets, ogee tips or splines, and flight tests, wind tunnel and water channel tests were performed. Best results are obtained with spoilers. It is concluded that the additional equipment gives rise to higher engine power delivery at ground approach/take off hence higher noise level and increased fuel consumption.

"EFFECTS OF VISCOSITY ON THE STABILITY OF A TRAILING-LINE VORTEX IN COMPRESSIBLE FLOW; FINAL REPORT"

NASA CR-194949, July 1994, Institute for Computer Applications in Science and Engineering, Hampton, VA

We consider the effects of viscosity on the inviscid stability of the Batchelor vortex in a compressible flow. The problem is tackled asymptotically, in the limit of large (streamwise and azimuthal) wavenumbers, together with large Mach numbers. Previous studies, with viscous effects neglected, found that the nature of the solution passes through different regimes as the Mach number increases, relative to the wavenumber. This structure persists when viscous effects are included in the analysis. In the present study the mode present in the incompressible case ceases to be unstable at high Mach numbers and a center mode forms, whose stability characteristics are determined primarily by conditions close to the vortex axis. We find generally that viscosity has a stabilizing influence on the flow, while in the case of center modes, viscous effects become important at much larger Reynolds numbers than for the first class of disturbance.

"LOOK AT INCIDENTS AND ACCIDENTS RECORDS AND LEARN TO IMPROVE PILOTS TRAINING"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 11-1 - 11-12.

While many people are doing some research on the wake vortex phenomenon to reduce the spacing minima because of the congestion now being experienced at major airports, accidents reports in France show that it would also be wise to look more thoroughly at general aviation and try to improve safety for pilots operating small aircraft under visual flight rules (VFR). Though the recent ICAO DOC 4444 which is now applied in France introduced increased spacing minima because of wake vortex, the procedures defined only apply to flights conducted under instrument flight rules (IFR). The situation is not crystal clear for light aircraft flying under VFR. Concerning the subject of wake vortices, the service that should be provided by Air Traffic Control is not clearly defined. For the past 3 years, 4 accidents and 1 incident caused by wake vortex have been reported to the French Accidents Investigations Office. In all cases, the aircraft was being operated under VFR for private purposes. As far as public transport is concerned, no accident was reported, only a few incidents which led to internal inquiries within the airline concerned. Not many incidents due to wake vortices are reported because, most of the time, the pilot does not identify clearly wake vortex as the cause, but often thinks it is due to some normal turbulence. This paper provides a comparative analysis of these accidents and incidents which occurred in France to small airplanes, and gives recommendations for improvements in the two fields concerned, Air Traffic Control and Pilots training.

"NASA WAKE VORTEX RESEARCH"

AIAA Paper No. 1993-4004, Monterey, CA, August 1993

NASA is conducting research that will enable safe improvements in the capacity of the nation's air transportation system. The wake-vortex hazard is a factor in establishing the minimum safe spacing between aircraft during landing and take-off operations and, thus, impacts airport capacity. The ability to accurately model the wake hazard and determine safe separation distances for a wide range of aircraft and operational scenarios may provide the basis for significant increases in airport capacity. Current and planned NASA research is described which is focused on increasing airport capacity by safely reducing wake-hazard-imposed aircraft separations through advances in several technologies including vortex motion and decay prediction, vortex encounter modeling, wake-vortex hazard characterization, and in-situ flow sensing.

Stowe, E. G.

"ANALOG PROCESSING ASSEMBLY FOR THE WAKE VORTEX LIDAR EXPERIMENT"

Langley Aerospace Research Summer Scholars, Part 2, January 1995, pp. 717-724

The Federal Aviation Administration (FAA) and NASA have initiated a joint study in the development of reliable means of tracking, detecting, measuring, and predicting trailing wake-vortices of commercial aircraft. Being sought is an accurate model of the wake-vortex hazard, sufficient to increase airport capacity by reducing minimum safe spacings between planes. Several means of measurement are being evaluated for application to wake-vortex detection and tracking, including Doppler RADAR (Radio Detection And Ranging) systems, 2-micron Doppler LIDAR (Light Detection And Ranging) systems, and SODAR (Sound Detection And Ranging) systems. Of specific interest there is the lidar system, which has demonstrated numerous valuable capabilities as a vortex sensor. Aerosols entrained in the vortex flow make the wake velocity signature visible to the lidar (the observable lidar signal is essentially a measurement of the line-of-sight velocity of the aerosols). Measurement of the occurrence of a wake vortex requires effective reception and monitoring of the beat signal which results from the frequency-offset between the transmitted pulse and the backscattered radiation. This paper discusses the mounting, analysis, troubleshooting, and possible use of an analog processing assembly designed for such an application.

"FAST ADAPTIVE 2D VORTEX METHODS"

Journal of Computational Physics, Vol. 132, 1997, pp. 108-122

We present a new approach to vortex methods for the 2D Euler equations. We obtain long-time high-order accuracy at almost optimal cost by using three tools: fast adaptive quadrature rules, a free-Lagrangian formulation, and a useful new analysis of the consistency error. Our error analysis halves the order of differentiability required of the flow and suggests an efficient new balance of smoothing parameters which works well with fast summation schemes. Numerical experiments with our methods confirm our theoretical predictions and display excellent long-time accuracy.

"MECHANISM OF VORTEX PERTURBATION VIA UNSTEADY PITCHING"

Journal of Aircraft, Vol. 55, No. 5, September-October 2018, pp. 1831-1838.

Experiments indicate that vortices trailing finite wings can be perturbed by periodic wing pitching, leading to rapid dissipation and bursting. To illustrate the perturbation mechanism, Betz vortex rollup relations are combined with the Theodorsen theory for unsteady lift response. A sinusoidal pitch motion on a rigid elliptic planform wing is computed in this study as one example. Pitching modifies the instantaneous lift due to the planform variations, via the reduced frequency, and the rollup relations are applied to low-frequency experimental conditions. The combined Betz-Theodorsen theory shows that relatively large spanwise perturbations of the vortex centers can be achieved and may accelerate the exponential growth associated with the Crow instability. In fact, 84.2% of the displacement of the unsteady trailing vortices due to unsteady pitching is oriented in the direction of the Crow instability. Furthermore, the axial velocity in the vortex center, calculated based on the Batchelor method, varies on the order of the flight speed. This forms two types of stagnation points produced by approaching and retreating axial core velocities; in the former case, conservation of mass leads to observations of 'bursting.' This observation can be explained adequately on the basis of quasi-steady considerations.

Strasser, M. N.

"THE AERODYNAMIC AND DYNAMIC LOADING OF A SLENDER STRUCTURE BY AN IMPACTING TORNADO-LIKE VORTEX: THE INFLUENCE OF RELATIVE VORTEX-TO-STRUCTURE SIZE ON STRUCTURAL LOADING"

PhD Thesis, December 2015, University of Arkansas, Fayetteville, Arkansas.

Structural loading produced by an impacting vortex is a hazardous phenomenon that is encountered in numerous applications ranging from the destruction of residences by tornados to the chopping of tip vortices by rotors. Adequate design of structures to resist vortex-induced structural loading necessitates study of the phenomenon that control the structural loading produced by an impacting vortex. This body of work extends the current knowledge base of vortex-structure interaction by evaluating the influence of the relative vortex-to-structure size on the structural loading that the vortex produces. A computer model is utilized to directly simulate the two-dimensional impact of an impinging vortex with a slender, cylindrical structure. The vortex's tangential velocity profile (TVP) is defined by a normalization of the Vatistas analytical (TVP) which realistically replicates the documented spectrum of measured vortex TVPs. The impinging vortex's maximum tangential velocity is fixed, and the vortex's critical radius is incremented from one to one-hundred times the structure's diameter. When the impinging vortex is small, it interacts with vortices produced on the structure by the free stream, and maximum force coefficient amplitudes vary by more than 400 percent when the impinging vortex impacts the structure at different times. Maximum drag and lift force coefficient amplitudes reach asymptotic values as the impinging vortex's size increases that are respectively 94.77 percent and

10.66 percent less than maximum force coefficients produced by an equivalent maximum velocity free stream. The vortex produces maximum structural loading when its path is shifted above the structure's centerline, and maximum drag and lift force coefficients are respectively up to 4.80 percent and 34.07 percent greater than maximum force coefficients produced by an equivalent-velocity free stream. Finally, the dynamic load factor (DLF) concept is used to develop a generalized methodology to assess the dynamic amplification of a structure's response to vortex loading and to assess the dynamic loading threat that tornados pose. Typical civil and residential structures will not experience significant response amplification, but responses of very flexible structures may be amplified by up to 2.88 times.

Strasser, M. N. and Selvam, R. P.

"SELECTION OF A REALISTIC VISCOUS VORTEX TANGENTIAL VELOCITY PROFILE FOR COMPUTER SIMULATION OF VORTEX-STRUCTURE INTERACTION"

Journal of the Arkansas Academy of Science, Vol. 69, 2015, pp. 88-97.

Structure loading by vortices is a relevant phenomenon in numerous fields of engineering significance. Computer modelling is a powerful tool that can be used to study the loading produced on structures by impacting vortices. Realistic simulation of vortex-loading of structures necessitates the use of a realistic vortex tangential velocity profile (TVP). The present study compiles measured TVPs from various types of experimentally-produced vortices as well as real-world tornado and hurricane vortices. The measured TVPs are compared with commonly-used analytical TVPs. Analytical TVPs that realistically represent the range of measured TVPs are identified and selected for use in future computer simulation studies.

Strawn, R. C.

"OVERSET-GRID CFD MODELS FOR ROTORS AND WAKES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Almost all of the aerodynamic design problems associated with rotorcraft involve interactions between the rotating blades and their aerodynamic wake systems. Prediction of the rotor wake is one of the most challenging problems in rotorcraft computational fluid dynamics (CFD). Typically, the computed vortical wakes diffuse too rapidly due to grid-related numerical dissipation. For general unsteady rotor flowfields, current numerical schemes and computational grids are unable to preserve the vortices long enough to accurately predict the noise and airloads caused by blade-vortex interactions (BVI's). This presentation describes results from steady-state Reynolds-averaged Navier-Stokes computations for hovering rotors and their vortex wake systems. The computations are designed to directly assess grid-related effects on the numerical results and employ: 1) structured overset-grids with high resolution on the rotor blades, 2) a systematic variation of grid resolution in the rotor wake, and 3) a systematic variation of outer boundary locations. The calculations show that the combination of high-order differencing schemes and fine computational meshes can provide rotor

blade performance predictions that are independent of both the rotor-wake grid size and the far-field boundary conditions. These performance predictions also show good agreement with experimental measurements for a four-bladed UH-60A model rotor in hover. The presentation will also assess the computational requirements for general unsteady forward-flight calculations with multiple blade-vortex interactions.

Strawn, R. C. and Ahmad, J. U.

"COMPUTATIONAL MODELING OF HOVERING ROTORS AND WAKES"

AIAA Paper No. 2000-0110, Reno, NV, January 2000

This paper presents a method for solving the Navier-Stokes equations for hovering rotors. This method runs efficiently on distributed memory parallel computers and uses a series of structured overset grids to model the near-body and off-body flowfields. The Navier-Stokes flow solver includes several enhancements for rotary-wing computations including steady-state rotational source terms, two-cell overlaps at overset grid boundaries, fourth-order spatial differencing, periodic and hovering-rotor far-field boundary conditions, and the development of a computationally-efficient system of off-body grids. Computed blade-loading results for two different grid densities in the rotor wake show good agreement with each other and also with experimental data from a UH-60 model rotor test.

Strawn, R. C. and Djomehri, M. J.

"COMPUTATIONAL MODELING OF HOVERING ROTOR AND WAKE AERODYNAMICS"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 786-793

Steady-state Reynolds-averaged Navier-Stokes computations are presented for a range of UH-60A model-rotor test cases in hover. The computations are designed to assess grid-related effects on the numerical results and employ 1) structured overset grids with high resolution on the rotor blades, 2) a systematic variation of grid resolution in the rotor wake, and 3) a systematic variation of outer-boundary locations. Computed rotor performance values agree very well with experimental measurements and show little sensitivity to either grid resolutions or outer-boundary locations. However, the computations uniformly overpredict the blade sectional thrust near the rotor tip. This overprediction of blade tip thrust is explained by an analysis of the circulation distribution in the computed rotor wake system.

Strawn, R. C., Kenwright, D. N. and Ahmad, J.

"COMPUTER VISUALIZATION OF VORTEX WAKE SYSTEMS"

AIAA Journal, Vol. 37, No. 4, April 1999, pp. 511-512

A new vortex detection scheme can identify vortex centers in overlapping regions of rotational flow, and it is easy to implement for structured-grid data sets. In addition to vortex identification, this

scheme can be used to guide adaptive-grid CFD methods that seek to locally improve the grid resolution for vortex wake systems. For rotorcraft applications, we expect that visualization tools such as this will become more and more important as solutions on larger computational grids begin to capture more of the fine details of the rotor blade-vortex interactions.

Streett, C. L.

"NUMERICAL SIMULATION OF FLUCTUATIONS LEADING TO NOISE IN A FLAP-EDGE FLOWFIELD"

AIAA Paper No. 1998-0628, Reno, NV, January 1998

In this paper we develop an approximate computational framework for simulation of the fluctuating flowfield associated with the complex vortex system seen at the side edge of a flap in a multi-element high-lift airfoil system. The eventual goal of these simulations is to provide an estimate of the spectral content of these fluctuations, in order that the spectrum of the noise generated by such flowfields may be estimated. Results from simulations utilizing this computational framework are shown.

"NUMERICAL ANALYSIS OF TRANSPORT AIRCRAFT USING DIFFERENT WING TIP DEVICES"

Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 92, 2006, pp. 59-68.

Numerical solutions of the Navier Stokes equations for a modern transport configuration with three different wing tip devices are presented. Solutions are obtained at high speed for the cruise configuration and at low speed for the corresponding take-off configuration. This study is performed within the European Union project M-DAW (Modelling and Design of Advanced Wing Tip Devices). The numerical results are analyzed to characterize the performance of the wing tip devices using global force coefficients, local distributions of force and moment, surface contours and skin friction lines. In addition, the vortex wake was analyzed in the near field tip region for take-off. Numerical results are compared with experimental data obtained in cryogenic wind tunnel tests at high speed in the ETW (European Transonic Wind tunnel) and at low speed in the DNW-KKK (Cryogenic Wind Tunnel Cologne).

Stremel, P. M.

"A METHOD FOR MODELING FINITE-CORE VORTICES IN WAKE-FLOW CALCULATIONS"

AIAA Paper No. 1984-0417, Reno, NV, January 1984

A numerical method for computing nonplanar vortex wakes represented by finite-core vortices is presented. The approach solves for the velocity on an Eulerian grid, using standard finite-difference techniques; the vortex wake is tracked by Lagrangian methods. In this method, the distribution of continuous vorticity in the wake is replaced by a group of discrete vortices. An axially symmetric distribution of vorticity about the center of each discrete vortex is used to represent the finite-core model. Two distributions of vorticity, or core models, are investigated: a finite distribution of vorticity

represented by a third-order polynomial, and a continuous distribution of vorticity throughout the wake. The method provides for a vortex-core model that is insensitive to the mesh spacing. Results for a simplified case are presented. Computed results for the roll-up of a vortex wake generated by wings with different spanwise load distributions are presented; contour plots of the flow-field velocities are included; and comparisons are made of the computed flow-field velocities with experimentally measured velocities.

"INVISCID COMPUTATION OF EFFECT OF WAKE VORTICES ON A SCALE-MODEL AIRPLANE"

Journal of Aircraft, Vol. 40, No. 1, January-February 2003, pp. 100-109

The forces and moments sustained by a scale-model airplane in the wake of another aircraft have been calculated using two different solvers. One solver uses a fourth-order central scheme with a specially adapted grid, whereas the other uses a chimera technique with second-order discretization. Additionally, simplified models were used on grids that are too coarse to represent vortices properly. These models work by handling the effect of the vortices by modifying the flux at the solid wall, or the fluxes in the domain. The experimental flowfield that contains wake vortices is modeled by a least-square fit analytical expression. This description is used as the inlet boundary condition for the Euler solvers. Numerical results agree with experiment and with previously published computations using panel methods.

Stuart, T. A., Mao, X. and Gan, L.

"TRANSIENT GROWTH ASSOCIATED WITH SECONDARY VORTICES IN GROUND/VORTEX INTERACTIONS"

AIAA Journal, Vol. 54, No. 6, June 2016, pp. 1901-1906.

The interaction of an isolated trailing vortex and the ground is investigated. An unsteady unperturbed flow is first calculated through a two-dimensional direct numerical simulation and then used as base flow for linear transient growth studies. The transient growth increases with Reynolds number and maximizes at streamwise wave number $3 \sim 5$ over the parameters considered. The most energetic initial perturbation is found to be located aside of the main vortex and convected by the base flow to the ground to interact with the separating boundary layer and the secondary vortex. Finally, the calculated perturbation is used to perturb the base flow in three-dimensional direct numerical simulation. It is observed that the secondary vortex and the rebound motion of the main vortex are both significantly suppressed. This observation indicates that the secondary structures are sensitive to external noise, and the widely reported secondary vortex and its induced rebound motion of the main vortex in two-dimensional direct numerical simulation would not appear or become much weaker in real conditions.

Stuber, K. and Gharib, M.

"EXPERIMENTS ON THE FORCED WAKE OF AN AIRFOIL"

AIAA Paper No. 1988-3840, Cincinnati, OH, July 1988

An experimental effort has been made to understand the nature of an airfoil wake whose oscillation frequency is controlled by the introduction of an external perturbation. The waves are introduced into the airfoil top and bottom surfaces' boundary layers by strip heaters; attention to the linear and nonlinear interactions of these wake waves has resulted in observation of three modes of interaction: (1) frequency locking, in which the vortex-shedding frequency is the same as the forcing frequency; (2) quasiperiodic vortex interaction, in which periodic clusters of vortices are observed in the wake; and (3) chaotic vortex interaction, in which the wake vortices exhibit a three-dimensional random structure.

Stuever, R. A. and Greene, G. C.

"AN ANALYSIS OF RELATIVE WAKE-VORTEX HAZARDS FOR TYPICAL TRANSPORT AIRCRAFT"

AIAA Paper No. 1994-0810, Reno, NV, January 1994

An analysis of relative wake-vortex hazards has been conducted for several typical transport configurations. The relative hazards associated with encountering aircraft wakes out of ground effect for various landing-spacing distances were assessed. The investigation was conducted to identify potential opportunities for safe reductions in wake-vortex landing-spacing distances, which can currently limit the operating capacity of major airports and create significant delays. The relative characteristics of the wakes of typical aircraft and their decay under various atmospheric conditions were first examined using a simple atmospheric vortex-decay model. A roll-axis, one-degree-of-freedom (1-DOF) representation of each aircraft was then employed to calculate relative wake upset hazards. A boundary of allowable vortex-induced bank angle versus altitude, established in a previous piloted-simulation investigation, served as the upset criteria. The effects of bank angle control and the geometry of vortex-pair linking were also studied to provide an additional measure of realism in the hazards assessment. Results suggest that there may be opportunities for reduced landing-spacing separations for certain aircraft pairs, especially under atmospheric conditions which promote rapid wake decay, and that the current U.S. landing-spacing weight-category boundaries may be too broad.

Stuever, R. A. and Stewart, E. C.

"THE ROLE OF SIMULATION IN DETERMINING SAFE AIRCRAFT LANDING SEPARATION CRITERIA"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 15-1 - 15-29

The role of flight simulation in determining safe aircraft landing separation criteria is reviewed and discussed. A broad conclusion is made that previous vortex-encounter simulations were useful for predicting the general response of an aircraft in the presence of trailing vortices and the type of separation criteria to emphasize. These simulations, however, were generally limited in scope and validation. Broad requirements for an accepted simulation methodology are presented. Key

technological issues are addressed, including the addition of high-fidelity vortex models and aircraft/vortex interaction effects in the simulation, and validation of simulations with experimental data. Finally, results from a preliminary one-degree-of-freedom simulation are shown. These indicate that reduced landing spacings may be feasible and that current aircraft categorizations should be reviewed.

Stuever, R. A., Stewart, E. C. and Rivers, R. A.

"OVERVIEW OF THE PREPARATION AND USE OF AN OV-10 AIRCRAFT FOR WAKE VORTEX HAZARDS FLIGHT EXPERIMENTS"

AIAA Paper No. 1995-3935, Los Angeles, CA, September 1995.

An overview is presented of the development, use, and current flight-test status of a highly-instrumented North American Rockwell OV-10A Bronco as a wake-vortex-hazards research aircraft. A description of the operational requirements and measurements criteria, the resulting instrumentation systems and aircraft modifications, system-calibration and research flights completed to date, and current flight status are included. The OV-10A performs several roles including meteorological-measurements platform, wake-decay quantifier, and trajectory-qualifier for wake encounters.

Stuff, R.

"THE RELATIONSHIP BETWEEN NEAR- AND-FAR-FIELD OF VORTEX WAKES FROM AIRCRAFT WITH HIGH ASPECT RATIO WINGS"

In New Results in Numerical and Experimental Fluid Mechanics III, Notes on Numerical Fluid Mechanics, Vol. 77, Eds. Wagner, et al., Springer-Verlag, Berlin Heidelberg, 2002, pp. 58-65.

Far field measurements of the vortex wake shed from a transport aircraft indicate that the trailing vortex pair from the main wing undergoes a Rayleigh-Ludwig instability and premature breakdown, if it encounters another vortex pair turning in the opposite sense. The origin of this latter vortex pair is the trim force of the horizontal tail, and, or, the reduction of lift across the fuselage due to the wing/fuselage junction. The opposite vortex pairs however, due to their self-induction, tend to move upwards whereas the main vortex pair moves downward. The condition, that the former does not happen is introduced as a necessary condition for premature vortex breakdown in the far field. This necessary condition can be checked upon in the near field. The Rayleigh-Ludwig instability then, is the sufficient condition for premature vortex breakdown.

Stuff, R.

"THE INVISCID MOTION OF A VORTEX PAIR IN A COMPRESSIBLE AND STRATIFIED ATMOSPHERE"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 31-1 to 31-10.

The movement of an inviscid vortex pair in a compressible atmosphere including buoyancy effects is described by analytic solutions. The effects of compressibility are dealt with in an isentropic atmosphere. The work of compression done by the atmosphere on the vortex is entirely consumed by the isentropic change of the thermodynamic state of the vortex pair. The acceleration of the accompanying and apparent mass is given by the displacement of the two vortices towards each other. The effects of buoyancy are investigated by means of a two-dimensional, incompressible, inviscid vortex pair which is heavier than the ambient fluid. It turns out that the condition of pressure continuity across the separating streamline can be achieved only by assuming an increase in circulation of the two vortices. The mass accompanying the vortex pair under the effect of non-conservative forces converts a fraction of its gravity potential into an increase of stagnation pressure. Both, the analytical formulas for compressibility and buoyancy, then, are combined to describe both effects simultaneously. Thus, inconsistencies of other papers are eliminated.

Stuff, R.

"ALLEVIATION OF AIRCRAFT VORTEX HAZARD THROUGH PASSIVE AERODYNAMIC MEASURES"

AIAA Paper No. 2003-1108, Reno, NV, January 2003

The hazard of wake vortices as encountered by following aircraft may be alleviated by a premature vortex breakdown because of the Rayleigh-Ludwig instability. Then, the rapidly increasing vortex cores soon meet at and merge across the wake center line. At this instant the circulation quickly decays, as the two vortex cores cancel each other due to their opposite vorticity. The Rayleigh-Ludwig instability, which is well known as an inviscid spiral instability occurring over delta wings, may also occur in the vortex wake shed from transport aircraft. The Rayleigh-Ludwig instability implies that the vorticity changes sign on each side of the wake. This may be accomplished by aerodynamic devices, or, modification of aerodynamic devices which, for other reasons than vortex breakdown, already are an integral part of the aircraft design. Thus, for example, the opposite vortex pair emanating in approach and climb from the horizontal tail may generate a premature vortex breakdown. On the one hand, the necessary condition is that the tail vortex pair is entrained into the descending wake of the main wing vortex pair and does not, due to its self-induction, move upward. On the other hand, the sufficient condition is that its circulation has a minimum value of about 20% of the wing vortex circulation. For alleviation of wake vortex hazard, the Rayleigh-Ludwig instability opens prospects for a novel category of passive aerodynamic measures, some of which are dealt with in the present paper.

Stuff, R.

"THE NEAR-FAR FIELD RELATIONSHIP OF VORTICES SHED FROM TRANSPORT AIRCRAFT"

AIAA Paper No. 2001-2429, Anaheim, CA, June 2001

A large amount of research effort has been devoted to the vortex breakdown of vortices caused by a Crow, Widnall or Crouch instability. In experiments dealt with here, a premature vortex breakdown in about 40 wingspans has been observed. The origin of this premature vortex breakdown is a counter-

rotating vortex emanating from inside flap edges or the horizontal tail. The origin of this instability is a counter-rotating vortex at the periphery of the wing vortex. In this case destabilizing centrifugal forces dominate restoring pressure forces. The instability was found by Rayleigh and generalized by Ludwig. A necessary condition for the occurrence of this instability is that the vortex pair emanating from the horizontal tail, due its self-induction, does not move upwards, whereas the main vortex pair moves downward. The necessary condition is used to establish the near-far field relationship. The instability of Rayleigh and Ludwig is the corresponding sufficient condition for premature breakdown of the vortex cores. Due to the rapid growth of the cores they become so large spatially that the two legs of the trailing main vortex pair meet and merge. After this merging the circulation rapidly decreases, which finally alleviates the hazard in encountering wake vortex.

Stuff, R.

"THE ROLE OF PIV IN THE DESIGN OF TRANSPORT AIRCRAFT FOR PREMATURE BREAKDOWN OF TRAILING VORTICES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

The hazard of wake vortices as encountered by following aircraft is given by circulation and vortex spacing. The discrete vortices are rolled up from the vortex sheet shed from wide body aircraft, and the hazard may be greatly reduced if the two legs of the trailing wing vortex pair meet and merge already in the extended near field. This can be accomplished by premature breakdown of vortex cores due to the Rayleigh-Ludwig instability. After this breakdown the vortex cores grow so rapidly that they come across the wake center line and merge with the opposite vorticity emanating from the other side of the aircraft. Only after this merger a rapid decay of circulation can be expected. As the Rayleigh-Ludwig instability seems not to be well known in the English literature, a review of vortex breakdown and instabilities will be given. Using these findings, any aircraft may be characterized by a design point in the diagram, where the circulation ratio of wing and tail vortex is plotted over the corresponding spacing ratio. From this diagram, the necessary condition for premature breakdown according to Ludwig can be taken. The necessary condition implies that the self-induction of the tail vortex is superseded by the induction from the wing vortex pair, so that the tail vortex moves downward. The analytical stability criteria of Ludwig provides the sufficient condition for premature vortex breakdown. Whereas 2 Component Particle Image Velocimetry (2C-PIV) can be used for the necessary condition, 3 Component Particle Image Velocimetry (3C-PIV, Stereoscopic PIV) must be used for the sufficient condition, since the stability criteria of Ludwig is given by the radial gradients of the swirl and axial velocity components.

Stuff, R. and Vollmers, H.

"AIRCRAFT WITH MEANS FOR A PREMATURE BREAKDOWN OF THE WING VORTEX PAIR"

US Patent No. 6,422,518 B1, July 2002.

For a premature breakdown of a wing vortex pair behind an aircraft in flight comprising a symmetry plane, two wings, a fuselage and a horizontal tail plane, the wing vortex pair being generated in the area of the tips of the wings, having a first spin direction and descending behind the aircraft, an interfering vortex pair, which is generated between the fuselage and the tips of the wings without merging already in the near field behind the wing with the wing vortex pair and which has a second spin direction that is opposed to the first spin direction, is retained behind the aircraft in an altitude range of the wing vortices of the wing vortex pair by adjusting to suitable values the relative circulation and the relative span of the interfering vortex pairs each related to the wing vortex pair. The interfering vortex pair includes portions of a fuselage vortex pair, which is generated in the junction area of the wings to the fuselage, and a tail plane vortex pair, which is generated in the area of the wing tips of the horizontal tail plane.

"NEAR- TO MIDFIELD-WAKE: EXPERIMENTAL CHARACTERISATION"

Proceedings 3rd ONERA-DLR Aerospace Symposium, Paris, France, June 2001, pp. S2-1/1-5

The wake of wide body aircraft is a hazard to following aircraft in approach, climb, and cruise. Thus, a large amount of experimental research effort has been devoted to instability and breakdown of vortices. However, investigations of the instabilities of vortices in the wake far field very often are lacking the link to the near field and are inconclusive as to the aerodynamic, whereas investigations of the wake in a wind tunnel very often miss the link to the mid- and far field at a sufficiently high Reynolds-number. For this reason, the wake of an Airbus A-300 with different flap settings was investigated in a joint ONERA/DLR-project in the catapult of ONERA Lille. The Particle Image Velocimetry was chosen as non-intrusive testing technique. In a particular setting of the landing flaps, a premature breakdown of the vortex cores was observed. The origin of the breakdown was understood as a Rayleigh-Ludwig instability, which occurs if destabilizing centrifugal forces dominate stabilizing pressure forces.

"INVESTIGATIONS OF HELICOPTER WAKE FLOW INCLUDING ROTOR-HEAD MOTION"

Journal of Aircraft, Vol. 55, No. 5, September-October 2018, pp. 2114-2126.

The present paper emphasizes on the characteristics of the wake flowfield emanating from a helicopter fuselage and rotor head, including cyclic and collective pitch motion. Predicting the convection of the coherent vortical flow structures generated by the fuselage as well as the rotor head is a difficult goal by the application of numerical methods. Furthermore, the accurate determination of the wake flowfield requires the detailed knowledge of the origin of the associated coherent structures. Therefore, numerical and experimental investigations have been conducted on a twin-engine light utility helicopter. The wind-tunnel model includes a fuselage and a rotating five-bladed rotor head. To obtain the wake flowfield, stereoscopic particle image velocimetry is applied. The numerical

investigations are performed with a commercial flow solver. The flow solver is based on the unsteady Reynolds-averaged Navier-Stokes equations. Turbulence modeling is performed with the scale-adaptive simulation model. The motion of the rotor head is covered by the moving and deforming mesh methods. The wake-flow velocity distribution obtained by the experimental data and the numerical results shows a good agreement and allows a detailed analysis of the dominant vortical flow structures propagating downstream.

Stumpf, E.

"STUDY OF FOUR-VORTEX AIRCRAFT WAKES AND LAYOUT OF CORRESPONDING AIRCRAFT CONFIGURATIONS"

Journal of Aircraft, Vol. 42, No. 3, May-June 2005, pp. 722-730

A sequence of numerical simulations for the efficient determination of four-vortex wakes, consisting of two counter-rotating vortex pairs, with low induced rolling moments after the unstable merging of inner and outer vortices, is proposed. After a systematic investigation of generic four-vortex systems in a second step, an airliner geometry in high-lift configuration is modified such that it produces a vortex wake like the identified optimal four-vortex system. The configuration modification is done using simple design rules. For verification of the existence of a similar four-vortex system, the wake vortex of the modified airliner configuration is simulated up to the extended near field in a final step. Two four-vortex configurations are considered in the present paper, different only in the vortex spacing ratio. A maximum reduction of rolling moment down to 44-52% of the rolling moment of a reference two-vortex system is achieved within a distance equivalent to 2.89 n miles for a real size Airbus A340. The realization of four-vortex wakes behind an individually modified high-lift configuration like the aforementioned promising generic four-vortex configurations is demonstrated.

Stumpf, E.

"NUMERICAL INVESTIGATION OF THE EFFECT OF THE HIGH-LIFT CONFIGURATION OF A TRANSPORT AIRCRAFT ON ITS VORTEX WAKE"

In New Results in Numerical and Experimental Fluid Mechanics III, Notes on Numerical Fluid Mechanics, Vol. 77, Eds. Wagner, et al., Springer-Verlag, Berlin Heidelberg, 2002, pp. 50-57.

A numerical investigation, based on the Euler equations, of the nearfield wake vortex of four high-lift configurations of a narrow body airliner is carried out. The main focus is to study to what extent the configurations meet a criterion for the accelerated destruction of wake vortices proposed by Rennich/Lele. Additionally a spatial direct numerical simulation of the wake up to 35 spans is presented for the airliner model in standard landing configuration.

Stumpf, E.

"NUMERICAL STUDY OF FOUR-VORTEX AIRCRAFT WAKES AND LAYOUT OF CORRESPONDING HIGH-LIFT CONFIGURATIONS"

AIAA Paper No. 2004-1067, Reno, NV, January 2004

A numerical strategy for the efficient determination of 4-vortex wakes, consisting of two counter-rotating vortex pairs, with low induced rolling moments after the unstable merging of inner and outer vortices is proposed. After a systematic investigation of generic 4-vortex systems in a second step an airliner geometry in high-lift configuration is modified such that it produces a vortex wake like the identified optimal 4-vortex system. The configuration modification is done using simple design rules. For verification of the existence of a similar 4-vortex system the wake vortex of the modified airliner configuration is simulated up to the extended nearfield in a final step. Two 4-vortex configurations are considered in the present paper, different only in the vortex spacing ratio. A maximum reduction of rolling moment down to 44-52% of the rolling moment of a reference 2-vortex system is achieved within a distance equivalent to 2.89 NM for a real size Airbus A340. The realization of 4-vortex wakes behind an individually modified high-lift configuration like the afore determined promising generic 4-vortex configurations is demonstrated.

Stumpf, E.

"VORTEX WAKE OF AN A/C IN HIGH-LIFT CONFIGURATION"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

By means of Euler computations and Direct Numerical Simulations the vortex wake of a narrow-body wind-tunnel-model in different flight configurations has been investigated. The simulation domain covers in total 45 spans; aircraft configurations are landing, take-off and two configurations with differential flap setting. Special emphasis was put on the influence of atmospheric turbulence on the evolving wake. For the nearfield calculation up to half a span behind the model, the DLR-Euler code Tau was used; the downstream flowfield was simulated with the DLR-Direct Numerical Simulation code Mesoscop.

Stumpf, E.

"NUMERICAL STUDY OF FOUR-VORTEX AIRCRAFT WAKES"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

For an alleviation of wake vortices, it seems most promising to make use of the inherent instability of vortex systems: Either by triggering actively the most unstable wavelength with counteracting flaps and spoilers as proposed by Crow & Bate and patented by Boeing (Crouch & Spalart) or by designing a highly unstable vortex system for which natural perturbations from the aircraft boundary layer or weak atmospheric turbulence are sufficient for an onset of instability. For a four-vortex system, consisting of two pairs of counterrotating vortices, a point vortex analysis gives the condition for equal sink speed of all vortices in a cubic equation correlating the spacing ratio of the counterrotating vortices of the two

pairs with the ratio of their circulations. As the vortices lie constantly in one plane during decent, the outer vortex pair imposes high strain on the inner one, thereby in the first stage amplifying the inherent instabilities on the inner vortex pair. The second stage of the instability begins as the growing perturbation on the inner vortices induces instability on the outer vortex pair.

"BENCHMARK TEST FOR EULER CALCULATIONS OF A HIGH LIFT CONFIGURATION VORTEX WAKE"

AIAA Paper No. 2002-0554, Reno, NV, January 2002

A benchmark test for Euler simulations of a high-lift configuration vortex wake is presented. Four different partners have used their in-house grid generators and Euler-codes within the framework of the European research program C-Wake for calculating the nearfield vortex wake of the DLR-F11 model in take-off configuration. Compared are nearfield results up to a half span downstream of the model wing tip obtained on structured and unstructured grids, employing second, third and fourth order accurate schemes. For validation 5-hole probe and pressure distribution measurements carried out in the DNW-NWB are used.

Stumpf, E., Rudnik, R. and Ronzheimer, A.

"EULER COMPUTATION OF THE NEARFIELD WAKE VORTEX OF AN AIRCRAFT IN TAKE-OFF CONFIGURATION"

Aerospace Science and Tech., Vol. 4, July 2000, pp. 535-543

Numerical simulations based on the three-dimensional Euler equations are used to investigate the predictive capability of an Euler code for calculations of the nearfield wake of a narrow-body airliner wind tunnel model in take-off configuration up to a half span behind the wing tip trailing edge. Simulation results on both structured and unstructured grids are presented. The results on the block-structured grid were obtained within the scope of the EU-project EUROWAKE. The simulation quality of the vortex formation and spatial development is analyzed by comparison to wind tunnel measurements of the spanwise lift distribution available from the EU-project DUPRIN II and to experimental PIV data available from the EU-project EUROWAKE.

Stumpf, E., Wild, J., Dafa'Alla, A. A. and Meese, E. A.

"NUMERICAL SIMULATIONS OF THE WAKE VORTEX NEAR FIELD OF HIGH-LIFT CONFIGURATIONS"

European Congress on Computational Methods in Applied Sciences and Engineering ECCOMAS 2004, Jyväskylä, Finland, July 2004

Euler simulations of the nearfield wake of the DLR-F11 model in take-off configuration and a very large transport model in landing configuration are performed using the DLR TAU code on unstructured grids. The aim of the investigation is firstly to analyze the predictive capability of an Euler code for

high-lift configuration vortex wakes and secondly to study configuration effects on the vortex wake nearfield. A grid adaption strategy and parameter settings for the flow simulation are determined by validation with 5-hole probe measurement results that lead to good agreement between simulation and experiment at a half wing span downstream of the model wing tip. The identical simulation procedure is applied to a very large transport aircraft configuration and the interaction between the outer region jet and the flap side-edge vortex is investigated.

"WAKE TURBULENCE MITIGATION FOR DEPARTURES (WTMD) PROTOTYPE SYSTEM"

NASA/CR-2008-215549, January 2008, Raytheon Co., Hampton, VA.

This document describes the software design of a prototype Wake Turbulence Mitigation for Departures (WTMD) system that was evaluated in shadow mode operation at the Saint Louis (KSTL) and Houston (KIAH) airports. This document describes the software that provides the system framework, communications, user displays, and hosts the Wind Forecasting Algorithm (WFA) software developed by the MIT Lincoln Laboratory. The WFA algorithms and software are described in a separate document produced by Lincoln Laboratory.

Sturgeon, M. C.

"WIND TUNNEL TESTS OF SOME LOW-COST SONIC ANEMOMETERS"

WMO Technical Conference on Meteorological and Environmental Instruments and Methods of Observation, May 2005, Bucharest, Romania.

Sonic anemometers for meteorological measurements have been around since the early 1970s. The early sonic anemometers were very expensive and did not have the high reliability, low-cost electronic components now available. Thus, early sonic anemometers had poor reliability and were mainly used for scientific research. In the last several years, manufacturers have started offering lower-cost sonic anemometers suitable for general meteorological use. The low maintenance and low electrical power requirements of these current sonic anemometers make them good candidates for remote sensing applications with solar panels. This paper presents test data for several available low-cost sonic anemometers using wind tunnel test method ISO 16622 'Meteorology -- Sonic anemometers/thermometers - Acceptance test methods for mean wind measurements.' The measurement performance differences of sonic anemometers and rotating anemometers are discussed in this paper.

Subaschandar, N. and Prabhu, A.

"TURBULENT NEAR-WAKE STUDIES BEHIND AN INFINITELY SWEPT WING"

Journal of Aircraft, Vol. 39, No. 2, March-April 2002, pp. 290-295.

The three-dimensional asymmetric turbulent near-wake behind an infinitely swept wing with GAW(2) airfoil has been investigated at low speeds. The near-wake in the present study is asymmetric because the boundary layers on the top and bottom surfaces of the model develop under different streamwise pressure gradients. Distributions of mean velocity, three turbulent normal stresses, and two important Reynolds shear stresses have been measured using hot-wire anemometry. The profiles of mean velocity and Reynolds shear stresses exhibit asymmetry near the trailing edge and seem to have become symmetric within a short distance of 60 trailing edge momentum thicknesses. Results of computation using K- ϵ turbulence model with a simple scheme to predict the near-wake behind the swept wing have also been presented and compared with the experimental data. The agreement of the predicted mean flow development with the experiment is fair considering the simplicity of the scheme.

Suciu, E. O.

"A FINITE ELEMENT ANALYSIS OF THE EXACT NONLINEAR FORMULATION OF A LIFTING SURFACE IN STEADY INCOMPRESSIBLE FLOW, WITH THE EVALUATION OF THE CORRECT WAKE GEOMETRY"

M.S. Thesis, December 1975, Boston University, Boston, MA

The problem of steady incompressible flow around wings with wake roll-up is considered. This problem requires the solution of an integral equation relating the values of the potential on the lifting surface and its wakes to the values of the normal derivative of the potential which are known from the boundary conditions. An iteration procedure is used to obtain the wake geometry; the velocities at the corner points of the wake elements are calculated and the (originally straight) wake streamlines are aligned to be parallel to the velocity vector. The procedure is repeated until convergence is attained.

Suciu, E. O. and Morino, L.

"NONLINEAR STEADY INCOMPRESSIBLE LIFTING-SURFACE ANALYSIS WITH WAKE ROLL-UP"

AIAA Journal, Vol. 15, No. 1, January 1977, pp. 54-58.

The problem of lifting surfaces in steady incompressible flow is considered. The problem is formulated in terms of an integral equation relating the potential discontinuity on wing and wake to the normal derivative of the potential (normal wash) on the lifting surface. The integral equation is approximated by a system of linear algebraic equations obtained by dividing the surfaces into small quadrilateral elements and by assuming the potential discontinuity and the normal wash to be constant within each element. The wake geometry is obtained through iteration by satisfying the condition that the velocity be tangent to the surface of the wake and that the discontinuity be constant along the streamlines. Numerical results are in good agreement with existing ones.

"ASYMPTOTIC THEORY OF THE VISCOUS INTERACTION BETWEEN A VORTEX AND A PLANE"

Fluid Dynamics, Vol. 37, No. 6, 2002, pp. 865-872

The problem of the viscous interaction between a flow induced by a vortex filament and an orthogonal rigid surface is solved for high Reynolds numbers using the method of matched asymptotic expansions. In view of the impossibility of matching the principal terms of the asymptotic expansions directly for the near-axial boundary layer and the main flow zone, the solution is obtained by introducing two intermediate zones. In this case a logarithmic singularity of the axial velocity arises inevitably on the vortex filament. In the near-axial and intermediate zones the solution is obtained numerically and analytically, respectively, while in the main zone the problem reduces to the problem of the flow induced by a line of weakly swirled vortex-sinks.

Sugimoto, T.

"INDUCED VELOCITY IN THE PLANE OF AN ELLIPTICALLY LOADED LIFTING LINE"

AIAA Journal, Vol. 40, No. 6, June 2002, pp. 1233-1236

The classical lifting line theory of Prandtl is first reviewed. Then with special attention to the treatment of singularities at the vortex sheet edges, the lifting line theory was utilized to obtain the distribution of induced velocity in the plane of an elliptically loaded lifting line and its wake. The resulting closed form solution, although simplistic in physical terms, may serve as a benchmark test for validating numerical schemes.

"ACCURACY ESTIMATION OF PROBABILISTIC WAKE VORTEX PREDICTION CONSIDERING WEATHER INFORMATION ERRORS"

AIAA Paper No. 2011-3195, June 2011, Honolulu, Hawaii.

Current wake vortex separation minima are a major impediment to increasing traffic capacity since they require greater separation than radar separation minima. The concept of dynamic wake vortex separation minima, which would allow reduced separations in favorable meteorological conditions when wake durations on flight paths become shorter, would allow an increase in capacity. This paper proposes a methodology that uses a probabilistic wake vortex prediction model to probabilistically assure that wake vortex encounter risk at reduced separations are equal or lower than the risks at current separations.

"NUMERICAL SIMULATIONS AND MEASUREMENTS OF THE HELICOPTER WAKE IN GROUND EFFECT"

Journal of Aircraft, Vol. 54, No. 1, January-February 2017, pp. 209-219.

When a helicopter takes off, lands, or makes hovering or taxiing flights in ground effect, its downwash interferes with the ground. Encounters with such highly turbulent helicopter wakes have resulted in the two small fixed-wing aircraft crashes in the United Kingdom. Due to these accidents, the Japan Aerospace Exploration Agency is investigating the helicopter wake structure in ground effect, especially during taxiing, by means of computational fluid dynamics and flight testing. The base computational fluid dynamics code is structured grid solver rFlow3D, which has systematically been developed for helicopter applications at the Japan Aerospace Exploration Agency. The rFlow3D solver is a highly versatile computational fluid dynamics code that can numerically simulate flows around helicopters with a wide range of Reynolds and Mach numbers and can perform rotor trim analysis with elastic blade deformations. In the flight experiment described herein, the Japan Aerospace Exploration Agency research helicopter H145 (EC145, BK117 C-2) performed taxiing above a runway, and its wakes were measured by Light Detection and Ranging and ultrasonic anemometers. The variation of the characteristic wake structure with the advance ratio was clearly revealed in the computational fluid dynamics and was supported indirectly by the flight experiment results.

"DYNAMICS OF THIN VORTEX RINGS"

J. Fluid Mech., Vol. 609, 2008, pp. 319-347

As part of a long-range study of vortex rings, their dynamics, interactions with boundaries and with each other, we present the results of experiments on thin core rings generated by a piston gun in water. We characterize the dynamics of these rings by means of the traditional equations for such rings in an inviscid fluid suitably modifying them to be applicable to a viscous fluid. We develop expressions for the radius, core size, circulation, and bubble dimensions of these rings. We report the direct measurements of the impulse of a vortex ring by means of a physical pendulum.

Sullivan, J. P., Widnall, S. E. and Ezekiel, S.

"A STUDY OF VORTEX RINGS USING A LASER DOPPLER VELOCIMETER"

AIAA Paper No. 1973-0105, Washington, DC, January 1973

Measurements of the axial and radial velocity distributions in vortex rings were made using a two-component laser Doppler velocimeter. The rings were generated by pulsing air through a sharp-edged orifice using a loudspeaker: the strength and vortex core size could be controlled somewhat by the duration and amplitude of the pulse. From detailed surveys of the velocity field, both the circulation and vorticity distribution were found for two different rings: one with a relatively thick core, the other with a thin core. The vorticity was found to be rather concentrated for both rings. Streamlines were also calculated and compared with observations. Vortex rings were found to be unstable to azimuthal perturbations; the observed mode number and growth rate are in reasonable agreement with theory.

"A PROGRAM TO COMPUTE THE BEHAVIOR OF A THREE-DIMENSIONAL TURBULENT VORTEX"

ARL-TR-74-009 and ARAP No. 200, February 1974, Aeronautical Research Assoc. of Princeton, Princeton, NJ

A program to compute the downstream behavior of a turbulent vortex has been prepared for Aerospace Research Laboratories. The mathematical basis and the numerical technique of the program are set forth. Subsidiary calculations are described. Finally, the structure of the program is explained and information needed to run it is given.

Sullivan, T. E. and Burnham, D. C.

"GROUND-WIND VORTEX SENSING SYSTEM CALIBRATION TESTS"

FAA-RD-80-13, February 1980, DOT Transportation Systems Center, Cambridge, MA

This report describes the collection of data related to the calibration of two systems for detecting and tracking aircraft wake vortices. The systems tested were the propeller anemometer Ground Wind Vortex Sensing System and the Pulsed Acoustic Vortex Sensing System. The data were analyzed and the location of the vortices as determined with these systems were compared with the vortex location as determined photographically.

Sullivan, T. E., Burnham, D. C. and Kodis, R. D.

"VORTEX SENSING TESTS AT LOGAN AND KENNEDY AIRPORTS"

FAA-RD-72-141, December 1972, DOT Transportation Systems Center, Cambridge, MA

This report describes a series of tests of wake vortex sensing systems at Logan and Kennedy Airports. Two systems, a pulsed acoustic radar (ACDAR) and an array of ground level pressure sensors, were tested. Site restrictions limited the Logan work to preliminary evaluation. The tests at Kennedy Airport established the general operating characteristics of both tracking systems. It was found that the acoustic sensor can detect and track the vortices of all commonly used commercial aircraft, though with varying degrees of sensitivity. The pressure sensors generally behaved best during conditions of low to moderate winds when the vortices could often be tracked laterally up to several hundred feet from the aircraft flight path.

Sullivan, T. E., Hallock, J. N. and Winston, B. P.

"ANALYSIS OF GROUND-WIND VORTEX SENSING SYSTEM DATA FROM O'HARE INTERNATIONAL AIRPORT"

FAA-RD-80-133, September 1980, DOT Transportation Systems Center, Cambridge, MA

From July 1976 through September 1977, aircraft wake vortex data were collected on the approach to runways 14R, 27R, and 32L at O'Hare International Airport. The vortices from over 21,000 aircraft were tracked using the propeller anemometer Ground-Wind Vortex Sensing System, and the vortex behavior as correlated with the associated ambient meteorological conditions. The primary purpose of the tests was the evaluation of the Vortex Advisory System (VAS) concept. The elliptical wind criterion used in the VAS was verified using the vortex data.

Sullivan, T. E., Hallock, J. N., Winston, B. P., McWilliams, I. G. and Burnham, D. C.

"AIRCRAFT WAKE VORTEX TAKEOFF TESTS AT TORONTO INTERNATIONAL AIRPORT"

FAA-RD-78-143, February 1979, DOT Transportation Systems Center, Cambridge, MA.

This report describes the collection and analysis of data related to the behavior of the wake vortices of departing aircraft. The test site was located on the departure end of Runway 23L at Toronto International Airport, Toronto, Ontario, Canada. Three arrays of Ground Wind Vortex Sensing Systems and one Monostotic Acoustic Vortex Sensing System were used to detect, track and measure the strength of the vortices. The data were analyzed to determine vortex lifetimes, transport characteristics and decay mechanism. The results of the data analysis were used to generate an elliptical wind rose criterion like that used in the Vortex Advisory System for reduction in interarrival aircraft spacings.

"DEVELOPMENT OF A SMALL AIR VEHICLE BASED ON AERODYNAMIC MODEL ANALYSIS IN THE TUNNEL TESTS"

Mechatronics, Vol. 16, Issue 1, February 2006, pp. 41-49

Tunnel tests play a critical role to aerodynamics analysis, but few work has been done in this area for developing small air vehicles. This paper presents development of an electrically powered small air vehicle prototype based on aerodynamic analysis in wind tunnel and water tunnel tests. Firstly, two airframe models in triangle and square wing planforms, each with a wingspan of 100 mm, are analyzed with a small-scale low speed wind tunnel. The purpose of the wind tunnel test is to examine the practical characteristics such as lift and drag coefficients. The test in a water tunnel is further carried out to investigate the relationship between the vortex airfoil design and turbulences created. In both wind tunnel and water tunnel tests, the airframe models, apparatus, and the methodology are discussed, and the testing results show that the triangle wing airfoil appears greater maximum lift coefficient and little occurrence of vortex and turbulences. Secondly, based on the verified wing planform in the tunnel tests, a small air vehicle prototype was designed and fabricated. The ground and onboard subsystems or components, such as flight control unit, vision system, and propulsion system etc., are studied. The materials and fabrication processes are also presented in the paper. Finally, the developed air vehicle prototype is successfully tested in the real flight.

"AN ADAPTIVE REGION METHOD FOR COMPUTATION OF VORTEX SHEET BEHIND WING IN COMPRESSIBLE FLOW"

ICAS 1992, Paper No. 7.4.1, September 1992, Beijing, China.

An adaptive region method is presented for the computation of vortex sheet behind wing in compressible flow, by adjusting automatically computation region in size on every Trefftz plane. The method can keep the boundary of computation region sufficiently away from the region of vorticity to ensure the accuracy with less computation time. In addition, the first derivatives of the potential on branch cuts is redefined and a second derivative of potential function is obtained for improving calculation of the cross velocity on branch cuts. Computation shows that the 'hook' at vortex tip which appeared by using Stremeland, Murman's method for elliptically loaded wing, is eliminated in the present method and the computation results are quite agreement with exact solution of Betz theory for elliptically loaded wing.

"WEATHER FIELD RECONSTRUCTION USING AIRCRAFT SURVEILLANCE DATA AND A NOVEL METEO-PARTICLE MODEL"

PLoS ONE, Vol. 13, Issue 10, October 2018, pp. e0205029-1 to e0205029-33.

Wind and temperature data are important parameters in aircraft performance studies. The lack of accurate measurements of these parameters forces researchers to rely on numerical weather prediction models, which are often filtered for a larger area with decreased local accuracy. Aircraft, however, also transmit information related to weather conditions, in response to interrogation by air traffic controller surveillance radars. Although not intended for this purpose, aircraft surveillance data contains information that can be used for weather models. This paper presents a method that can be used to reconstruct a weather field from surveillance data that can be received with a simple 1090 MHz receiver. Throughout the paper, we answer two main research questions: how to accurately infer wind and temperature from aircraft surveillance data, and how to reconstruct a real-time weather grid efficiently. We consider aircraft as moving sensors that measure wind and temperature conditions indirectly at different locations and flight levels. To address the first question, aircraft barometric altitude, ground velocity, and airspeed are decoded from down-linked surveillance data. Then, temperature and wind observations are computed based on aeronautical speed conversion equations. To address the second question, we propose a novel Meteo-Particle (MP) model for constructing the wind and temperature fields. Short-term local prediction is also possible by employing a predictor layer. Using an unseen observation test dataset, we are able to validate that the mean absolute errors of inferred wind and temperature using MP model are 67% and 26% less than using the interpolated model based on GFS reanalysis data.

"ROTOR VORTEX WAKE DISTORTION AND ITS INDUCED VELOCITY IN GROUND EFFECT AT LOW SPEED"

Acta Aerodynamica Sinica, Vol. 7, March 1989, pp. 35-41

The vortex wake and its induced velocity of a helicopter rotor operating near the ground at low forward speeds have been studied using a simplified free wake-ground vortex model. The vortex wake near the rotor plane is distorted significantly because of the flowfield of the ground and ground vortex, resulting in large variation on the induced velocity distribution at the rotor plane, especially near the rotor leading edge. The variation of the induced velocity distribution at the rotor plane caused by the ground and ground vortex through distorting the rotor near-wake is much larger than that induced directly by the ground and ground vortex. The free wake-ground vortex model can be used to predict the induced velocity distribution at the rotor plane with reasonable accuracy.

"A FLOW VISUALIZATION STUDY OF VORTEX INTERACTION WITH THE WAKE OF A SPHERE"

Transactions of the ASME, Vol. 122, September 2000, pp. 560-568

A study of the interaction between an initially columnar intake vortex (hereinafter referred to as the primary vortex) and vortex structures in the wake of a single sphere (hereinafter referred to as secondary vortices) is performed using a series of flow visualization experiments, in which a sphere is towed toward a stationary vortex with ambient axial flow and gradually decelerated to rest at a specified distance from the vortex core axis. Both the primary vortex core and the boundary layer of the sphere are visualized using laser-induced fluorescent dyes of two different colors, which are illuminated either with a laser sheet or a laser volume. The strength of the primary vortex is measured using particle-image velocimetry, which is also used to measure the strength of the secondary vortices in select cases. The form of the sphere wake in the presence of the primary vortex and the effect of the induced velocity from the secondary vortices on the primary vortex are studied for different values of the vortex-sphere separation distance, the sphere diameter, and the primary vortex core radius. Weak secondary vortices are observed to induce formation of small-amplitude waves of varying core area on the primary vortex, eventually forming a turbulent sheath surrounding the primary vortex. Stronger secondary vortices have an increasingly strong effect on the primary vortex, including large-amplitude variation in core area, outward ejection of fluid from the primary vortex core, and breakdown of the primary vortex.

"REVIEW AND PROSPECT OF SUPERSONIC BUSINESS JET DESIGN"

Progress in Aerospace Sciences, Vol. 90, 2017, pp. 12-38.

This paper reviews the environmental issues and challenges appropriate to the design of supersonic business jets (SSBJs). There has been a renewed, worldwide interest in developing an environmentally friendly, economically viable and technologically feasible supersonic transport aircraft. A historical

overview indicates that the SSBJ will be the pioneer for the next generation of supersonic airliners. As a high-end product itself, the SSBJ will likely take a market share in the future. The mission profile appropriate to this vehicle is explored considering the rigorous environmental constraints. Mitigation of the sonic boom and improvements aerodynamic efficiency in flight are the most challenging features of civil supersonic transport. Technical issues and challenges associated with this type of aircraft are identified, and methodologies for the SSBJ design are discussed. Due to the tightly coupled issues, a multidisciplinary design, analysis and optimization environment is regarded as the essential approach to the creation of a low-boom low-drag supersonic aircraft. Industrial and academic organizations have an interest in this type of vehicle are presented. Their investments in SSBJ design will hopefully get civil supersonic transport back soon.

Sun, Z., Li, Q. and Bruecker, C.

"THE SHORT-WAVELENGTH INSTABILITY IN THE IMPINGING VORTEX RING MEASURED BY SCANNING-PIV"

19th International Symposium on the Application of Laser and Imaging Techniques to Fluid Mechanics, July 2018, Lisbon, Portugal.

Scanning-PIV using the drum scanner is employed to study the impingement of a vortex ring onto a solid surface. Both the wall-normal and wall-parallel planes are measured. The former reveals the expansion of the vortex ring and the generation of the secondary and even the tertiary rings in the impingement. The latter successfully visualized the development of the azimuthal instability in the primary and secondary rings. The well-understood long-wavelength instability is found to occur when the secondary ring moves into the primary one. Apart from the azimuthal instability of long-wavelength, another azimuthal instability phenomenon of short-wavelength is visualized. This short-wavelength instability along the primary ring happens when it approaches the surface and being stretched.

Suponitsky, V., Cohen, J. and Bar-Yoseph, P. Z.

"NUMERICAL INVESTIGATION OF THE EVOLUTION OF A LOCALIZED VORTEX DISTURBANCE IN UNIFORM SHEAR FLOW"

AIAA Paper No. 2003-3603, Orlando, FL, June 2003

The motivation of the present research is to understand the generation of coherent structures in turbulent boundary layers from a localized finite amplitude vortical disturbances. Our basic methodology is to follow the evolution of a localized vortical disturbance in an unbounded laminar uniform shear flow instead of a turbulent environment. Here we focus only on the interaction between the shear of the base flow and the disturbance and do not consider other effects such as the presence of a wall or the non-uniformity of the shear of the base flow. The numerical simulation are performed by the commercial CFD code ('FLUENT') based on the infinite volume approach. For the case of a small amplitude initial Gaussian vortex the numerical solution of the full Navier-Stokes equations follows

closely the analytical solution of the linearized equations. When the amplitude of the disturbance is small, the disturbance evolves into a pair of quasi-streamwise counter-rotating elongated vortices, similar to the ones observed in the near-wall region of a turbulent boundary layer independent of the initial disturbance geometry. On the other hand, when the amplitude of the initial disturbance is large the initial disturbance eventually evolves into a hairpin shape vortex. During its evolution the strength of the vortical structure as well as its inclination angle relative to the direction of the base flow, strongly depend on the initial geometrical shape of the small amplitude initial disturbance, although the resulted structures are very similar.

Surendraiah, M.

"AN EXPERIMENTAL STUDY OF ROTOR BLADE VORTEX INTERACTION"

NASA CR-1573, December 1969, Penn State University, Dept. Aerospace Engineering, University Park, PA

Results of an experimental investigation of the instantaneous blade airloads and their time derivatives are presented for a rotor blade intersecting a completely rolled-up trailing vortex. Parameters such as the rotor rotations per minute, vortex strength, and intersection angle were examined. Sample photographic records are presented in order to show the influence of the tip vortex on the blade loading.

Surmacz, K. and Lotnictwa, I.

"DYNAMICS OF A VORTEX RING AROUND A MAIN ROTOR HELICOPTER"

ICAS 2014, September 2014, St. Petersburg, Russia.

The main goal of the work was an analysis of the dynamics of vortex ring formation process and determinants of the occurrence of vortex ring state (VRS) in a main rotor of a helicopter. VRS occurs in the vertical decent of a helicopter (or close to this maneuver). The paper presents results obtained by CFD analysis and from the wind tunnel test investigation. The visualization of a flow field provided information on the changing nature of the flow during the movement of helicopter.

Sussmann, R.

"VERTICAL DISPERSION OF AN AIRCRAFT WAKE: AEROSOL-LIDAR ANALYSIS OF ENTRAINMENT AND DETRAINMENT IN THE VORTEX REGIME"

Journal of Geophysical Research, Vol. 104, No. D2, January 1999, pp. 2117-2129

Vertical dispersion of contrails in the vortex regime is investigated by focusing on the role of entrainment and detrainment of exhaust with respect to the pair of trailing vortices. A ground-based back-scatter-depolarization lidar with an integrated CCD camera provides information on optical and geometrical parameters of the contrail in the time span between 5.7 and 50.3 s behind a B747-400

aircraft. This is combined with coincident airborne in situ measurements of turbulence and the vertical profiles of temperature and wind speed in a case study. The two wingtip vortices, separated by 47 m, are descending with an increasing speed (2.5-3.1 m/s for 10.8-47.8 s behind aircraft) in the weakly non-stably stratified atmosphere. The turbulent vertical dissipation rate on the day of the study above southern Germany is a factor of 1000 higher than found typically above oceans at cruising altitude. At 4.2 s behind the aircraft, a diffuse secondary wake starts to evolve above the two wingtip vortices. After about 50 s the secondary wake encloses a cross-sectional area (4410 square m) comparable to that of the primary wake (4620 square m) and a relative ice surface area of 1:5. The observed early onset of the secondary wake is conjectured to be due to turbulent detrainment of fluid out of the primary wake which can be enhanced by detrainment due to baroclinic forces later in the vortex regime evolution. By exclusion of other mechanisms of secondary wake formation, detrainment of fluid from the primary wake is concluded to be the precondition for secondary wake formation. Detrainment due to baroclinic forces, shear or turbulence is, in general, unlikely to be absent for typical atmospheric conditions. It is suggested that the ambient humidity level may determine when a secondary wake is visible above a vortex pair and when it is not.

Sussmann, R. and Gierens, K. M.

"LIDAR AND NUMERICAL STUDIES ON THE DIFFERENT EVOLUTION OF VORTEX PAIR AND SECONDARY WAKE IN YOUNG CONTRAILS"

Journal of Geophysical Research, Vol. 104, No. D2, January 1999, pp. 2131-2142.

Vortex-regime evolution of contrails is investigated by focusing on the role of ambient humidity. Lidar cross-section measurements and observational analysis are combined with numerical simulations of fluid dynamics and microphysics. Contrail evolution behind four-turbofan aircraft is classified into three different scenarios. In the case of ice-subsaturated air, a visible pair of wingtip vortices is formed that disappears at the end of the vortex regime. In case of ice supersaturation, a diffuse secondary wake evolves above the wingtip vortices. It is due to detrainment of ice particles growing by sublimation of ambient humidity. A vertical wake-gap opens between the wingtip vortices and the secondary wake. It is due to subsaturated air moving upward along the outer edges of the sinking vortex tubes accumulating around the upper stagnation point of the vortex system. The vertical wake-gap preferably occurs in the wake of heavy (four turbofans) aircraft, since the vortices behind light aircraft migrate down too slowly. The secondary wake is composed of nonspherical particles larger than the ones in the wingtip vortices which are spherical particles and/or particles smaller than about 0.5 microns. In most cases the secondary wake is the only part of a contrail that persists after vortex breakdown. This is because the ice in the vortex tubes evaporates due to adiabatic heating as the vortices travel downward. Only in the rare case of higher ambient ice supersaturation (greater than 2 percent) do both parts of a contrail contribute to the persistent ice cloud.

Sussmann, R. and Gierens, K. M.

"DIFFERENCES IN EARLY CONTRAIL EVOLUTION OF TWO-ENGINE VERSUS FOUR-ENGINE AIRCRAFT: LIDAR MEASUREMENTS AND NUMERICAL SIMULATIONS"

Journal of Geophysical Research, Vol. 106, No. D5, March 2001, pp. 4899-4911.

Jet- and vortex-regime evolution of contrails behind cruising aircraft is investigated by focusing on the role of aircraft type. Cross-section measurements by ground-based lidar and observational analysis are combined with numerical simulations of fluid dynamics and microphysics in the wake of a two-engine aircraft. Depending on ambient humidity levels, contrail evolution behind short-/medium-range twin-turboprop airliners is classified into two scenarios, which contrasts with the three scenarios observed for a wide-body four-turboprop aircraft. In the case of ice-subsaturated ambient air, a short visible contrail is formed behind a two-engine aircraft that disappears before the ice is fully entrained into the wingtip vortices (in most cases about 4 s behind aircraft). The early evaporation of the ice is mainly due to the fast initial jet expansion, mixing the exhaust with the ambient air. Contrails behind a wide-body four-engine aircraft always survive at least until vortex breakdown (i.e., typically 2 min behind aircraft). This is simply due to the larger ice mass in the contrail because of the higher fuel flow rate. Generally, in the case of ice supersaturation, a diffuse secondary wake evolves above the primary vortex wake. For a two-engine aircraft, always the whole contrail persists, while for a four-engine aircraft, the ice inside the primary wake disappears in most cases after vortex breakdown, when the relative humidity is only slightly above ice saturation. In the more rare cases of higher ice-supersaturation the ice in the primary wake survives vortex breakdown and becomes part of the persistent contrail.

"VORTEX DYNAMICS BEHIND CRUISING AIRCRAFT STUDIED BY A GROUND-BASED SCANNING LIDAR AND AIRBORNE IN SITU MEASUREMENTS"

Proceedings SPIE, Vol. 3104, Lidar Atmospheric Monitoring, May 1997, pp. 212-223.

By LIDAR and CCD camera analysis the geometrical evolution of a vortex phase contrail (descent rate 2.7 m/s, vortex separation 47 m, vertical extension 140 m after 77 s) is analyzed. The contrail of a four-engine aircraft is showing a diffuse central wake phenomenon. From coincident in situ measurements all relevant meteorological parameters are characterized. Ambient humidity had been close to ice saturation. From this a non-exhaust formation of ice can be excluded. Also, the mechanism of non-entrainment of exhaust into the vortices is excluded of being responsible for the observed early onset of the central wake (870 m behind aircraft). The central wake onset originates from early detrainment starting after a 3/4 roll-up period of the vortex. Baroclinic and shear forces do not contribute to the detrainment (imaginary Brunt-Vaisala frequency -0.00003 inverse seconds squared, shear -0.01 inverse seconds, bulk Richardson number -0.3). Ambient turbulence had been fully developed with an inertial range and locally isotropic turbulence for wavenumbers 0.004 - 0.1 radians/m. The eddy dissipation rate 7.4 ± 0.00005 meters squared per seconds cubed exceeds the values found over the North Atlantic flight corridor at cruising altitude by a factor of 1000. Turbulence was identified as the dominating detrainment mechanism.

Suthon, P. B.

"INTERACTION OF A VORTEX PAIR WITH A FREE SURFACE: MEASUREMENTS AND COMPUTATIONS"

M.S. Thesis, June 1990, Naval Postgraduate School, Monterey, CA

An investigation of the interaction of two-counter-rotating vortices with a free surface has been undertaken. Experiments were carried out in two water basins and in a long towing tank using measurements, flow visualization, and an infrared camera. The results have shown that all types of vortex pairs over a wide range of Froude Numbers give rise to three-dimensional surface disturbances, known as scars and striations. The striations are a consequence of the short wavelength instability inherent to the vortex pair itself. The scars are transported outward by the vortex pair and are comprised of a constellation of coherent vortical structures (whirls). The experiments have provided sufficient understanding of the physics of the phenomenon and led to the development of a numerical model based on vortex dynamics. This model proved to be capable of explaining the physical processes involved in the evolution of the three-dimensional footprints of the vortex pair.

"ROTOR WAKE STRUCTURE DEVELOPMENT IN LOW REYNOLDS NUMBER CONDITIONS"

AIAA Paper 2018-1830, January 2018, Kissimmee, FL.

Two-component particle image velocimetry (PIV) and performance measurements were used to study tip vortex and wake sheet development on small-scale rotor blades. Unique features of the wake structures have been associated with the aerodynamic inefficiency of rotors operating in low Reynolds number conditions. This work seeks to explore how these features develop over a range of Reynolds numbers by varying the rotational speed and size of the blades. A vortex identification scheme was used to locate downstream tip vortices and characterize their aperiodic wandering behavior for different operational conditions. Development of tip vortices was found to depend significantly on the thrust coefficient making the comparison at different Reynolds numbers challenging. When observed at constant wake age, the wandering motion of the vortices behaved independently of Reynolds number scaling. The normalized standard deviation of the tip vortex wander was found to match well with historically observed trends, but a difference in magnitude suggests aperiodicity depends strongly on blade number instead.

"DEVELOPMENT OF AN INDICIAL MODEL OF HELICOPTER TAIL ROTOR ORTHOGONAL BLADE VORTEX INTERACTION"

AIAA Paper No. 2005-0469, Reno, NV, January 2005

This paper describes the development of an indicial model of orthogonal blade vortex interaction. This type of interaction can be experienced by the tail rotor of a helicopter in certain flight states and is a known noise generator. The work uses a substantial database of experimental measurements, made

at the University of Glasgow during a five-year research program, to validate the indicial model predictions. The blade response during orthogonal blade vortex interaction is strongly dependent on the axial flow within the vortex core. Depending on the vortex core size, however, it is likely that only a small proportion of the chord is subject to this cross-flow at any instant in time. In addition, after the initial vortex cutting, the axial flow stagnates quite rapidly. These features present modeling challenges and this is demonstrated by showing that a simple indicial model driven by a classical vortex core model, in which the blade is represented as a point, significantly over-predicts the blade response. It is also shown that a more sophisticated representation, in which the chordal distribution of cross-flow is accounted for in the indicial model, produces considerably improved predictions. At this stage it becomes apparent that comparison of the model with the experiment is compromised by the three-dimensionality of the measured data. This is explored by numerically simulating the experiment with a vortex wake code. Indicial predictions based on this simulation are found to display many of the essential features of the measured data.

"INVERSE-IMAGING METHOD FOR DETECTION OF A VORTEX IN A CHANNEL"

AIAA Journal, Vol. 41, No. 9, September 2003, pp. 1743-1751

A simple vortex-imaging algorithm using a least-square method is considered. The position and the circulation of a vortex convected in a channel are identified from the time history of pressure at a limited number of points on the wall. The capabilities of the algorithm are demonstrated using two-dimensional direct numerical simulations. A few observer points on one side of the wall are sufficient to detect the position and the circulation of a compact vortex to a reasonable degree of accuracy. An advanced algorithm can even detect two nearby vortices to the same degree of accuracy. Because the algorithm assumes a point vortex solution, the accuracy of the detection deteriorates as the vorticity distribution spreads.

Sviridenko, Y. N.

"APPLICATION OF THE METHOD OF GENERALIZED VORTEX PARTICLES TO SIMULATION OF AN AIRCRAFT VORTEX WAKE"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 24-32

The paper considers the application of the vortex particle method to solve the problem on the formation of the vortex wake behind an aircraft. To obtain the shape of the vortex wake, a two-dimensional unsteady problem on the motion of vortex particles in self-induced flowfield is solved. In this formulation, time plays a role of the third spatial coordinate. The application of the vortex particle method allows one to control during the problem's solution the conservation of the integrals of the system's motion: momentum, angular momentum, and energy of the vortex system. Developed in the work was an algorithm of vortex particles merging and the formation of cores with allowance for the

conservation of the system's first integrals. Examples are presented of the application of the method to several problems on the roll-up of the vortex sheet behind an aircraft. As initial vorticity distributions, analytical relationships and distributions were used, which were obtained in computing flow around a complete aircraft configuration with a panel method.

Sviridenko, Y. N.

"AN INVESTIGATION OF NUMERICAL SCHEMES OF DIFFERENT ACCURACY ORDERS FOR DETERMINATION OF THE VORTEX SHEET'S SHAPE IN THE NEAR WAKE BEHIND AN AIRCRAFT"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 60-65

Addressed in this paper is the problem of modeling the vortex wake behind an aircraft's wing. For computing load distribution and circulation of the vortices shed from the wing's trailing edge a panel method of symmetric singularities is used. Then, the spanwise circulation distribution obtained is used for determining circulation values of individual vortex filaments representing the vortex sheet behind an aircraft. The shape of the vortex sheet is obtained in the core of an iteration process by way of orienting the vortex filaments along local streamlines. The primary objective of this work is an analysis of numerical schemes of different orders of accuracy used in modeling the vortex sheet behind the wing. First-, second-, and third-order accurate schemes were considered. As test configurations, two geometries were considered: an isolated wing and a wing with a part span slotted flap. Effects of the numerical schemes' parameters on the convergence of the iteration process were also analyzed.

Swanson, A. A.

"APPLICATION OF THE SHADOWGRAPH FLOW VISUALIZATION TECHNIQUE TO A FULL-SCALE HELICOPTER ROTOR IN HOVER AND FORWARD FLIGHT"

AIAA Paper No. 1993-2140, August 1993, Monterey, CA.

The wide-field shadowgraph flow visualization technique was used for the first time with a full-scale helicopter rotor. This was accomplished during testing of a Sikorsky S-76 main rotor in the NASA Ames National Full-Scale Aerodynamics Complex 80- by 120-Foot Wind Tunnel. Hover, low-speed forward flight, and descent operating conditions were studied. Preliminary results are very promising with rotor wake tip vortex roll-up, inboard wake vorticity, and flow unsteadiness due to test section recirculation effects in hover. Shadowgraphs of blade/vortex interactions were also acquired. Simultaneous top and side view shadowgraphs of the rotor wake were acquired by a newly developed synchronized digital imaging system. The imaging system proved to be a highly successful tool which made real-time examination of selected regions of the rotor wake possible.

"AIRLOADS MEASUREMENTS FROM A 1/4-SCALE TILTROTOR WIND TUNNEL TEST"

25th European Rotorcraft Forum, Paper No. P1, Rome, Italy, September 1999

Blade airloads data were acquired for a 1/4-scale tiltrotor model tested at the Duits-Nederlandse Windtunnel in The Netherlands. For the first time, detailed airloads measurements were acquired for an isolated tiltrotor model utilizing one hundred and fifty dynamic pressure transducers. Simultaneous acoustic measurements were made in a plane below the model rotor to correlate airloads with tiltrotor noise. Rotor performance data and wake geometry data were also acquired. Samples of the airloads data are presented for several key operating conditions. The effects of rotor thrust and model shaft angle on the blade airloads are discussed. Comparisons are made between blade pressure data, acoustic data and laser light sheet results. Negative lift at the blade tip was found over a wide range of conditions for the tiltrotor in helicopter mode. Single and multiple blade-vortex interactions were measured and correlated with acoustic data and measured wake geometry. The data acquired during this test provide a fundamental set of aeroacoustic measurements that can be used to validate tiltrotor analyses.

Swedish, W. J.

"EVALUATION OF THE POTENTIAL FOR REDUCED LONGITUDINAL SPACING ON FINAL APPROACH"

FAA-EM-79-7, August 1977, Mitre Corp., McLean, VA

Reducing the separations between aircraft can improve airport capacity and decrease delays. This report addresses the feasibility of reduced IFR separation standards on final approach, and identifies the characteristics of the ATC system which affect or are affected by the separation standards. This study has been limited to conditions during which wake turbulence is not a factor. Given this assumption, separation reduction will be most limited by the need to avoid simultaneous runway occupancy by successive arrivals. As the interval between landings decreases, so must the time spent on the runway, if dual runway occupancy is to be avoided. For acceptable performance, the average runway occupancy time must be no more than 50 seconds for a 2.5 nmi minimum separation standard or 37 seconds for a 2.0 nmi standard, with the current ATC system. Various technical improvements now under development may make it possible to operate a 2.0 nmi minimum with average runway occupancies as great as 45-50 seconds. Adequate communications and surveillance for the controller, and enforcement of current ATC procedures are also required for operations with reduced separations. An alternative solution to the runway occupancy problem is to use a pair of close-spaced, dependent (dual-lane) runways and alternate arrivals between them. Reduced separation on approach to a single runway cannot be realized until the wake vortex problem is resolved.

Swedish, W. J.

"THE REQUIREMENTS FOR REDUCED IFR SEPARATIONS ON FINAL APPROACH"

Proceedings 25th Conf., Air Traffic Control Assoc., Arlington, VA, October 1980, pp. 39-43

This paper examines the factors which affect the feasibility of reducing IFR standards from a minimum of 3.0 nmi to 2.5 or 2.0 nmi. For those aircraft pairs which are not restricted by wake vortices,

separation reduction is likely to be limited by the rate at which aircraft must go around to avoid simultaneous runway occupancy. The runway occupancy performance required to avoid an unacceptable increase in the go-around rate is determined. The impacts of ATC improvements such as metering and spacing on the runway occupancy requirements and on the controller's decision-making workload are then presented. Alternating arrivals to close-spaced parallel runways are discussed as one means to avoid the constraints of runway occupancy and, possibly, wake vortices. Lastly, it is proposed that further research on reduced separations should address a single specific airport, to narrow the range of variables and thereby facilitate the identification of problems and solutions.

Swirydczuk, J.

"A VISUALIZATION STUDY OF THE INTERACTION OF A FREE VORTEX WITH THE WAKE BEHIND AN AIRFOIL"

Experiments in Fluids, Vol. 9, Issue 4, June 1990, pp. 181-190.

The two-dimensional interaction of a single vortex with a thin symmetrical airfoil and its vortex wake has been investigated in a low turbulence wind tunnel having velocity of about 2 m/s in the measuring section. The flow Reynolds number based on the airfoil chord length was 4,500. The investigation was carried out using a smoke-wire visualization technique with some support of standard hot-wire measurements. The experiment has proved that under certain conditions the vortex-airfoil-wake interaction leads to the formation of new vortices from the part of the wake positioned closely to the vortex. After the formation, the vortices rotate in the direction opposite to that of the incident vortex.

Swithenbank, J. and Chigier, N. A.

"VORTEX MIXING FOR SUPERSONIC COMBUSTION"

Proceedings 12th Symposium Combustion Inst., 1969, Pittsburg, PA, pp. 1153-1162.

Fundamental concepts of mixing and combustion theory are examined to define an optimum system. By analogy with the familiar parameter 'combustion intensity' a 'mixing intensity' is defined as the total mass of fuel and air mixed per unit time, volume, and density. Mixing intensity is related to the mean kinetic energy of turbulence generated in a mixing system. The efficiency of generation of turbulence is defined by the ratio of the kinetic energy of turbulence generated to the kinetic energy loss from the mean flow. Bluff body mixers are compared with turbulent jet mixers, and turbulence intensities are determined as a function of fuel/air ratio and jet-to-stream-velocity ratio. For turbulence generated by a baffle system or by jets, the mixing intensity is shown to be proportional to the rms velocity and the square root of the number of sources. Substantial increases in mixing rates can be obtained by applying a swirling motion to the central fuel jet. Radial and axial pressure gradients are set up which, in the case of strong swirl, result in reverse flow along the axis. Empirical equations for velocity decay, mass entrainment, and angle of jet expansion are given as functions of the degree of swirl. However, further work is needed on the behavior of these parameters in an external flow field. For the combustion chamber of a scramjet, the degree of swirl imparted to the fuel can be altered readily by varying the

proportion of fuel introduced axially and tangentially into the swirl chamber. The rate of mixing, angle of jet expansion, and the size of internal reverse-flow can all be controlled by variation of the swirl number. With the ability to initiate and remove the reverse-flow region, an optimized combustion system could operate efficiently from low-subsonic to high-supersonic Mach numbers.

Switzer, G. F.

"VALIDATION TESTS OF TASS FOR APPLICATION TO 3-D VORTEX SIMULATIONS"

NASA CR-4756, October 1996, Research Triangle Institute, Research Triangle Park, NC.

Direct analytical solutions can be useful in validating the core formulation of numerical systems. In this document an exact analytical solution to the Navier-Stokes equation is compared to the numerical results from the three-dimensional Terminal Area Simulation System (TASS). This exact solution, of which the derivation is included, is for Beltrami type flow. Direct comparison of TASS to the analytical Beltrami solution is then used in evaluating the accuracy of TASS.

Switzer, G. F.

"TWO-DIMENSIONAL SIMULATION OF WAKE VORTEX INTERACTION FROM MULTIPLE AIRCRAFT"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 212-222

This numerical experiment investigates the significance of wake interaction from multiple aircraft in the region of the runway threshold. The study is chosen from the 1995 Memphis observations of cases 1493 to 1496 because of close spacing and varied strengths of the wake vortex systems. The observed environmental input conditions are of weak crosswinds with a mean value of 1 m/s. The model vortex systems are injected at times and altitudes corresponding to that of the actual aircraft. A video of potential temperature and vorticity shows the dynamics of the vortex interaction. The observations from the video are that vortex movement may change direction from downwind to upwind due to influence of other vortex systems and vortices from different aircraft may couple to produce new vortex systems. However, the interaction from multiple vortex systems did not create significant departures from what was predicted with an isolated vortex system. Finally, the trajectory of altitude and lateral position is compared for Memphis case 1494 and 1496 showing good agreement.

Switzer, G. F. and Proctor, F. H.

"NUMERICAL STUDY OF WAKE VORTEX BEHAVIOR IN TURBULENT DOMAINS WITH AMBIENT STRATIFICATION"

AIAA Paper No. 2000-0755, Reno, NV, January 2000.

A three-dimensional large eddy simulation model is used to investigate the sensitivity of ambient stratification with turbulence on the behavior of aircraft wake vortices. Modeled ambient turbulence

levels range from very weak to moderate, and stratification levels range from strongly stable to unstable. The results of profound significance from this study are: 1) very little sensitivity between vortex linking time and the level of stratification, 2) the mean vortex separation remained nearly constant regardless of stratification and turbulence (at least prior to linking), 3) the wake vortices did not rise regardless of the level of stratification, and 4) for very strong stratification, the vortex stopped descending and quickly dissipated even before vortex linking could occur. These results are supported by experimental data and are contrary to conclusions from other numerical studies that assume laminar flow and/or relatively-low Reynolds numbers.

Switzer, G. F. and Proctor, F. H.

"WAKE VORTEX PREDICTION MODELS FOR DECAY AND TRANSPORT WITHIN STRATIFIED ENVIRONMENTS"

AIAA Paper No. 2002-0945, Reno, NV, January 2002

This paper proposes two simple models to predict vortex transport and decay. The models are determined empirically from results of three-dimensional large eddy simulations, and are applicable to wake vortices out of ground effect and not subjected to environmental winds. The results from the large eddy simulations assume a range of ambient turbulence and stratification levels. The models and the results from the large eddy simulations support the hypothesis that the decay of the vortex hazard is decoupled from its change in descent rate.

Switzer, G. F., Proctor, F. H., Ahmad, N. N. and Duparcmeur, F. M. L.

"AN IMPROVED WAKE VORTEX TRACKING ALGORITHM FOR MULTIPLE AIRCRAFT"

AIAA Paper No. 2010-7993, Toronto, Canada, August 2010.

The accurate tracking of vortex evolution from Large Eddy Simulation (LES) data is a complex and computationally intensive problem. The vortex tracking requires the analysis of very large three-dimensional and time-varying datasets. The complexity of the problem is further compounded by the fact that these vortices are embedded in a background turbulence field, and they may interact with the ground surface. Another level of complication can arise, if vortices from multiple aircrafts are simulated. This paper presents a new technique for post-processing LES data to obtain wake vortex tracks and wake intensities. The new approach isolates vortices by defining 'regions of interest' (ROI) around each vortex and can identify vortex pairs from multiple aircraft. The paper describes the new methodology for tracking wake vortices and presents application of the technique for single and multiple aircraft.

Swol, C. D.

"SIMULATION-BASED ANALYSIS OF WAKE TURBULENCE ENCOUNTERS IN CURRENT FLIGHT OPERATIONS"

MS Thesis, August 2009, Virginia Polytechnic Institute and State University, Blacksburg, VA.

One way to address the need for increased airspace system capacity is to reduce the separation requirements between aircraft in-flight. A key limiting factor to any reduction in separation is wake turbulence. The potential for aircraft to encounter wake turbulence poses a threat to both safety as well as increased efficiency. This research effort seeks to develop a model that can be used to evaluate the potential for wake encounters in today's flight operations, as well as serve as a tool for evaluating future reduced separation scenarios. The wake encounter model (WEM) achieves this goal by integrating results from NASA's TDAWP wake turbulence prediction model with a flight operations model based on radar flight track data. Unique in this model's design, is the ability to evaluate the potential for wake encounters throughout the terminal area versus previous research which has largely been restricted to areas near the runway. Expanding the model's reach provides not only a more thorough analysis of potential wake encounters, but also creates an effective tool for evaluating future reduced separation scenarios. The WEM model was used to evaluate operations at three metropolitan airspaces in the United States: Atlanta, Los Angeles and New York. The results from these model runs indicated that potential wake encounters in today's operations were few. More importantly, the results from the WEM create a baseline for wake turbulence exposure in today's system, by which future scenarios can be compared against as part of any comprehensive reduced separation safety analysis.

Syal, M. and Leishman, J. G.

"MODELING OF BOMBARDMENT EJECTIONS IN THE ROTORCRAFT BROWNOUT PROBLEM"

AIAA Journal, Vol. 51, No. 4, April 2013, pp. 849-866.

The modeling of bombardment ejections, as they affect the uplift of dust particles and the formation of a brownout dust cloud generated by a rotorcraft in ground effect operations, is discussed. Bombardment ejections take place when a previously suspended particle in the flow collides with a sediment bed and ejects many more particles, leaving a crater behind. A model, based in part from research in aeolian sediment transport, was developed to better represent the mechanisms of bombardment-induced particle ejections during rotorcraft brownout conditions. This method was then coupled to a Lagrangian solver for the rotor flow and a Lagrangian particle dynamics simulation. It is shown how bombardment can play a critical role in the uplift and entrainment of smaller-sized particles from the underlying bed below a rotor. In particular, it is shown how the rotor blade tip vortices and/or regions of flow recirculation near the rotor can eject many particles by bombardment, resulting the rapid development of intense dust clouds. The formation of vortex wake bundling ahead of the rotor disk was shown to provide the conditions particularly ripe for the ejection and uplift of large quantities of dust particles by means of bombardment mechanisms.

Sychev, V. V.

"ASYMPTOTIC THEORY OF VORTEX BREAKDOWN"

Rossiyskaya Akademiya Nauk, Izvestia, Mekhanika Zhidkosti I Gaza, ISSN 0568-5281, No. 3, June 1993, pp. 78-90

The phenomenon of vortex breakdown is investigated by using an asymptotic analysis of a system of Navier-Stokes equations at large Reynolds numbers. A criterion for vortex breakdown is formulated; the flow structure is described as a whole and in the direct vicinity of the breakdown point. It is shown that vortex breakdown is a two-stage process, and a description of each stage is provided. [In Russian.]

Sydney, A. J. and Milluzzo, J. I.

"EFFECTS OF VORTEX NUMBER ON THE DEVELOPMENT OF VERTICALLY DOMINATED WAKES"

AIAA Paper 2018-4158, June 2018, Atlanta, GA.

The interaction of vortical flows is prominent throughout wakes created by vehicles that require lifting surfaces (e.g., airplanes, rotorcraft, submarines, etc.). While the interactions between the two vortices produced by a single lifting surface have been investigated, wakes that include a third and fourth vertically displaced vortex of varying strength and direction of rotation are not as well understood. The additional vortices produced by low aspect ratio, perpendicular lifting surfaces will fundamentally change the vortex dynamics and mechanics of vortex breakdown. In fact, the development of the vortices will be affected by several wake characteristics, including vortex direction of rotation, vortex strength, vortex spacing, and number of vortices. The goal of the present work is to provide an understanding of the vortically dominated wake consisting of up to four spatially displaced vortices that are produced by low aspect ratio lifting surfaces. Wake features such as vortex development, vorticity distribution, trajectories, and vortex strength are being investigated. These wake characteristics are studied experimentally using Particle Image Velocimetry (PIV) in the United States Naval Academy (USNA) Closed Circuit Wind Tunnel (CCWT). This paper focuses on the results examining the effects of number of vortices. The results show that number and distribution of vortices significantly affect not only the vortex trajectories but the overall development of the downstream wake.

Szkatula, L., Zouaoui, Z. and Grant, R. J.

"DYNAMICS OF VORTICAL FLOWS INDUCED BY SWEEPED-NOTCHED WINGS IN AIRCRAFT WAKE SIMULATIONS"

J. Aircraft, Vol. 45, No. 2, March-April 2008, pp. 448-460

The motivation behind the present investigations is the alleviation of vortex wake hazard. The influence of wingtip geometry modifications on the near-field wake behind swept-notched wings is investigated up to 24 span-lengths, using computational fluid dynamics, 3-D parallel simulations are run at a chord-based Reynolds-number of $5.34 \times 10,000$. The effectiveness of notched wing modifications on wake properties is assessed via comparison with conventional and original notched wings. Current results are promising: the tip and flap vortices produced by the swept-notched wings remain distinct

and unmerged, unlike circulations and vorticity values that are substantially lower than the original notched wing. Numerical data clearly indicate that such geometrical combinations break apart the concentrated area of streamwise vorticity shed by the wing into three or more less intense regions, significantly reducing the wake strength and induced rolling moment, and affecting the location and merging process of the overall wake system.

Szymendera, C. J.

"COMPUTATIONAL FREE WAKE ANALYSIS OF A HELICOPTER ROTOR"

M.S. Thesis, May 2002, Pennsylvania State University, Philadelphia, PA

One of the most important issues in understanding the behavior of rotorcraft is the accurate prediction of the rotor wake. Understanding the complex nature of the wake is necessary for the prediction of such factors as blade loading acoustics, and vibration. A free wake vortex lattice method was used to predict the wake structure and blade loading for a rotor in arbitrary motion. The blades were modeled as flat plates, and ring vortices were distributed on the surface of the blades. As the blades rotated, vortices were shed into the wake and then moved with a local velocity induced by the effects of the vortices on the blades and in the wake. The wake was allowed to freely deform over time into its natural structure. The lift was determined from the strength of each vortex on the blade, calculated by applying the boundary condition of no flow normal to the blade. On a helicopter in forward flight, the advancing blades usually experience high Mach numbers at the tip. Therefore, it is important to be able to accurately predict the blade loading in compressible flow. The free wake method, though, calculates induced velocities using the Biot-Savart Law, which is only applicable to incompressible flow. A Prandtl-Glauert correction was applied then to the Biot-Savart Law, which allowed the code to accurately model compressible flow. The code was validated using two experimental hover cases, one in which the flow was entirely incompressible and one in which the flow was compressible at the tips, and then extended to handle any arbitrary motion of the helicopter.

"A QUALITATIVE INTRODUCTION TO THE VORTEX-RING-STATE, AUTOROTATION, AND OPTIMAL AUTOROTATION"

NLR-TP-2010-282, May 2011, National Aerospace Laboratory, Amsterdam, The Netherlands.

The main objective of this paper is to provide the reader with some qualitative insight into the areas of Vortex-Ring-State (VRS), autorotation, and optimal autorotation. First this paper summarizes the results of a brief VRS literature survey, where the emphasis has been placed on a qualitative description of the following items: conditions leading to VRS flight, the VRS region, avoiding the VRS, the early symptoms, recovery from VRS, experimental investigations, and VRS modeling. The focus of the paper is subsequently moved towards the autorotation phenomenon, where a review of the following items is given: the maneuver, the height-velocity zones, and factors affecting autorotation. Finally, the paper

concludes by providing a literature survey relative to single-engine helicopter optimal autorotation, and its associated problem formulation as a nonlinear, constrained, optimal control problem.

"ANALYZING COMPLEX WAKE-TERRAIN INTERACTIONS AND ITS IMPLICATIONS ON WIND-FARM PERFORMANCE"

The Science of Making Torque from Wind 2016, published in IOP Journal of Physics: Conference Series Vol. 753, 2016, pp. 032063-1 - 032063-12.

Rotating wind turbine blades generate complex wakes involving vortices (helical tip-vortex, root-vortex etc.). These wakes are regions of high velocity deficits and high turbulence intensities and they tend to degrade the performance of down-stream turbines. Hence, a conservative inter-turbine distance of up-to 10 times turbine diameter (10D) is sometimes used in wind-farm layout (particularly in cases of at terrain). This ensures that wake-effects will not reduce the overall wind-farm performance, but this leads to larger land footprint for establishing a wind-farm. In-case of complex-terrain, within a short distance (say 10D) itself, the nearby terrain can rise in altitude and be high enough to influence the wake dynamics. This wake-terrain interaction can happen either (a) indirectly, through an interaction of wake (both near tip vortex and far wake large-scale vortex) with terrain induced turbulence (especially, smaller eddies generated by small ridges within the terrain) or (b) directly, by obstructing the wake-region partially or fully in its own-path. Hence, enhanced understanding of wake-development due to wake-terrain interaction will help in wind farm design. To this end the current study involves: (1) understanding the numerics for successful simulation of vortices, (2) understanding fundamental vortex-terrain interaction mechanism through studies devoted to interaction of a single vortex with different terrains, (3) relating influence of vortex-terrain interactions to performance of a wind-farm by studying a multi-turbine wind-farm layout under

different terrains. The results on interaction of terrain and vortex has shown a much faster decay of vortex for complex terrain compared to a flatter-terrain. The potential reasons identified explaining the observation are (a) formation of secondary vortices in ow and its interaction with the primary vortex and (b) enhanced vorticity diffusion due to increased terrain-induced turbulence. The implications of this vortex-terrain interactions on wind-farm performance is observed by comparing two LES simulations of a multi-turbine wind-farm layout (in real actual complex terrain and a made-up at terrain scenario) with the observed annual power data at the actual wind-farm. The comparison reveals drop in power production due to terrain and wake effects for flatter terrain case. The insights from this study can serve as a step towards enhancing wake-dissipation through either artificial obstruction or artificial terrain modifications.

"METEOROLOGICAL TOWER REPORT"

Report DOT/VNTSC-FAA-07-06, November 2008, Volpe National Transportation Systems Center, Cambridge, MA.

The Campbell Scientific CSAT3 sonic anemometers are chosen as the turbulence sensor. To qualify CSAT3, wind velocity measurements from the sonic and traditional three-axis propeller anemometers were made on a tower and compared. The data analysis was done in the framework of linear regression on the entire dataset, and special attentions were paid to probe interference, frequency response, sensor thresholds and angular response of the instruments. The result of this in-situ calibration against propellers demonstrated that the sonic anemometer chosen measured the low frequency wind fluctuation correctly, thereby establishing a necessary step in qualifying the sensor for turbulence measurements. To establish a reliable means of monitoring the health of the entire measurement chain as well as identifying periods of questionable data, hourly based linear regression and root-mean-square error statistics are explored. The method demonstrated its ability to efficiently isolate specific erroneous data periods, and examples of this utility were illustrated. The calibration process concluded that the entire measurement system chain involving the sonic anemometers has been qualified, and capable of supporting the meteorological data collection needs of the mid-term phase of the wake turbulence program.

"CURRENT ASSESSMENTS OF BOEING-MESA CFD TOOLS FOR APPLICATIONS TO ROTOR PERFORMANCE/WAKE COMPUTATION IN HOVER FLIGHT"

Proceedings of the ARO Rotorcraft Wake Prediction Basic Research Workshop, March 2009, Georgia Institute of Technology, Atlanta, GA, p. 79.

The presentation will provide detailed information pertaining to the coupling techniques of Vortran-M model developed originally by Professor Brown (University of Glasgow, UK) with the OVERFLOW solver. Under this approach, the main goal is to tightly couple the techniques used in the Vorticity

Transport Model (VTM) with the OVERFLOW solver to enhance the rotor wake capturing for both hover and forward flight regimes, specially BVI flows. As the result, the computational grid needed for a typical rotor aerodynamics performance computation can be kept to an optimum size in comparison to the historically very large grid size needed in the past to obtain a reasonable estimation of rotor, say, Figure-of-Merit values. This approach will also offer a reduction in both memory requirements and CPUs resources. Therefore, it enables a much larger run matrix to be performed over a reasonable time frame. In its final form, it is expected that the newly developed OV_VTM solver will become a more practical CFD tool for preliminary design applications. Further, the past results obtained for 500E aircraft main rotor performance using OVERFLOW solver will be presented to enable a fair assessment of its capabilities in computing the rotor hover performance in the absent of the VTM model.

Tadmor, G.

"OBSERVERS AND FEEDBACK CONTROL FOR A ROTATING VORTEX PAIR"

IEEE Transactions on Control Systems Technology, Vol. 12, No. 1, January 2004, pp. 36-51

An observer is developed to estimate and to feedback-regulate the location of the vorticity centroid and the mutual distance of an interacting, same sign vortex pair. The combination of the crude approximation provided by very low-order vortex models, and high nonlinearity, even at that level, seem to make sensitive gain scheduling and high-order vector field derivatives in geometrical observer design methods, ill suited for the system at hand. This paper explores possibilities for dynamic extraction of needed information directly from leading frequencies and phasors of a sensor signal, using an extended Kalman filter. Intended advantages include simplicity, robustness, and the filtering of unmodeled dynamics.

"EXPERIMENTAL STUDY ON JET BLAST AT LABORATORY SCALE"

Journal of Energy and Power Engineering, Vol. 8, 2014, pp. 1386-1392.

The flow field of 3D (three-dimensional) wall-jet is investigated. Jet-blast from airplane is simulated by wall-jet setup using a sonic nozzle at a laboratory scale. Far field velocity and fluctuation distributions are measured by using X-type hot wire anemometer at four measurement planes. As a result, the flow properties of streamwise component are consistent with data which are obtained in previous researches. The secondary flow is also measured on each measurement plane. Reynolds stresses are analyzed from the fluctuation of the secondary flow. The law of similarity is observed in the dimensionless distributions of mean velocity and fluctuation. However, the distributions in nearer field (i.e., in the measurement plane at $X/D = 100$) tend to disobey the similarity law, especially in the cases of fluctuation. It seems that Jet-blast is not fully developed by reaching $X/D = 100$. The experimental results are compared with computational results which are obtained by CFD (computational fluid dynamics) with SST (shear-stress transport) turbulence model. And it is shown that the results by the simulation with SST turbulence model do not follow the similarity law. The

present database of the Reynolds stresses is critically important for development of a new turbulence model of RANS (Reynolds-averaged Navier-Stokes) simulations on wall-jet.

"ON THE EFFECT OF TIP VORTICES IN LOW-REYNOLDS-NUMBER POST-STALL FLOW CONTROL"

AIAA Paper 2009-0376, Jan. 2009, Orlando, FL

We numerically investigate the application of steady blowing to three-dimensional stalled flows around low-aspect-ratio rectangular flat-plate wings at a Reynolds number of 300. The objective of this study is to explore techniques to enhance lift by directly modifying the dynamics of the wake vortices. Out of various combinations of forcing location and direction considered, we identify two configurations that provide significant lift enhancement. In these cases, actuation appears to strengthen the tip vortices for increased downward induced velocity upon the leading-edge vortices. This in turn moves the low-pressure core directly above the top surface of the wing to greatly enhance lift.

Taira, K., Rowley, C. W., Colonius, T. and Williams, D. R.

"LIFT ENHANCEMENT FOR LOW-ASPECT-RATIO WINGS WITH PERIODIC EXCITATION"

AIAA Journal, Vol. 48, No. 8, August 2010, pp. 1785-1789.

To enhance lift on low-aspect-ratio rectangular flat-plate wings in low-Reynolds-number post stall flows, periodic injection of momentum is considered along the trailing edge in this numerical study. The purpose of actuation is not to reattach the flow but to change the dynamics of the wake vortices such that the resulting lift force is increased. Periodic forcing is observed to be effective in increasing lift for various aspect ratios and angles of attack, achieving a similar lift enhancement attained by steady forcing with less momentum input. Through the investigation on the influence of the actuation frequency, it is also found that there exists a frequency at which the flow locks on to a time-periodic high-lift state.

" STATISTICAL CHARACTERIZATION OF ATMOSPHERIC TURBULENT SCALES IN HOT-DRY AND HOT-HUMID CLIMATES"

AIAA Paper 2019-1869, January 2019, San Diego, CA.

Atmospheric turbulent characteristics were statistically quantified regarding the integral length scale, energy dissipation rate, and turbulence intensity in the surface layer and the troposphere in hot-dry and hot-humid climates at different geographical locations. Meteorological data were collected at each location using ultrasonic anemometers, rawinsonde balloons, and SODARs in collaboration with the NASA Armstrong Flight Research Center and the NASA Langley Research Center during the Sonic Booms

in Atmospheric Turbulence (SonicBAT) projects conducted in 2016 and 2017. Based on various meteorological datasets of wind speed, temperature, and relative humidity, an approach to derive the integral length scale was explored by deriving the energy dissipation rate from those time-series variations. Using two independent methods to derive the energy dissipation rate from autocorrelation analysis and from the fast Fourier transform, unknown coefficients were determined by the best-fitting method so that the two derived values are in agreement. Results indicated that the derived length scales were consistent with those reported in previous studies in their orders. The integral length scales range from 10^0 – 10^3 throughout the surface to the upper air in hot-dry and hot-humid climates. Clear differences were also seen in such turbulent statistics as time cycle depending on relative humidity.

"INTERACTION BETWEEN A COLUMNAR VORTEX AND EXTERNAL TURBULENCE"

In IUTAM Symposium on Elementary Vortices and Coherent Structures: Significance in Turbulence Dynamics, edited by S. Kida, Springer, The Netherlands, 2006, pp. 31-38.

The interaction between a columnar vortex and external turbulence is investigated numerically. As columnar vortices, the Lamb-Oseen vortex and the q-vortex are used. The columnar vortex is immersed in an initially isotropic homogeneous turbulence field, which itself is produced by a direct numerical simulation of decaying turbulence. Using visualization techniques, we investigate the formation of inhomogeneous fine turbulent eddies around the columnar vortex, vortex-core deformations and the dynamical evolution in the passive scalar field.

Takahashi, N., Ishii, H. and Miyazaki, T.

"THE INFLUENCE OF TURBULENCE ON A COLUMNAR VORTEX"

Physics of Fluids, Vol. 17, March 2005, pp. 035105-1-035105-14.

The interaction between a columnar vortex and external turbulence is investigated numerically. A Lamb-Oseen vortex is immersed in an initially isotropic homogeneous turbulence field, which itself is produced numerically by a direct numerical simulation of decaying turbulence. The formation of inhomogeneous fine turbulent eddies around the columnar vortex and the vortex-core deformations are studied in detail by visualizing the flow field. The initially random turbulent eddies (worms) are wrapped around the columnar vortex and become spirals. Statistical quantities, such as two-point-energy spectra and two-point-ensrophy spectra, are evaluated and compared with the theoretical predictions from rapid distortion theory. The axial velocity correlation dominates near the vortex surface, whereas the radial velocity correlation becomes larger where the worms are wrapped. Where the columnar vortex is strong compared with the external turbulence, external velocity disturbances are blocked by the vortex and they cannot penetrate the vortex core directly, whereas various types of vortex waves (Kelvin waves) are excited.

Takahashi, R. K. and McAlister, K. W.

"PRELIMINARY STUDY OF A WING-TIP VORTEX USING LASER VELOCIMETRY"

NASA/TM-88343, AVSCOM TM 86-A-2, January 1987, Aeroflightdynamics Directorate, US Army Aviation Research and Technology Activity, Ames Research Center, Moffett Field, CA

Measurements have been made in the wake of a semi-span NACA 0015 airfoil with emphasis on the region of the wing tip vortex. The spanwise and streamwise velocity components were measured using a two-component laser Doppler velocimeter. The purpose of the study was to initiate the operation of a laser velocimeter system and to perform preliminary wake measurements in preparation for a more extensive study of the structure and near field development of a tip vortex.

Takahashi, T. T. and Delisle, M. R.

"(UN)STABILIZED APPROACH -- AN INTRODUCTION TO DYNAMIC FLIGHT CONDITIONS DURING TAKEOFF AND LANDING CLIMB"

AIAA Paper 2018-3500, June 2018, Atlanta, GA.

In this paper, we introduce the mathematics necessary to simulate unstable flight performance -- that is flight with an inadvertent change in speed, altitude or flight path. Using typical aircraft aerodynamic and propulsion data, representing a configuration like the A320, we perform trade studies to understand the weight and configuration effects of 'out-of-trim' flight during takeoff and landing climb. We found that pilots could lose airspeed quite quickly. During AEO second segment climb, a 1-degree error in trimmed angle-of-attack causes the aircraft to lose -0.6 knots per second. During OEI second segment climb, a 3-degree angle-of-attack trim error causes the aircraft to lose speed at -3.5 knots per second. It would stall after 5 seconds of out-of-trim flight.

"TOPOLOGICAL APPROACH TO MULTISENSORY REALIZATION OF WAKE TURBULENCE"

AIAA Paper 2014-2335, June 2014, Atlanta, GA.

It is important to analyze the process of wake turbulence collapse to avoid serious accidents. In this study, we propose a topology-based multisensory realization method that allows observers to comprehend the behavior of wake turbulence phenomena in more intuitive manner. We propose the use of adaptive visual transfer functions as well as haptic transfer functions with three degrees of freedom to produce three-dimensional forces, which allow the identification of the location and strength of a target vortex. We evaluate the effectiveness of our method using a time-varying three-dimensional wake turbulence dataset.

Tam, K. K.

"A NOTE ON THE FLOW IN A TRAILING VORTEX"

J. Engineering Mathematics, Vol. 7, January 1973, pp. 1-6

It is shown that if the equations governing the fluid motion in a trailing vortex are linearized more than one solution can be constructed. Within the framework of the linear theory, there is no criterion to determine which solution is to be used. To clarify the situation, the Navier-Stokes equations are formulated in parabolic coordinates, and asymptotic solutions are sought which are valid for downstream. It is found that the axial velocity defect decays algebraically.

"EXPERIMENTAL INVESTIGATION OF A TORNADO-LIKE VORTEX USING A PARTICLE IMAGE VELOCIMETRY"

19th International Symposium on the Application of Laser and Imaging Techniques to Fluid Mechanics, July 2018, Lisbon, Portugal.

A simple, small size vortex generator has been constructed to develop the structure and behavior of the various type vortices, where many vortices are unsteady. An artificial tornado-like vortex is described in this paper. The flow field measurements were made by using a particle image velocimetry (PIV) technique. Main hardware components of the PIV system are a dual-pulse laser illumination system with high repetition rate, a high-speed, high-resolution digital camera and a tracer seeding system. The PIV system was installed in a clean room. In the present PIV system, the accuracy of the velocity is dependent the accuracy of the time interval between the 1st and 2nd laser emissions, i.e., the pulse separation. And, it is very important that the timings of the 1st and 2nd laser emissions suit the 1st and 2nd exposure times to the camera sensor, respectively. Scrutinizing the characteristics of the pulse laser and digital camera, the dual-pulse laser PIV with the pulse separation of 1.00 microseconds was established. In the present experiments the Reynolds number Re and the swirl ratio S were used as the experimental parameters. The working fluid is discharged from the decompression chambers of the vortex generator by an electrical blower. By adjusting the blower power supplied, it is possible to change Re between 131 and 895. Also, by adjusting only the location of partition, S can be changed between 1.48 and 14.7. Under the conditions of Re and S , the vortex breakdown phenomenon including two or more axial bubbles and an annulus vortex is observed. For the higher S , a complicated tornado-like vortex including two or three subsidiary vortices is also observed near the partition surface simulated the ground of the earth. The radial distribution of the static pressure on the partition surface for the cases of the various Re and S are measured, and compared with the distributions estimated using the azimuthal velocity profiles in the axial-cross plane at close vicinity of the partition surface, measured by the PIV.

"HIGHLY EFFICIENT UNSTEADY PANEL TIME-MARCHING FREE WAKE FOR AERODYNAMICS OF ROTORCRAFT"

Journal of Aircraft, Vol. 51, No. 1, January-February 2014, pp. 54-61.

A highly efficient unsteady panel time-marching free wake is established to achieve fast and accurate prediction of the unsteady aerodynamics of a helicopter. The unsteady panel method is used to calculate the airload of rotor blades, and the free-wake method is applied to simulate the dynamics of rotor wake. The two methods are tightly coupled by convecting panels to vortex filaments, and the rotor wake is divided into three parts to reduce the computational cost. The first is shed wake indicated by doublet panels. The second is near-wake filaments, which are described by a series of vortex filaments attaching to the shed wake. The third is far-wake filaments connecting to the near-wake filaments. A velocity-field integration technique is adopted to overcome the singularity problem during the interaction of the rotor wake with blades. Helicopter rotors including the Caradonna-Tung and the AH-1G rotors are simulated in hover and forward flight to validate the accuracy and efficiency of the present approach. The predicted blade pressure and load distribution agree well with the measured data and computational-fluid-dynamics results in hover and low-speed forward flight. Compared to computational fluid dynamics and the traditional panel/vortex-rings free-wake method, the present method is more efficient.

Tan, K. J. B., Wang, P. C. and Srigrarom, S.

"LOW-SPEED POST-STALL WING WAKE IMPINGEMENT ON HORIZONTAL STABILIZER OF THE COMMON RESEARCH MODEL"

AIAA Paper 2018-3898, June 2018, Atlanta, GA.

Results from Reynolds-Averaged computational studies of the span-wise flow field between the horizontal stabilizer and wing of the NASA Common Research Model are presented. It is observed early on that the horizontal stabilizer is engulfed at multiple post-stall angles due to the vertical extent of the wings wake. Discernible flow patterns can be observed such as an up wash and a weak inboard wake vortex that originates from the wing inboard section. The up wash can be attributed to the kink in the wing trailing edge, known as the Yehudi break, which also causes the wake to display characteristic features. As the span-wise extent of the break's location is close to the stabilizer, results suggest levels of interaction between this up wash together with the weak inboard wake vortex. A shift in the inboard wake vortex can also be observed between the presented range of angles of attack. To offer insight on this, results follow velocity contours and vector fields of the wake through these two post-stall angles at 14 degrees and 16 degrees, just forward of the horizontal stabilizer and along stream-wise stations between the wing and tail.

"EXPERIMENTAL STUDY OF THE INTERACTION BETWEEN BURGERS VORTEX AND A SOLID PARTICLE USING 2D PIV MEASUREMENT"

Journal of JSEM, Vol. 9, Special Issue, 2009, pp. 17-20.

In recent years, many researchers study on characteristics concentrations of particles in turbulent flows. However, it is difficult to observe experimentally interaction between the particles and turbulent vortices because of strong nonlinearity of turbulence. In the present study, we focus on the elementary step of an interaction between single vortex tube and a solid particle in a solid-liquid two-phase flow. Burger's vortex is chosen as single vortex tube. Burger's vortex is the simplest model of turbulence.

Tanaka, Y., Tsuji, T. and Tanaka, T.

"INTERACTION BETWEEN A BURGERS VORTEX AND WAKE VORTEX STRUCTURE GENERATED BY A SETTLING PARTICLE"

Journal of JSEM, Vol. 9, Special Issue, 2009, pp. 1-6.

In the present study, interactions between a single particle and a single Burgers vortex are observed by using 2D-PIV measurements as elementary interactions for modeling particle-laden turbulent flows. We focus on the interaction between a Burgers vortex and wake structure generated by a settling particle. It is found that the interaction between the vortices shed from the particle and the Burgers vortex induces the large fluctuation in the circulation of the vortex. Moreover, fragmentation and emergence of the Burger's vortex core are observed.

Tang, C. C. K., Leung, R. C. K. and Ko, N. W. M.

"INTERACTION OF TWO PERTURBED VORTEX RINGS WITH PHASE DIFFERENCE"

13th Australasian Fluid Mechanics Conference, December 1998, Monash University, Melbourne, Australia.

A numerical study of interaction of two coaxial weakly perturbed vortex rings with phase difference 90 degrees and without 0 degrees is reported. The model of the vortex rings is generated by thin vortex filament and their evolution is solved by means of three-dimensional vortex blob method. Phase difference of the two vortex rings is an important parameter to their evolution and the slip through process.

Tang, S. and Ko, N. W. M.

"SOUND SOURCES IN THE INTERACTIONS OF TWO INVISCID TWO-DIMENSIONAL VORTEX PAIRS"

J. Fluid Mechanics, Vol. 419, 2000, pp. 171-201

The sources of sound during the interactions of two identical two-dimensional inviscid vortex pairs are investigated numerically by using the vortex sound theory and the method of contour dynamics. The sound sources are identified and then separated into two independent components, which represent the contributions from the vortex centroid dynamics and the microscopic vortex core dynamics. Results show that the sound generation mechanism of the latter is independent of the type

of vortex pair interaction, while that of the former depends on the jerks, accelerations, and vortex forces on the vortex pairs. The power developed by the vortex forces is found to be important in the generation of sound when the vortex cores are severely deformed and their centroids are close to each other. The isolated source terms also explain the appearance of wavy oscillations on the time variations of the sound source strengths in the vortex ring and the two-dimensional vortex interaction systems.

Tang, S. K. and Ko, N. W. M.

"BASIC SOUND GENERATION MECHANISMS IN INVISCID VORTEX INTERACTIONS AT LOW MACH NUMBER"

Journal of Sound and Vibration, Vol. 262, Issue 1, April 2003, pp. 87-115

The sound generation mechanisms during finite core vortex interactions at low Mach number are investigated in the present study. The theoretical deductions show clearly that the basic sound generation mechanisms are associated with the vortex core deformation and the vorticity centroid dynamics, independent of the vortex system. Such deductions are substantiated by numerical experiments with the interactions of two-dimensional vortices, vortex pairs and vortex rings. Detailed discussions on the similarities and differences between the sound generation processes of the two-dimensional and axisymmetric vortex systems are given. The relative importance of the two sound generation mechanisms in these vortex systems, their characteristics, and interactions, which are hardly found in existing literature, are also examined. The present findings have also generalized and substantiated the previous results of the authors on the topic.

Tang, S. K. and Ko, N. W. M.

"ON SOUND GENERATED FROM THE INTERACTION OF TWO INVISCID COAXIAL VORTEX RINGS MOVING IN THE SAME DIRECTION"

Journal of Sound and Vibration, Vol. 187, Issue 2, October 1995, pp. 287-310

Sound generation due to the interaction between two inviscid coaxial vortex rings moving along a common axis in the same direction is investigated numerically by using the method of contour dynamics and the far field equations. The results show the occurrence of the slip-through process, incomplete slip-through, coalescence and partial coalescence. They also illustrate that the radial accelerations and the rate of change of the axial accelerations of the vorticity centroids of the vortex rings are important in the generation of sound during the interaction. The axial separation of the vorticity centroids of the vortex rings and the third time derivative of the vortex impulse are found to be important only in the case of partial coalescence. As the vortex ring interactions considered in the present study are found in axisymmetric jets, the present results suggest that the jerk and acceleration of flow structures may be related to the generation of jet noise at low Mach number.

Tang, S. K. and Ko, N. W. M.

"SOUND GENERATION BY A VORTEX RING COLLISION"

Journal of Acoustical Society of America, Vol. 98, No. 6, December 1995, pp. 3418-3427.

A collision between two vortex rings and its sound generation is studied numerically using the contour dynamics method. Results suggest that the radial acceleration and the rate of change of the axial acceleration of the vortex rings are the more important dynamic parameters for sound generation during the interaction. The former is important at or near the pass-through instant when the vortex rings are coplanar and are of unequal strength. The latter, being important in the sound generation during a head-on collision before the vortex ring cores are very close to each other, especially when the rings are thin, is also important in sound generation by an unequal strength vortex ring collision after the pass through when the vortex cores are separated by a distance so that the mutual induction strength does not result in significant change of the impulse of the stronger ring.

Tangler, J. L.

"VORTEX DIFFUSION AND DISSIPATION"

US Patent 4,046,336, September 1977

Vortex diffusion means for an aircraft having lift structure rooted therein that extends outboard to a structure tip from which a discrete tip vortex develops when said tip is propelled through the air. A sub-wing extends from the tip of the lift structure. Preferably, the sub-wing has its leading edge or upper lead surface tangent to the upper lead surface of the lift structure and a span axis parallel to the span axis of the lift structure. The sub-wing's chord is sized to equally divide the bound vorticity shed at the tip of the lift structure so that twin discrete vortices are generated. One discrete vortex forms along the streamwise edge of the lift structure's tip and the other forms along the streamwise edge of the sub-wing's tip. The distance between the two vortices is in the range of from 25 to 50% of the local chord of the lift structure.

Tangler, J. L.

"EXPERIMENTAL INVESTIGATION OF THE SUBWING TIP AND ITS VORTEX STRUCTURE"

NASA CR-3058, November 1978, Bell Helicopter Textron, Fort Worth, TX.

Vortex diffusion resulting from the interaction of twin vortices generated by a 'subwing' tip was experimentally investigated. The purpose of the investigation was to provide a better understanding of the subwing's vortex structure relative to a square tip for several angle of attack and yaw angles. This comparison included subwings of various chord size and airfoil thickness. Flow visualization, together with performance and wake measurements, provided a comparison between the square tip and subwing tips during both a semi-span wind-tunnel test and a small-scale rotor hover-stand test. Through these studies, the subwing chord to main chord ratio which generated twin vortices was found to be 0.20. When the tip shed circulation was divided into twin vortices, the maximum circumferential

velocity in each vortex was lowered relative to a comparable square tip. The influence of yawed flow on the operation of the subwing was not a significant factor for yaw angles corresponding to those that occur on a helicopter rotor blade during partial power descent. Comparisons of subwings having different airfoil thicknesses showed this parameter to be unimportant. No noticeable difference in performance between the subwing and square tip could be detected at medium rotor thrust coefficients.

Tank, W. G.

"WAKE DETECTION WITH A VHF CW BISTATIC RADAR"

AIAA Paper No. 1997-0061, Reno, NV, January 1997

A proof-of-concept field test to demonstrate airplane wake detection with a VHF radar is described. The radar used for the test is a 10 watt, cw bistatic radar that operates at a frequency of 148.4 MHz with a system sensitivity of -134 dBm. No attempt was made to optimize system hardware or signal processing for wake detection; the radar was simply used 'as is' for the demonstration tests. These were conducted at the National Oceanic and Atmospheric Administration (NOAA) Research Facility at Idaho Falls, Idaho. For them, the radar antennas were positioned, and elevation angles adjusted, such that the radar common volume -- the intersection of the 3dB transmit and receive antenna patterns -- was normal to and at the altitude of the flight track of a B727 airplane performing flybys past an instrument tower used to study wake wind speeds and internal structures. There were three definite and two probable wake detections out of a total of 15 flybys that offered the possibility for wake detection. Radar returns from wakes are due to backscattering as a coherent interaction between the radar signal and half-wavelength fluctuations in radio refractive index caused by turbulence inside the wake volume. The probability density of the magnitude of such fluctuations indicates that the one-in-three wake detection success rate at Idaho Falls was as expected, considering the 'as is' system sensitivity of the test radar. This now suggests an intriguing possibility. Every airport with Instrument Landing System (ILS) capabilities utilizes inner, middle, and outer VHF fan beam markers at increasing distance from runway thresholds, to assist approaching airplanes in maintaining the standard 3.5 deg. approach glide slope. These marker beacons could serve as the transmitters for bistatic radars to warn airplanes in the landing/takeoff cycle of residual wakes in airport approach zones.

"THE DISSIPATIVE EFFECTS OF JET AIRCRAFT WAKES ON FOG"

Bulletin of the American Meteorological Society, Vol. 53, No. 11, November 1972, p. 115

An investigation was made of the imprint in fog of the landing approach of a Boeing 747 aircraft wake. It was found that the individual vortices increase in size downstream until they meet at the vertical plane of symmetry, at which point they interact, with annihilation gradually taking place. A typical observed lifetime of the visible wake is 2-5 min.

"A FLOW VISUALIZATION STUDY ON FEEDBACK CONTROL OF VORTEX SHEDDING FROM A CIRCULAR CYLINDER"

J. Fluids and Structures, Vol. 10, Issue 8, Nov. 1996, pp. 965-970

This note presents flow visualization results to show the response of wake flows behind a cylinder to the feedback suppression and excitation. The experiments were conducted in a water channel and the feedback perturbations were introduced into the wake by oscillating the cylinder transverse to the oncoming flow. The visualization photographs directly illustrated the wake flows under the feedback suppression and excitation at Reynolds numbers up to 25 percent above the natural onset Reynolds number for vortex shedding.

Tardif, R. and Zwack, P.

"PROVIDING METEOROLOGICAL SUPPORT TO THE AIRCRAFT VORTEX SPACING SYSTEM USING THE COBEL ONE-DIMENSIONAL MODEL"

Project Report, September 1998, University of Quebec, Montreal, Canada.

Efforts are currently underway to develop the Aircraft Vortex Spacing System to dynamically determine the required aircraft spacing in the approach zone of busy airports according to aircraft type and meteorological conditions. The role of an important sub-system of the AVOSS is to provide timely and accurate meteorological input to wake vortex transport/decay algorithms. A coupled 3D/1D numerical prediction system is proposed. An operational 3D mesoscale model is used to provide input to a high-resolution boundary layer model to produce detailed forecasts of the lower atmospheric vertical structure. The COBEL column model, developed in France at the Paul Sabatier University, is used for that purpose. A real-time version of the system, incorporating data assimilation capabilities, was developed and tested during the AVOSS field deployment at the Dallas-Fort Worth airport in the fall of 1997. Preliminary results from the deployment show that high-resolution diagnosed and predicted profiles of boundary layer temperature and wind agree well with the available observations. Computed values of turbulence kinetic energy also agree well with the observations during the night, but COBEL seem to provide values that are too large during sunny days. This issue remains to be investigated further. Refinement of the data assimilation method currently implemented in the column model is also recommended.

"AIRBORNE LIDAR WIND DETECTION AT 2 MICRONS"

Proceedings SPIE, Vol. 2464, Air Traffic Control Technologies, June 1995, pp. 109-115.

NASA and the FAA have expressed interest in laser radar's capabilities to detect wind profiles at altitude. Several programs have been addressing the technical feasibility and utility of laser radar atmospheric backscatter data to determine wind profiles and wind hazards for aircraft guidance and

navigation. In addition, the U.S. Air Force is investigating the use of airborne lidar to achieve precision air drop capability, and to increase the accuracy of the AC-130 gunship and the B-52 bomber by measuring the wind field from the aircraft to the ground. There are emerging capabilities of airborne laser radar to measure wind velocities and detect turbulence and other atmospheric disturbances out in front of an aircraft in real time. The measurement of these parameters can significantly increase fuel efficiency, flight safety, airframe lifetime, and terminal area capacity for new and existing aircraft. This is achieved through wind velocity detection, turbulence avoidance, active control utilization to alleviate gust loading, and detection of wingtip wake vortices produced by landing aircraft. This paper presents the first flight test results of an all solid-state 2-micron laser radar system measuring the wind field profile 1 to 2 km in front of an aircraft in real time. We find 0.7-m/s wind measurement accuracy for the system which is configured in a rugged, light weight, high-performance ARINC package.

"COHERENT LIDAR AIRBORNE WINDSHEAR SENSOR: PERFORMANCE EVALUATION"

Applied Optics, Vol. 30, No. 15, May 1991, pp. 2013-2026.

National attention has focused on the critical problem of detecting and avoiding windshear since the crash on 2 Aug. 1985 of a Lockheed L-1011 at Dallas/Fort Worth International Airport. As part of the NASA/FAA National Integrated Windshear Program, we have defined a measurable windshear hazard index that can be remotely sensed from an aircraft, to give the pilot information about the wind conditions he will experience at some later time if he continues along the present flight path. A technology analysis and end-to-end performance simulation measuring signal-to-noise ratios and resulting wind velocity errors for competing coherent laser radar (lidar) systems have been carried out. The results show that a Ho:YAG lidar at a wavelength of 2.1 microns and a CO₂ lidar at 10.6 microns can give the pilot information about the line-of-sight component of a windshear threat from his present position to a region extending 2-4 km in front of the aircraft. This constitutes a warning time of 20-40 s, even in conditions of moderately heavy precipitation. Using these results, a Coherent Lidar Airborne Shear Sensor (CLASS) that uses a Q-switched CO₂ laser at 10.6 microns is being designed and developed for flight evaluation in the fall of 1991.

Tartaglione, J. J.

"AN ANALYSIS OF THE AIRCRAFT TRAILING VORTEX SYSTEM"

AIAA Paper No. 1978-0312, Washington, DC, February 1978

A review of the aircraft trailing vortex system is presented. Particularly the transport and decay of the vortex systems and its potential hazard to other aircraft is discussed. In addition, an analysis of trailing vortex decay data is presented. Although various theories have been proposed for predicting the decay of a vortex system, most of them have failed when compared with flight test data. Recently J. D. Iversen proposed a method for correlating trailing vortex data based upon a variable eddy viscosity vortex decay model. His model was applied to previously uncorrelated flight test data. The data used,

which was obtained by the National Aviation Facilities Experimental Center (NAFEC), includes measurements of the vortex structure behind nearly all the large commercial jet transports. The correlation technique was found to successfully collapse the trailing vortex data to a single curve. Thus, Iversen's assumption of variable eddy viscosity is the key factor that enables a universal collapse of both the model and flight test data.

Tatnall, C. R.

"A PROPOSED METHODOLOGY FOR DETERMINING WAKE-VORTEX IMPOSED AIRCRAFT SEPARATION CONSTRAINTS"

M.S. Thesis, August 1995, George Washington Univ., Washington, DC.

The main objective of this thesis is to develop a rational approach to determining the aircraft spacings required to comply with a prescribed limit on the amount of roll-upset due to wake-vortex interactions. This is done by analytically modeling the vortex-induced flow field, and using a theoretical approach to obtain expressions for the vortex-induced lift and roll moment on a following aircraft. Transient dynamic models are developed to determine the maximum potential vortex-induced roll upset, employing a derived conservative vortex decay law. The models are applied in order to find time-separations required for each aircraft pair in a given representative aircraft population, so that a prescribed upset limit is not exceeded. Next, a method for quantifying the total system capacity loss (lost time) due to partitioning the aircraft into classes and assigning conservative spacings for the class-pair combinations is derived, so that the class-based spacing system which maximizes airport capacity can be determined.

Tatnall, C. R.

"AN INVESTIGATION OF CANDIDATE SENSOR-OBSERVABLE WAKE VORTEX STRENGTH PARAMETERS FOR THE NASA AIRCRAFT VORTEX SPACING SYSTEM (AVOSS)"

NASA CR-1998-206933, March 1998, George Washington University, Joint Institute for Advancement of Flight Sciences, Hampton, VA

The counter-rotating pair of wake vortices shed by flying aircraft can pose a threat to ensuing aircraft, particularly on landing approach. To allow adequate time for the vortices to disperse/decay, landing aircraft are required to maintain certain fixed separation distances. The Aircraft Vortex Spacing System (AVOSS), under development at NASA, is designed to prescribe safe aircraft landing approach separation distances appropriate to the ambient weather conditions. A key component of the AVOSS is a ground sensor, to ensure safety by making wake observations to verify predicted behavior. This task requires knowledge of a flowfield strength metric which gauges the severity of disturbance an encountering aircraft could potentially experience. Several proposed strength metric concepts are defined and evaluated for various combinations of metric parameters and sensor line-of-sight elevation angles. Representative populations of generating and following aircraft types are selected, and their associated wake flowfields are modeled using various wake geometry definitions. Strength metric

candidates are then rated and compared based on the correspondence of their computed values to associated aircraft response values, using basic statistical analyses.

Tauszig, L.

"NUMERICAL DETECTION AND CHARACTERIZATION OF BLADE VORTEX INTERACTIONS USING FREE WAKE ANALYSIS"

M.S. Thesis, August 1998, Pennsylvania State University, Philadelphia, PA

A free wake methodology has been implemented to predict the location of the tip vortices released by a helicopter rotor. In conjunction with the free wake model, a method to detect Blade Vortex Interaction (BVI) - called the spherical detection criteria - has been developed. From the geometry of the wake and the location of the blade, this criterion detects the occurrence of BVI and allows a detailed characterization of the interaction, including parameters such as angle of interaction and wake age. Validation of the free wake methodology has been achieved through comparison of time-averaged inflow and wake geometry with experimental data. The predicted blade vortex interactions have also been validated against acoustical measurements. The current methodology correlates well with experimental data and captures the trend of the change in BVI location as shaft angle and advance ratio are changed. The implementation of this model is computationally efficient and will be valuable to the study of both passive and active rotor designs for alleviation of blade vortex interaction.

"LIFT MODULATION WITH LATERAL WING-TIP BLOWING"

J. Aircraft, Vol. 25, No. 4, April 1988, pp. 311-316

The utilization of a thin jet of air exiting in the spanwise direction from a slot at each of the tips of a straight wing has been investigated as a means of generating weak lift modulation. A theory showing the analytical relationship between blowing intensity and aerodynamic forces was developed and its results were compared against experiments. It was found that the lift gain due to lateral blowing depends on the $2/3$ power of the jet blowing intensity.

Taylor, L. W. and McLaughlin, M. D.

"A MODIFIED NEWTON-RAPHSON ANALYSIS OF FLIGHT MEASUREMENTS OF THE TRAILING VORTICES OF A HEAVY JET TRANSPORT"

NASA TN D-7404, August 1974, NASA Langley Research Center, Langley Station, VA

A modified Newton-Raphson method has been used to determine the parameters in equations describing the vortex flow to obtain a best match with flight measurements of the flow behind the C-5A airplane. The flight measurements were made using a specially instrumented T-33 airplane which passed as closely as possible to the centers of the trailing vortices at several distances behind the C-5A

airplane. The flight measurements were transformed to flow velocity relative to an inertial frame of reference. The assumed form of the flow consisted of the superposition of two counterrotating, finite core vortices. The positions of the vortex centers, their total circulation, the effective eddy viscosity and measurement bias were the parameters adjusted. Previous analyses of the experimental data have used graphical techniques to determine vortex-flow parameters. The modified Newton-Raphson method of analysis eliminates considerable manual labor and yields more consistent vortex-flow parameters.

Taylor, R. M.

"AERODYNAMIC SURFACE TIP VORTEX ATTENUATION SYSTEM"

US Patent 5,158,251, October 1992.

Apparatus and method for attenuating fluid foil tip vortices, featuring a 'Coanda tip' and a 'Coanda curtain.' The fluid foil tip has a Coanda surface and means for discharging compressed fluid adjacent thereto; a resultant fluid barrier is formed generally chordwise and perpendicular to the fluid foil plane and tangential to the fluid foil tip upon Coanda entrainment and deflection of the discharged compressed fluid. The fluid barrier prevents crossflow from the higher-pressure fluid region to the lower pressure fluid region, the fluid regions being separated by the fluid foil when moving relatively through a fluid, the fluid barrier thereby stemming tip vortex generation at its source.

"FLIGHT TEST INVESTIGATION OF ROTORCRAFT WAKE VORTICES IN FORWARD FLIGHT"

DOT/FAA/CT-94/117, February 1996, FAA Technical Center, Atlantic City Airport, NJ

This report presents the results of helicopter flight tests and wake vortex measurements which were designed to provide data necessary for the assessment of hazards to following aircraft. The tests described in this report were conducted using small probe airplanes and a Laser Doppler Velocimeter for wake vortex measurements during forward-flight helicopter operations. Four helicopters, having weights ranging from 7,600 to 70,000 pounds, were used in the tests as the wake vortex generating aircraft. Wake vortex strength and decay characteristics as determined from the flight test results are discussed. In the absence of encounter measurements for the case of hover flight, it is recommended that small airplanes, at the same altitude and downwind of a hovering helicopter, maintain at least 500 feet of separation.

"MODELLING AND SIMULATION STUDIES OF THE RUNWAY CAPACITY OF CHANGI AIRPORT"

The Aeronautical Journal, Vol. 122, No. 1253, July 2018, pp, 1022-1037.

International air travel becomes more affordable over the years with the introduction of low-cost carriers (LCCs) in Asia Pacific. As a result, this region has seen an exponential growth in its air traffic movements. Asia Pacific has been recording faster air traffic growths, compared to regions such as Europe and North America. This is largely due to emerging markets and developing economies in Asia Pacific. This is especially seen in the demand and supply for LCCs in Southeast Asia. Changi Airport, being one of the major air traffic hubs in Asia, is facing overloaded traffic in the future due to this exponential growth. Although a new runway and new terminals are proposed and in the process of being built, the coming years could still bring a huge challenge to the airport, if its existing capacity is not maximized to cope with the increasing traffic demand. Hence, we studied the impacts of increasing LCC flights on the airport runway capacity. Different runway operational scenarios were simulated to investigate their advantages and disadvantages. It is found that the segregated parallel arrival-departure runway operation is beneficial. By simulating various operational scenarios with the projected increasing flight movements, it is found that a dedicated runway to medium-sized arrival aircraft may be more beneficial, as this would possibly enable it to have a higher runway capacity.

Tendero, J. A., Paredes, P., Roura, M., Govindarajan, R. and Theofilis, V.

"BIGLOBAL AND POINT VORTEX METHODS FOR THE INSTABILITY ANALYSIS OF WAKES"

AIAA Paper 2013-2820, June 2013, San Diego, CA.

To better understand destruction mechanisms of wake-vortices behind aircraft, the point vortex method for stability (inviscid) used by Crow is here compared with viscous model global stability analysis of the linearized Navier-Stokes equations acting on a two-dimensional basic flow, i.e. BiGlobal stability analysis. The fact that the BiGlobal method is viscous, and uses a finite area vortex model, gives rise to results somewhat different from the point vortex model. It adds more parameters to the problem, but is more realistic.

Tendero, J. A., Theofilis, V., Roura, M. and Govindarajan, R.

"ON VORTEX FILAMENT METHODS FOR LINEAR INSTABILITY ANALYSIS OF AIRCRAFT WAKES"

Aerospace Science and Technology, Vol. 44, 2015, pp. 51-68.

Linear stability analysis of vortical systems is discussed in a systematic manner using the classic inviscid vortex filament method. Well-known results are recovered as special cases of a unified linearization procedure. The symmetries of the vortex systems analyzed are exploited to obtain an analytical picture of different classes of growing and decaying eigenmodes. Finally, comparisons with viscous global linear theory reveal the limits of applicability of the vortex filament method for the instability analysis of realistic vortex systems.

Teo, R. and Tomlin, C. J.

"COMPUTING PROVABLY SAFE AIRCRAFT TO AIRCRAFT SPACING FOR CLOSELY SPACED PARALLEL APPROACHES"

Proceedings of the Digital Avionics Systems Conference, Philadelphia, PA, October 2000

One of the requirements for closely spaced parallel approaches (CSPA) is the proof that possible blunders of the adjacent aircraft do not lead to a loss of separation. Our paper addresses this problem by considering the blunderer as a 'pursuer' and the other aircraft as an 'evader'. We then use differential game methodology to find the safe region in which it is guaranteed that blunders do not lead to a loss of separation. We apply the technique to a practical case to show how the minimum safe longitudinal separation (MSLS) can be computed. Finally, simulation is performed to show how the technique can be used as an alerting algorithm for onboard on-line computation.

Teo, R. and Tomlin, C. J.

"COMPUTING DANGER ZONES FOR PROVABLY SAFE CLOSELY SPACED PARALLEL APPROACHES"

Journal of Guidance, Control, and Dynamics, Vol. 26, No. 3, May-June 2003, pp. 434-442.

The use of a differential game and an optimal control theoretic approach for computing danger zones for this problem is new. The space outside the danger zone is deemed provably safe, implying that during blunder situations emergency evasive maneuvers starting from outside the zone are guaranteed to be safe within limits on the maneuver severity of both the blundering and evading aircraft. In addition, these zones can be computed online in real time with knowledge of the current state. The algorithm also provides the minimum runway spacings for independent approaches and the minimum longitudinal separation between aircraft for dependent approaches. The algorithm for computing the zones has been validated with over one million simulation runs, where the adjacent aircraft performed various blunder trajectories. The validation shows that the algorithm could successfully alert and prevent collisions in 100 percent of the simulations run.

Teo, R., Jang, J. S. and Tomlin, C. J.

"FLIGHT DEMONSTRATION OF PROVABLY SAFE CLOSELY SPACED PARALLEL APPROACHES"

AIAA Paper 2005-6197, August 2005, San Francisco, CA.

In poor visibility, paired approaches to airports with closely spaced parallel runways are not permitted, thus halving the arrival rate. With Global Positioning System technology, datalinks, and cockpit displays, this could be averted. One important problem is ensuring safety during a blundered approach by one aircraft. This is on-going research. A danger zone around the blunderer is required. If the correct danger zone could be calculated, then it would be possible to get 100 percent of clear-day capacity in poor-visibility days even on 750-foot runways. The danger zones vary significantly (during an approach) and calculating them in real time would be very significant. Approximations (e.g. outer bounds) are not good enough. This paper presents a way to calculate these danger zones in real time for a very broad class of blunder trajectories. The approach in this paper differs from others in that it

guarantees safety for any possible blunder trajectory if the speeds and turn rates of the blunder are within certain bounds. In addition, the approach considers all emergency evasive maneuvers whose speeds and turn rates are within certain bounds about a nominal emergency evasive maneuver. For all combinations of these blunder and evasive maneuver trajectories, it guarantees that the evasive maneuver is safe. For more than 1 million simulation runs, the algorithm shows a 100 percent rate of Successful Alerts and a 0 percent rate of Collisions Given an Alert. The evaluation of the proposed scheme was demonstrated with two different types of test platforms, the Stanford DragonFly unmanned aerial vehicles and the Boeing testbed of F-15 and T-33 aircraft. The experiment involved two aircraft, where one aircraft is assigned as pursuer and the other as evader. The algorithm proved the guaranteed safety (maintaining a minimum separation distance) for every single flight test performed, and demonstrated that it can run it in real-time.

Teske, M. E.

"COMPUTER PROGRAM FOR PREDICTION OF THE DEPOSITION OF MATERIAL RELEASED FROM FIXED AND ROTARY WING AIRCRAFT"

NASA CR-3780, March 1984, Continuum Dynamics, Princeton, NJ

This is a user manual for the computer code 'AGDISP' (AGricultural DISPersal) which has been developed to predict the deposition of material released from fixed and rotary wing aircraft in a single-pass, computationally efficient manner. The formulation of the code is novel in that the mean particle trajectory and the variance about the mean resulting from turbulent fluid fluctuations are simultaneously predicted. The code presently includes the capability of assessing the influence of neutral atmospheric conditions, inviscid wake vortices, particle evaporation, plant canopy and terrain on the deposition pattern.

Teske, M. E. and Thistle, H. W.

"ATMOSPHERIC STABILITY EFFECTS IN AIRCRAFT NEAR-WAKE MODELING"

AIAA Journal, Vol. 40, No. 7, 2002, pp. 1467-1469

The note illustrates that atmospheric stability effects in the aircraft near-wake can be simulated using the UNIWAKE code. The vortex decay rates under various atmospheric stability conditions computed from UNIWAKE are then integrated into AGDISP and AgDRIFT codes, developed by the Departments of Agriculture Forest Service and the Environmental Protection Agency, for studying dispersion of sprays behind aircraft.

Teske, M. E. and Thistle, H. W.

"RELEASE HEIGHT AND FAR-FIELD LIMITS OF LAGRANGIAN AERIAL SPRAY MODELS"

Transactions of the ASAE, Vol. 46 (4), 2003, pp. 977-983.

The Lagrangian equation solver in the aerial application models AGDISP (version 8.08) and AgDRIFT (version 2.0.08) can predict deposition from high release heights and to distances far downwind, beyond where these models have been validated. The appropriateness and applicability of model extension to higher release heights and to farther downwind distances are examined by examining model inputs, model uncertainty, and data variability as these limits are approached. The models appear appropriate if the aircraft vortices influence the behavior of the released spray material. While the models have been validated to release heights of 10 m and downwind distances of 800 m, release height extension appears warranted, whereas downwind deposition extension does not. However, relative deposition effects may be examined further downwind.

Teske, M. E. and Thistle, H. W.

"A SIMULATION OF RELEASE HEIGHT AND WIND SPEED EFFECTS FOR DRIFT MINIMIZATION"

Transactions of the ASAE, Vol. 42 (3), 1999, pp. 583-591.

The near-wake portion of the USDA Forest Service aerial application prediction model FSCBG is applied to a sensitivity study of the length of the spray boom relative to the length of the aircraft wingspan or helicopter rotor diameter. Building on extensive previous work, this study examines the predictions by the near-wake Lagrangian trajectory model of swath width, mean deposition within the spray block, and drift fraction downwind of the edge of the field. Ten aircraft and four BCPC droplet size distributions are used to simulate a typical agricultural application scenario. Findings from this study demonstrate the effects of varying boom length on downwind drift, the reduction of downwind drift with larger droplets, and the inherent ability of certain aircraft type to reduce downwind drift more easily than others. Model results indicate that a broad range of boom length (between 60 and 100% of aircraft wingspan or helicopter rotor diameter) recovers approximately the same levels of downwind drift, decreasing levels of mean deposition within the spray block, and increasing swath width between flight lines. The suggestion that boom length should be less than 75% of wingspan or rotor diameter is perhaps based more on the anticipated position of the rolled-up vortices than on solid experimental evidence.

Teske, M. E., Bilanin, A. J. and Barry, J. W.

"DECAY OF AIRCRAFT VORTICES NEAR THE GROUND"

AIAA Journal, Vol. 31, No. 8, August 1993, pp. 1531-1533

Between 1985 and 1991, a series of aircraft flybys above tower grids instrumented with propeller anemometers produced a large data base on vortex motion near the ground. Anemometer tower grids recorded the ambient vertical time histories as various aircraft repeatedly traversed normal to the grid. These digitized velocity traces produced an aircraft wake signature that could be used to infer the strength and lateral and vertical motion of the aircraft vortex pairs generating the traces. A vortex decay coefficient as a function of initial vortex circulation strength, ambient turbulence level, and aircraft semispan was obtained.

Teske, M. E., Birchfield, N. B. and Bird, S. L.

"DEVELOPMENT AND VALIDATION OF A MECHANISTIC GROUND SPRAYER MODEL"

ASAE/CSAE Paper No. 040136, Ottawa, Canada, August 2004

This paper summarizes the development of a mechanistic ground sprayer model, built upon the same analytical Lagrangian approach used in the aerial spray model AGDISP. For the ground sprayer model the wake and turbulence of the aircraft are removed and more detailed modeling of the nozzle jets (and jet entrainment) are included. The ground model predicts the spray deposition downwind from the application area for any set of initial conditions, and recovers results consistent with Spray Drift Task Force field data.

"FIELD MEASUREMENTS OF HELICOPTER ROTOR WASH IN HOVER AND FORWARD FLIGHT"

J. Aircraft, Vol. 34, No. 6, November-December 1997, pp. 813-814

Up to now, the effect of a passing helicopter on the local meteorology, particularly near a forest fire, has been understood only from a qualitative standpoint. Because the quantitative data are considered important in understanding fire propagation and the dispersal of pesticides and other contaminants, a cooperative field study was recently conducted to collect such data, with the hope that these data may be used to validate models of helicopter wakes, suggest operational methods for fighting forest fires, and provide insight into the dispersal of dusts, aerosols, and other contaminants in the atmosphere.

"VORTEX ROLL-UP, MERGING AND DECAY WITH THE UNIWAKE COMPUTER PROGRAM"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 33-1 - 33-2.

The numerical simulation of vortex merging and decay, particularly behind large commercial aircraft, was initially made possible by the NASA WAKE code developed in 1975. Significant enhancements to that code were achieved in the last three years with the development of the UNIWAKE code for the Department of Transportation. This code combines four elements of the merging process: (1) a vortex lattice model patterned after the work of Margason and Lamar to determine the wing loading; (2) a Betz roll-up model of the load distribution, including axial velocity effects; (3) a turbulent transport finite difference model extending the previous WAKE solution scheme to fourth-order accuracy; and (4) a three-dimensional unsteady analysis replacing the merged vortices by curved vortex elements, leading to vortex linking and pinch-off. This paper summarizes each model stage, and examines extensions for solution improvement.

Teske, M. E., Quackenbush, T. R., Sykes, R. I. and Bilanin, A. J.

"LONG-TIME AIRCRAFT VORTEX WAKE PREDICTIONS AND PLUME EVOLUTION CONSEQUENCES"

AIAA Paper No. 1997-1843, Snowmass Village, CO, June 1997

This paper summarizes ongoing work on the prediction of wake/exhaust mixing for subsonic aircraft, with particular emphasis on long-time wake effects. The primary objective of this work addresses the need for a continuous model prediction of the wake of a subsonic aircraft (from the trailing edge of the wing to times late downstream), its entrainment of engine products, and the consequences of the chemistry of these products on the atmosphere; in particular, the process of exhaust mixing, dispersion and chemical reactions in the upper atmosphere, and the assessment of atmospheric effects of commercial aviation. The modeling described here brings together two validated computer models: UNIWAKE, a near-wake model for vortex roll-up and entrainment, and SCIPUFF, a widely used atmospheric plume dispersion model. The coupled model tracks gas-phase species, temperature and velocity fields, and passive tracers in the presence of realistic wind fields, over periods of 24 hours or more after initiation of the wake trail.

Teske, M. E., Thistle, H. W. and Ice, G. G.

"TECHNICAL ADVANCES IN MODELING AERIALY APPLIED SPRAYS"

Transactions of the ASAE, Vol. 46 (4), 2003, pp. 985-996

Since the 1989 publication of the original modeling approaches assembled into AGDISP, significant advances have been made in the development and validation of spray drift models. The latest version of AGDISP (version 8.08) now embodies the latest refinements to the computational engine first developed for NASA, improved by the USDA Forest Service, and implemented by the Spray Drift Task Force and the U.S. Environmental Protection Agency into a regulatory version. This article updates the previous summary of AGDISP, builds on a recent publication summarizing the regulatory version of the model, and includes the most recent modeling additions of atmospheric stability effects, vortical decay, simple terrain features, plant canopy, riparian barriers, and the aerial release of dry materials.

Teske, M. E., Thistle, H. W., Latham, M. and Reynolds, W. H.

"APPLICATION OPTIMIZATION FOR MOSQUITO VECTOR CONTROL"

ASAE/CSAE Paper No. 044201, Ottawa, Ontario, Canada, August 2004

This paper explores the behavior of aircraft vortices in an early-morning environment. Model calculations are run to the point of complete vortical decay, at which time the downwind and vertical incremental distances from the point of release are obtained. In this way, sensitivity to atmospheric stability, crosswind, evaporation, drop size distribution, and aircraft type may be explored. The relative displacement of the spray material may then be used to estimate where to release the spray material in order to reach a specified target several kilometers downwind.

Teske, M. E., Valcore, D. L. and Hewitt, A. J.

"AN ANALYTICAL GROUND SPRAYER MODEL"

ASAE Paper No. 01-1051, Sacramento, CA, July 30-August 1, 2001

This paper summarizes an analytical ground sprayer model developed with the same Lagrangian approach used in AGDISP and AgDRIFT, and validated with field data collected by the Spray Drift Task Force. The model predicts the deposition downwind from the application area for any set of initial conditions, and recovers results consistent with those obtained for aerial application by the aerial model.

Teske, M. E., Wachspress, D. A. and Thistle, H. W.

"PREDICTION OF AERIAL SPRAY RELEASE FROM UAVS"

Transactions of the American Society of Agricultural and Biological Engineers, Vol. 61, No. 3, 2018, pp. 909-918.

This article summarizes the ability of CHARM+AGDISP to predict the drift and deposition of sprays released from rotary wing unmanned aerial vehicles (UAVs). This predictive capability results from merging algorithms for spray transport, as found in AGDISP (AGricultural DISPersal), with CHARM (Comprehensive Hierarchical Aeromechanics Rotorcraft Model). The resulting software tracks the release of spray droplets from nozzles on the UAV to deposition on the ground. To date, both AGDISP and CHARM, a code that provides a complete representation of the time-varying, unsteady flow field surrounding a helicopter during transient maneuvering flight near the ground, have been extensively validated. The CHARM+AGDISP software is applied to two UAVs to explore the flow field regimes that present challenges for effective UAV operations. The simulations undertaken indicate flight conditions that yield acceptable deposition levels and minimize drift; inversely, conditions are also identified that result in off-target drift that may be problematic.

Tetzlaff, G., Franke, J. and Schilling, V.

"WAKE VORTEX PROPAGATION IN THE ATMOSPHERIC BOUNDARY LAYER"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 47-1 - 47-19

The Rhein-Main Airport in Frankfurt, Germany, has two parallel runways separated by 518 m. This distance is not sufficient to operate the runways independently. To achieve a part time independent operation for Frankfurt a three-phase program was designed. In a first phase wind sensors were deployed to simply answer the question whether wake vortices are capable to travel across to the other runway in critical strength. The second phase tries to define the weather situations and their operational handling during which an independent operation would be within regulations. The

methods employed in this phase do not solely rely on the experimental findings but also include the results of numerical simulations of the vortex propagation at the surface. The third phase will incorporate the findings of the first two phases in the actual running of the airport. This will happen stepwise and carefully scaled in close contact with all involved parties.

"VORTEX FLOWS IN WAKES"

Proceedings of Boundary Layer Symposium, ER-8290, Lockheed-Georgia Research Lab., 1965, pp. 151-178

A steady solution of the viscous Navier-Stokes equations for a vortex flow field has been obtained. A perturbation form of the circulatory terms leads to a nonlinear, total differential equation having a solution characterized by spatially periodic waveforms, including nonlinear harmonics as multiples of the fundamental. The existence of aperiodic spatial waveforms is shown to be dependent upon an hypothesized form of the axial stream function used in a variable-separable solution. The perturbation transformation and the omission of explicit time-dependency result in a formulation which is not useful for evaluating the magnitudes of the circulation and stream function. Rather, they permit a study of quasi-periodic waveforms in the stream function for a vortex flow.

Theisen, J. G.

"VORTEX PERIODICITY IN WAKES"

AIAA Paper No. 1967-0034, New York, NY, January 1967

An analytic solution is presented for the Navier-Stokes equations associated with vortex flows, including nonlinear, viscous terms. Appropriate consideration of three-dimensional disturbances, recently observed experimentally in wakes has enabled reduction of these equations to tractable form using perturbation analysis. Both stable and unstable, peripherally periodic modes for a vortex with large swirl (small Rossby number) are determined for radial and tangential velocities as functions of the radial inflow Reynolds number and the Rossby number.

Theisen, J. G.

"V/STOL STABILITY AND CONTROL IN TURBULENCE"

Proceedings of the National Aerospace Meteorology Conference, AMS/AIAA, 1968, pp. 505-514

The six-degree-of-freedom equations of motion employed in early simulations of wake penetration dynamics are described. Both digital and analog computers were employed with a fixed base simulator, useful for basic stability and trend studies.

Theisen, J. G. and Scruggs, R. M.

"VISCID EFFECTS ON WAKE TURBULENCE PERSISTENCE AND STABILITY"

Proceedings of the Sixth Conference on Aerospace and Aeronautical Meteorology, American Meteorological Society, 1974, pp. 370-377

A mathematical analysis is given which describes the basic features of the process of the generation of an axial periodicity in vortices which are being fed non-conservatively by the shear layers of an external flow in a non-axisymmetric manner. The existence of atmospheric wind-shear mechanisms provides a broad-band, periodic feeding of vorticity along the axis of a vortex contrail, so that the source of energy to amplify a resonant excitation such as vortex burst is apparent. Also, differential flap motion could excite the non-axis-symmetric modes observed.

Theisen, J. G. and Scruggs, R. M.

"AIRCRAFT WAKE VORTEX DYNAMIC STABILITY SUBJECTED TO REAL ATMOSPHERIC EFFECTS"

LG75-ER0125, June 1975, Lockheed-Georgia, Marietta, GA

Three-dimensional turbulence theory is used with a vortex filament model of aircraft contrails to predict the probability that the theoretical core-wise wavelengths can be amplified to cause a 'breakdown' of the primary axisymmetric vortex. Such a cascading of energy is ideally sought as a possible solution of the vortex wake hazard problem.

Theisen, J. G., Scruggs, R. M. and Dixon, C. J.

"VORTEX WAKE OPERATING PROBLEMS, ANALYSIS AND TESTING"

LG73-ER-0021, August 1973, Lockheed-Georgia Company, Marietta, G.

A mathematical analysis is given which describes the features of the process of the generation of an axial periodicity in vortices which are being fed non-conservatively by the shear layers of an external flow in a non-axisymmetric manner. A vortex-lattice computer simulation is described of a tip-mounted nacelle with power effects on the wing vortex wake. Canted end-plates were also simulated, and the effects on span-lift distribution were similar, to first order, compared with the nacelle mounted cases.

"HELICOPTER FLIGHT DYNAMIC SIMULATION WITH REFINED AERODYNAMICS AND FLEXIBLE BLADE MODELING"

Journal of Aircraft, Vol. 39, No. 4, July-August 2002, pp. 577-586.

A coupled rotor-fuselage flight dynamic model that includes a maneuvering free wake model and a coupled flap-lag-torsion flexible blade model, as well as the results of an investigation on some effects

of inflow and blade modeling on the free-flight response of a hingeless rotor helicopter to pilot inputs, are described. The wake model is a relaxation type free wake, capable of modeling the wake geometry changes due to maneuvers; no assumptions are made on the wake geometry, which is free to evolve based on the maneuver. Theoretical predictions are compared with flight-test data. The results show that the free-flight, on-axis response to pilot pitch and roll inputs can be predicted with good accuracy with a relatively unsophisticated model. It is possible to predict the off-axis response from first principles, that is, without empirically derived correction factors and without assumptions on the wake geometry. To do so, however, requires sophisticated modeling. Both a free wake model that includes the wake distortions caused by the maneuver and a refined flexible blade model must be used. Most features of the off-axis response can be captured using a dynamic inflow theory extended to account for maneuver-induced wake distortions, for a fraction of the cost of using a free wake model. The most cost-effective strategy, for typical flight dynamic analyses and if vibratory loads are not required, is probably to calibrate such a theory using the more accurate free-wake based model, and then use it in all calculations.

"SPRAY DROPLET TRAJECTORY LENGTH IN AMBIENT VORTICES"

ASAE/CSAE Paper No. 041088, Ottawa, Ontario, Canada, August 2004

The length of droplet trajectories is important in applied deposition modelling of aerial sprays. The length of the trajectory determines the time over which evaporation will act on a droplet as well as the likelihood a droplet will encounter a canopy element. In this paper vortical motion in the atmosphere is parameterized by analyzing time series of wind speed data. Resultant discrete vortices are then defined and fit to a Lamb Vortex. Individual droplets are numerically dropped into the vortices and trajectory pathlength calculated. Trajectories of 50 drops are nearly circular while 350 drops are only slightly deflected by the lowest energy vortex analyzed here.

"IMPROVING THE MITIGATION OF WIND HAZARDS IN ATM OPERATIONS WITH GROUND-BASED WIND DOPPLER LIDARS"

Fifth SESAR Innovation Days, December 2015, Bologna, Italy.

Weather is one of the major causes of flight delays and accidents. Among all the weather conditions for aircrafts, wind and wind hazards like wake vortices and wind shears require to be monitored with high spatial and temporal resolution sensors to reduce their impact on air traffic for improving safety and/or for optimizing ATM. Among the different available sensor technologies, Doppler LIDAR sensors as remote sensors allow to obtain high spatial (5 m to 200 m) and temporal (1 Hz to 20 Hz) resolution and accurate wind measurement (typically 0.5 m/s). But the use of these sensors remains relatively limited for ATM and few are used for operational purposes in ATM. This paper presents the developments of a new generation of Doppler LIDAR systems for measuring wind and monitoring wind

hazards around airports. Their intrinsic performances in terms of measurement range and accuracy are described. Several applications of such LIDAR technology are then presented like wind measurements, wind shears detection and wake vortices monitoring thanks to several experiments performed on airports. As perspectives the paper proposes the potential benefits of using such atmospheric LIDAR sensors for optimizing air traffic like airport capacities and for improving air traffic safety.

Thobois, L. P. and Cariou, J. P.

"WIND MEASUREMENTS WITH GROUND-BASED FIBER-BASED WIND DOPPLER LIDAR SYSTEMS FOR AVIATION WEATHER APPLICATIONS"

AIAA Paper 2015-3399, June 2015, Dallas, TX.

In air traffic operations, weather is one of the major causes of flight delays and accidents. Among all the weather conditions for aircrafts, wind and wind hazards like wake vortices and wind shears require to be monitored with high spatial and temporal resolution sensors in order to reduce their impact on air traffic for improving safety and / or for optimizing ATM. Among the different available sensor technologies, Doppler LIDAR sensors as remote sensors allow to obtain high spatial (5 m to 200 m) and temporal (1 Hz to 20 Hz) resolution and accurate wind measurements (typical 0.5 m/s). But these sensors remain confidential and few are used for operational purposes. This paper will present the developments of a new generation of Doppler LIDAR systems for measuring wind and monitoring wind hazards around airports. Their intrinsic performances in terms of measurement range and accuracy will be described. Several applications of such LIDAR technology will be then presented like wind measurements, wind shears detection and wake vortices monitoring thanks to several experiments performed on airports. As perspectives the paper will propose the potential benefits of using such atmospheric LIDAR sensors for optimizing air traffic like airport capacities and for improving air traffic safety.

"DEPLOYMENT OF A NEXT GENERATION AND OPERATIONAL LIDAR SOLUTION FOR MONITORING WAKE VORTICES FOR SUPPORTING NEW WAKE TURBULENCE REGULATIONS"

AIAA Paper 2016-3273, June 2016, Washington, DC.

Numerous studies have been performed to better understand the behavior of wake vortices with regards to aircraft characteristics and weather conditions since ten years. These studies have led to the development of the aircraft recategorization (RECAT) programs. Its phase one focused on redefining distance separation matrix with six static aircraft wake turbulence categories. In Europe, the RECAT-EU regulation is now entering under operational implementation in several key airports. As proven by several research projects in the past, LIDAR sensors can be considered as the ground truth wake vortex measurements for assessing the safety impact of a new wake turbulence regulation at an airport in quantifying the risks given the local specificities. LIDAR's can also be used to perform risk monitoring after the implementation. In this paper, a methodology to measure wake vortices with scanning

coherent Doppler LIDARs is described as well as its contribution to the safety assessment and risk monitoring phases. The wake vortex algorithm used for post-processing the raw LIDAR data is presented and evaluated on limited datasets. Finally, the use of this LIDAR based solution for supporting the implementation of new wake turbulence regulation is described along with preliminary results of an on-going field campaign.

Thobois, L. P., Krishnamurty, R., Cariou, J. P., Dolfi-Bouteyre, A. and Valla, M.

"WIND AND EDR MEASUREMENTS WITH SCANNING DOPPLER LIDARS FOR PREPARING FUTURE WEATHER DEPENDENT SEPARATION CONCEPTS"

AIAA Paper 2015-3317, June 2015, Dallas, TX.

Since a decade, numerous studies have been performed to better understand the behavior of wake vortices in regards to aircraft characteristics and weather conditions. These studies have led to the development of the RECAT aircraft recategorization programs which consist for Phase one in redefining distance separation matrix for six static aircraft classes. If the benefits of such a new regulation have been demonstrated, highest benefits could be obtained with dynamic distance separations concepts with real time weather observations. In this context, new operational sensor technologies have been developed in the UFO European FP7 project to bring accurate and resolved observations that could be integrated into weather dependent separation ATM software. In this study, the methods developed for postprocessing radial data into wind vectors and turbulent eddy dissipation rate (EDR) will be presented as well as their validation with simulations or specific tests. The experiment performed at Toulouse-Blagnac airport in France will be described as well as the main sensors developed for the project. These methods will be then applied to the Toulouse LIDAR database. The results will be analyzed and compared with other sensors especially a research aircraft to assess the availability and accuracy of LIDAR data.

"MEASURING WAKE VORTICES AND WIND SHEARS IN REAL-TIME WITH A SCANNING WIND DOPPLER LIDAR"

92nd American Meteorological Society Annual Meeting, January 2012, New Orleans, LA.

Measuring and foreseeing wind conditions near airports are crucial issues for air traffic safety. Coherent laser radars or LIDARs can be very powerful devices for measuring wind shears on dangerous airports or wake vortices. LEOSPHERE has developed a scanning wind doppler lidar, the Windcube200S for these needs. Deployed on a French airport this lidar has been used to detect wake vortices and follow them under various atmospheric conditions. Given specific swept scenarios, the Windcube200S has been able to detect the wake vortices of heavy, medium, and small aircrafts during takeoff and landing. Wake vortices have been monitored for a period of 30 to 60 seconds that allowed to analyze their trajectories and their shapes evolution. Several analyses have been achieved in order to determine the influence of the wind conditions on the trajectories of wake vortices. Finally, a dedicated

post-treatment has been developed for identifying the cores of wake vortices and for calculating their circulations.

Thobois, L., Loaec, S., Cariou, J.-P. and Sauvage, L.

"MEASURING WAKE VORTICES AND WIND SHEARS IN REAL-TIME WITH A SCANNING WIND DOPPLER LIDAR"

WMO Technical Conference of Meteorological and Environmental Instruments and Methods, October 2012, Brussels, Belgium.

Measuring and foreseeing wind conditions near airports are crucial issues for air traffic safety. Since aircraft maneuverability is the worst during takeoff and landing phases, strong air movements near airports such as wind shears or wake vortices can have dramatic consequences on aircrafts. These phenomena are nevertheless very different since wind shears are generated by geography around airports, whereas wake vortices are created by aircrafts themselves. Wind shears usually appear in airports located near coasts, valleys, or mountains. These geographical items induce different winds in direction and in intensity depending on meteorological conditions. Wake vortices are generated by all the planes. Size and intensity of wake vortices are directly linked to the flight speed and by plane characteristics, such as weight and wingspan. Even if strong efforts have been done to study and model wind shears and wake vortices, on-site measurements remain the best way to detect them as they depend a lot on meteorological conditions near airports especially wind and turbulence. Coherent laser radars or LIDARs can be very powerful devices for measuring wind shears on dangerous airports or wake vortices. LEOSPHERE has developed a scanning wind doppler lidar, the Windcube200S for these needs. Deployed on a French airport in the framework of the European project SESAR, this lidar has been used to detect wake vortices and follow them under various atmospheric conditions. Given specific swept scenarios, the Windcube200S has been able to detect the wake vortices of heavy, medium, and small aircrafts during takeoff and landing. Wake vortices have been monitored for a period of 30 to 60 seconds that allowed to analyze their trajectories and their shapes evolution. Several analyses have been achieved to determine the influence of the wind conditions on the trajectories of wake vortices. A variety of trajectories have been put in front. Finally, a dedicated post-treatment has been developed for identifying the cores of wake vortices and for calculating their circulations.

"HIGH-RESOLUTION SIMULATIONS OF PARALLEL BLADE-VORTEX INTERACTIONS"

AIAA Journal, Vol. 48, No. 10, October 2010, pp. 2313-2324.

The physics of a parallel blade-vortex interaction is studied numerically and the predicted pressure and acoustic results are compared with experimental measurements. A high-resolution solution of the compressible Euler equations is performed on structured overset meshes. Initially, a two-dimensional airfoil-vortex interaction is studied for both a case where the vortex misses the blade and a case of

direct impact. The vortex is initiated in the flow as a perturbation to the freestream conditions and is free to evolve, thus allowing for the deformation of the vortex as it interacts with the blade to be studied. The simulation is seen to accurately reproduce the experimental results and the emission of the acoustic waves from the airfoil surface is observed in detail. Acoustic energy generated by the interaction is seen to primarily radiate from the leading-edge section of the airfoil with a weaker contribution coming from the trailing edge. The simulations are then extended to three-dimensional moving overset meshes where the vortex generation and convection is also resolved. The numerical methodology is seen to accurately preserve the vortex strength and accurately reproduce the experimentally measured blade surface pressures and acoustics. The computations presented here face similar challenges to that encountered in the simulation of realistic helicopter blade-vortex interaction, but the computational costs are such that the solutions can be well resolved, and comprehensively validated using moderate resources.

Thom, A. D.

"ANALYSIS OF VORTEX-LIFTING SURFACE INTERACTIONS"

PhD Thesis, August 2011, University of Glasgow, Glasgow, Scotland.

The interaction of a vortex with a lifting surface occurs in many aerodynamic systems, and can induce significant airloads and radiate impulsive noise. Yet due to their complex nature, the ability to accurately model the important flow physics and noise radiation characteristics of these interactions in realistic situations has remained elusive. This work examines two cases of vortex-lifting surface interactions by enhancing the capabilities of a high-fidelity flow solver. This flow solver utilizes high spatial discretization accuracy with a fifth order accurate WENO scheme, and overset meshes to accurately resolve the formation, evolution and interaction of a tip vortex using an inviscid approximation of the fluid. An existing computational infrastructure is further developed and applied to analyze blade-vortex interactions that occur on a helicopter rotor. An idealized interaction is studied, where an independently generated vortex interacts with a rotor. It is found that through the employment of adequate spatial and temporal resolution, the current methodology can resolve the important details of the interaction over a range of vortex-blade miss distances. A careful study of the spatial and temporal resolution requirements is conducted to ensure that the computed results converge to the correct physical solution. It is also demonstrated that a linear acoustic analysis can accurately predict the acoustic energy propagated from these interactions to the far-field, provided the blade surface pressures are accurately computed. The methodology is then used to study an idealized propeller wake-wing interaction, which occur behind a tractor mounted turboprop. A computationally efficient method of modelling the wake-wing interaction is developed and the computed surface pressures of the interaction are confirmed to agree well with the experimental data. The analysis is coupled to an optimization algorithm to determine a novel wing design, and it is found that significant drag reductions can be achieved with small changes in the twist distribution of the wing.

Thomas, D. D.

"TURBULENCE RELATED ACCIDENTS, WORLDWIDE SYNOPSIS"

FAA Symposium on Turbulence, Federal Aviation Administration, Washington, DC, March 1971, p. 2.

Wake turbulence accidents are rare in air carrier operations, but clear air turbulence accidents are reaching the frequency of cloud associated accidents. One-half of all the turbulence accidents in general aviation are fatal, and one out of four of the total turbulence accidents involves wake vortex turbulence while clear air turbulence accidents are infrequent.

"AN AIRLINE PERSPECTIVE: CURRENT AND FUTURE VISION FOR TURBULENCE FORECASTING AND REPORTING"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 11, 2016, Springer International Publishing Switzerland, pp. 227-242.

The flight planning process is the most critical time for the turbulence forecaster. It is the time that routes and altitudes are selected, and fuel is added for any necessary deviations. Aviation meteorologists can have a significant impact at this stage of flight planning. Internationally, flights are given preference for route and altitude selection based on the time the flight plan is filed. It is difficult for flights to change altitude once the flight plan has been accepted, since flights over the oceans cannot be seen on radar and have to be sequenced in space and time. If turbulence is not considered at the planning stage, altitude deviations for turbulence may not be allowed if there are other aircraft above and below the flight. Therefore, advanced knowledge of turbulence gives the advantage to the airlines that forecast turbulence accurately. The turbulence forecaster can also provide significant value during the flight following process. Monitoring real-time satellite and weather radar observations, as well as automated aircraft and manual pilot reports, can help verify model data and identify areas of un-forecasted turbulence. This enables Human-in-the-Loop adjustments to the Numerical Weather Prediction (NWP) models and ability to provide updates to flights while en route. A case study from 30 June 2014 over the upper Midwest USA demonstrates this process in detail. As NWP models improve, the role of the operational aviation meteorologist will evolve. In tandem, additional insight by the research community into the current operational forecast processes is important to successfully transition to automated turbulence forecasting. Improved methods of observing and reporting turbulence, and more efficient ways of distributing and displaying the turbulence forecasts for avoidance, will be needed.

Thomas, N. and Gunasekaran S.

"AFFECTING WINGTIP VORTEX BY INFLUENCING WING SURFACE-FLOW DIRECTION"

AIAA Paper 2018-0344, January 2018, Kissimmee, FL.

The aerodynamic efficiency of a NACA 0012 AR 4 wing was affected through periodic contours aligned in the flow direction resembling a wrinkled texture. Streamwise and cross-stream Particle Image

Velocimetry (PIV) were conducted at the University of Dayton Low Speed Wind Tunnel around Reynolds number of 135,000 on the NACA 0012 AR 4 wing with and without surface contours. Wings with 6 contour sections was designed by spline fitting two NACA 0012 airfoil profiles in the spanwise direction. Both 2D (wall-to-wall model) configuration and 3D configuration of the wings were tested to determine the effects of surface contours on the parasite and induced drag of the wing. Streamwise PIV results indicated an increase in momentum deficit in the wake of the mid-contour region due to enhanced boundary layer separation from the upper surface of the mid-contour region. The cross-stream PIV results indicated a decrease in the magnitude of azimuthal velocity, circulation, and RMS quantities in the wingtip vortex with the surface contours. The reduction in the wingtip vortex properties indicates that the contours were effective in blocking the spanwise flow feeding into the wingtip vortex on the surface of the wing.

Thomas, P. and Vogt, S.

"INTERCOMPARISON OF TURBULENCE DATA MEASURED BY SODAR AND SONIC ANEMOMETERS"

Boundary-Layer Meteorology, Vol. 62, 1993, pp. 353-359.

The capability of SODAR to measure the mean wind field in the lower boundary layer is well known and documented. Therefore, mean wind data are easily obtainable by means of the SODAR-technique, and are used to simulate the transport of pollutants after their release into the atmosphere. But when calculating the diffusion of pollutants, information about atmospheric turbulence is needed, too. In principle, a SODAR can measure turbulence data like the standard deviation of the vertical wind speed or horizontal wind direction. But when measuring turbulence data with a SODAR, one is beset by a host of limitations like volume sampling, spatial and temporal separation of sampling volume, attenuation of the acoustic waves and the slow speed of sound. Therefore, successful turbulence measurements with SODAR are not numerous and little is known about the quality of these data. In this context an intercomparison between a REMTECH-SODAR and a sonic anemometer mounted at the 100 m level of our meteorological tower was performed in summer 1990 at the Kemforschungszentrum Karlsruhe. The intercomparison is in two parts: (1) Half hour mean values of the standard deviation of the vertical wind speed are intercompared by scatter plots and by a linear regression and correlation analysis. (2) During 7 periods, 2 hours each, and covering atmospheric stabilities from unstable to slightly stable, the instantaneous vertical wind speeds were measured by both instruments and spectra were calculated. The intercomparison demonstrates that DOPPLER-SODAR sounding is a reliable technique to determine besides the mean field, also atmospheric turbulence data like $\Sigma(w)$.

"THE OBSERVATION OF THE SIMULTANEOUS DEVELOPMENT OF A LONG- AND A SHORT-WAVE INSTABILITY MODE ON A VORTEX PAIR"

J. Fluid Mech., Vol. 265, 1994, pp. 289-302

Experiments on the stability of vortex pairs are described. The vortices (ratio of length to core diameter of up to 300) were generated at the edge of a flat plate rotating about a horizontal axis in water. The vortex pairs were found to be unstable, displaying two distinct modes of instability. For the first time, as far as it is known to the authors, a long-wave as well as a short-wave mode of instability were observed to develop simultaneously on such a vortex pair. Experiments involving single vortices show that these do not develop any instability whatsoever. The wavelengths of the developing instability modes on the investigated vortex pairs are compared to theoretical predictions. Observed long wavelengths are in good agreement with the classic symmetric long-wave bending mode identified by Crow (1970). The developing short waves, on the other hand, appear to be less accurately described by the theoretical results predicted, for example, by Widnall, Bliss & Tsai (1974).

"ADVANCES IN AIR TO AIR REFUELLING"

Progress in Aerospace Sciences, Vol. 71, 2014, pp. 14-35.

An increasing interest over the last decade in developing unmanned aerial systems' technologies has prompted research into methods for automating air to air refueling processes. Furthermore, for systems with increased autonomy the necessary logic and flight control systems to perform autonomous air to air refueling is now being pursued. There has already been significant research in position tracking, rendezvous scheduling, apparatus modelling, wake effects, and vision-based sensors to support refueling of unmanned systems and to increase the autonomy in manned aircraft refueling. Many of these build upon considerable research and understanding that has matured for manned air to air refueling. This paper reviews the current, and future, state of research in this area.

"OBLIQUE SHOCK-VORTEX INTERACTION"

Proc. Appl. Math. Mech., Vol. 2, 2003, pp. 334-335

Breakdown of a slender vortex caused by an oblique shock is studied using numerical solutions of the Euler equations for unsteady three-dimensional flow. A Burgers vortex with a given circulation and axial velocity distribution is prescribed at the inflow boundary. The calculations show that like in incompressible flows supersonic breakdown is primarily controlled by pressure forces. The shock is deformed into an 's'-shaped part near the vortex core where the shock becomes normal. The results indicate that initiation of breakdown is more sensitive to variations in the axial velocity than in the circulation, and that the flow structure is clearly time-dependent.

Thomer, O., Krause, E. and Schroder, W.

"INTERACTION BETWEEN LONGITUDINAL VORTICES AND NORMAL AND OBLIQUE SHOCKS"

In *Vortex Dominated Flows*, edited by D. Blackmore, E. Krause and C. Tung, 2005, World Scientific, New Jersey, Chapter 12, pp. 199-227.

Breakdown of a slender vortex caused by normal (NSVI) and oblique shocks (OSVI) is studied using numerical solutions of the Euler and Navier-Stokes equations for unsteady, three-dimensional, supersonic flow at free stream Mach numbers of 1.6 and 2.0. At the inflow boundary a slender Burgers vortex with a given circulation and axial velocity distribution is prescribed. The calculations using approximately 2 million grid points show that breakdown is primarily controlled by pressure forces and is therefore easily initiated when the vortex interacts with a normal shock. Oblique shocks are deformed into an 's'-shaped part near the vortex core where the shock becomes normal. The results also indicate that initiation of breakdown is more sensitive to variations in the axial velocity component than in the circulation of the vortex, and that the flow structure is time-dependent. A simple breakdown criterion based on the axial momentum flux is presented for both NSVI and OSVI.

Thomer, O., Schroder, W. and Krause, E.

"NUMERICAL INVESTIGATIONS ON SUPERSONIC VORTEX BREAKDOWN"

Proceedings in Applied Mathematics and Mechanics, Vol. 1, 2002, pp.310-311.

Breakdown of a slender vortex caused by a normal shock is studied using a numerical solution of the Navier-Stokes equations for unsteady, three-dimensional, supersonic flow at a free stream Mach number of 1.6. The numerical results clearly reveal the time-dependent flow structure for both the axial and the radial direction. The results compare well with recent experimental findings.

Thomer, O., Schroder, W. and Krause, E.

"NORMAL SHOCK VORTEX INTERACTION"

RTO AVT Symposium on 'Advanced Flow Management: Part A - Vortex Flows and High Angle of Attack for Military Vehicles', Loen, Norway, May 2001.

Breakdown of a slender longitudinal vortex caused by a normal shock is studied with a numerical solution of the EULER and the NAVIER-STOKES equations for time-dependent, three-dimensional, supersonic flow at a free stream MACH number of 1.6 and different vortex strengths. When breakdown occurs, a free stagnation point is formed downstream from the shock, followed by a region of reversed flow with a bubble-like flow structure. The burst part of the vortex grows in the axial and radial directions until the bubble reaches a stable position. The shock remains normal near the axis of the vortex but is curved further away from it. The flow downstream from the shock is slightly oscillating. The numerical results clearly reveal the time-dependent flow structure in the axial and the radial direction. The results compare well with recent experimental findings.

Thomer, O., Schroder, W. and Krause, E.

"NORMAL AND OBLIQUE SHOCK-VORTEX INTERACTION"

Proceedings of International Conf. RDAMM-2001, June 2001, Novosibirsk, Russia, pp. 737-749.

Breakdown of a slender vortex caused by normal and oblique shocks is studied using numerical solutions of the Euler and Navier-Stokes equations for unsteady, three-dimensional, supersonic flow at free stream Mach numbers of 1.6 and 2.0. At the inflow boundary a Burgers vortex with a given circulation and axial velocity distribution is prescribed. The calculations using approximately 2 million grid points show that breakdown is primarily controlled by pressure forces and is therefore easily initiated when the vortex interacts with a normal shock. Oblique shocks are deformed into an 'S'-shaped part near the core where the shock becomes normal. The results also indicate that initiation of breakdown is more sensitive to variations in the axial velocity than in the circulation, and that the flow structure is clearly time-dependent.

"A PRELIMINARY TOWING TANK STUDY OF THE TRAILING VORTEX GENERATED BY A RECTANGULAR WING, INCLUDING THE EFFECTS OF SEVERAL TIP MODIFICATIONS"

ARL/A-Note-342, September 1973, Aeronautical Research Labs., Melbourne, Australia

The structure of the trailing vortex generated by a rectangular wing in a small towing tank has been studied using the hydrogen bubble flow visualization technique. The effects on the vortex of starting and stopping the towing carriage and of passing a body through the vortex core have been examined. A total of fourteen modifications to the basic wing have been tested for the effect of each on the trailing vortex.

Thompson, D. H.

"EXPERIMENTAL STUDY OF AXIAL FLOW IN WING TIP VORTICES"

J. Aircraft, Vol. 12, No. 11, November 1975, pp. 910-911

This note describes a qualitative towing tank study of some of the factors which control the axial flowfield in a trailing vortex and attempts an explanation of the differing results of previous axial velocity measurements. The towing tank tests showed that the axial velocity distribution in a wing tip vortex can take the form of a centerline velocity excess, a centerline velocity deficit, or a centerline velocity combined with a core edge velocity excess. The velocity distribution at any station behind the wing depends on the wing section, tip shape, Reynolds number, wing incidence and distance of the station from the wing.

Thompson, J. F., Shanks, S. P. and Wu, J. C.

"NUMERIC SOLUTION OF THREE-DIMENSIONAL NAVIER-STOKES EQUATIONS SHOWING TRAILING TIP VORTICES"

AIAA Journal, Vol. 12, No. 6, June 1974, pp. 787-794

Numerical solution of the incompressible Navier-Stokes equations in integro-differential form is applied to time-dependent flow about a rectangular slab at an angle of attack. With this formulation the solution is obtained in the entire unbounded flowfield, but with actual computation required only in regions of significant vorticity. This allows considerable reduction in computer storage, since only points in regions of significant vorticity need be stored at any time. The computational field thus expands in time. (This method is not to be confused with 'vortex methods' using discrete vortices and images.) The finite numerical calculation field in the integro-differential formulation is, in effect, infinite, and the necessity of locating 'infinity' at a finite distance is avoided. Although it is not necessary in this numerical method to calculate the velocity at points outside the region of nonzero vorticity, the velocity at these points and, in fact, to infinity, is determined by the solution via an integral over the vorticity distribution. The method requires two orders of magnitude less computer storage than do methods based on the differential formulation. Results have been obtained for the development of trailing tip vortices and the force coefficients.

"TERMINAL AREA SEPARATION STANDARDS: HISTORICAL DEVELOPMENT, CURRENT STANDARDS, AND PROCESSES FOR CHANGE"

ATC-258, Jan. 1997, MIT Lincoln Laboratory, Lexington, MA.

This paper gives an overview and summary of the separation requirements for air traffic control in the U.S. National Airspace System with emphasis on those relevant to terminal landing operations. These requirements are documented in the FAA's Air Traffic Control Order 7110.65J, as amended, and various national and local Orders. These requirements are also addressed in the Aeronautical Information Manual, the International Civil Aviation Organization's Standards and Recommended Practices, and the Federal Aviation Regulations. The purpose of this paper is to assist those people involved with the introduction of new technologies and procedures in the terminal airspace by providing them with an understanding of the separation requirements, the need for those requirements, and the processes used to change the requirements.

"VISUALIZATION AND MEASUREMENT OF THE TIP VORTEX CORE OF A ROTOR BLADE IN HOVER"

Journal of Aircraft, Vol. 25, No. 12, Dec. 1998, pp. 1113-1121

Detailed measurements with a laser Doppler velocimeter (LDV) have been performed in the tip region and in the tip vortex core of a single-bladed model rotor in hover. The testing was conducted at a rotor tip speed of 32 m/s, a Reynolds number of 269,000, and at two values of the rotor thrust coefficient, 0.0022 and 0.0057. Strobed laser sheet flow visualization was used to verify the steadiness of the tip vortex trajectory in the near wake and quantify the vortex trajectory to guide LDV surveys of the vortex core. A remotely aligned off-axis receiving optics system enabled measurement of vortex core velocity

profiles at large focal lengths. The core self-induced velocity components extracted from these data are presented. The data exhibit evidence of secondary structure even inside the rotational core of the vortex. The axial velocity profile along the core has been extracted and presented in the wake of a spinning rotor. It is seen that the tip vortex of a rotating blade differs considerably in structure from a fixed-wing vortex.

"WAKE VORTEX MODELING FOR AIRBORNE AND GROUND-BASED MEASUREMENTS USING A COHERENT LIDAR"

Proceedings of the Conference, Air Traffic Control Technologies, Orlando, FL, April 18-19, 1995, Society of Photo-Optical Instrumentation Engineers (SPIE) Proceedings, Vol. 2464, 1995, pp. 63-78

Simulated signatures of aircraft wakes as detected by a scanning coherent short wavelength lidar are presented and characterized for several candidate surveillance scenarios. Ground-based and airborne scanning configurations that emulate candidate operational detection and warning systems are compared for spatial coverage and detection capability as a function of system design parameters and atmospheric conditions. Examples of trailing geometries characteristic of onboard wake detection and warning systems are presented. The dependence of predicted detection capability on hydrodynamic parameters, such as vortex circulation, axial motion in the wake vortices, and ambient turbulence is discussed. Simulated wake signatures are compared to observations for wakes observed at Denver's Stapleton International Airport in 1993.

"2 MICRON COHERENT LASER RADAR FOR ON-BOARD AIRCRAFT VORTEX WAKE DETECTION: PATTERN RECOGNITION TECHNIQUES AND TECHNOLOGY ASSESSMENT"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 42-1 - 42-27

A model for estimating the performance of a coherent lidar for detecting and tracking aircraft vortex wakes is described. The goal of the analysis is to assess and predict detection performance of the coherent lidar system as a function of its design and in a variety of operating environments. For this purpose, an existing laser system performance simulator has been modified to apply to aircraft wake detection. The model has three basic elements: a description of the velocity and scattering properties of the wake itself, a specification of the laser optics and scanning procedures, and a simulation and error analysis of the data processing algorithms. Standard models for atmospheric absorption, scattering and coherence loss together with representations of ambient turbulence are used to describe the operating environment. The numerical simulation provides a detailed emulation of the characteristics of the laser signal returned from the atmosphere. Pulsed, CW, focused and unfocused configurations can be simulated. Various measures of performance can be implemented ranging from simple Doppler exceedances along given lines of sight to relatively complex 2D and 3D pattern

recognition concepts. In this paper, spatial displays will be used of the detected pattern of line-of-sight velocity and Doppler spread as well as spatial displays of the probability that a given vortex wake is present as a function of its hypothesized position (matched filter detection).

"SCANNING LASER DOPPLER VELOCIMETER SYSTEM SIMULATION FOR SENSING AIRCRAFT WAKE VORTICES"

J. Aircraft, Vol. 13, No. 8, August 1976, pp. 605-613

The objectives of this study are to simulate the responses of the Scanning Laser Doppler Velocimeter System in a vortex wake environment and to display the spatial signatures. From analysis of these signatures and future parallel processing of flight data and simulated data, optimal detection tactics can be established. A hydrodynamic model is developed that represents the trailing vortex sheet and wind shear as discrete free vortices distributed over a two-dimensional grid. The effects of buoyant exhaust and atmospheric stratifications can be incorporated in the Boussinesq approximation; the atmospheric turbulence can be simulated by constructing specific realization.

Thomson, J. A. L. and Meng, J. C. S.

"SIMULATION AND DATA ANALYSIS OF A SCANNING LASER DOPPLER VELOCIMETER"

Proceedings Minnesota Symposium on Laser Anemometry, Univ. Minnesota, Minneapolis, 1976, pp. 231-276

The paper discusses the spectral signal characteristics of coaxial scanning laser Doppler velocimeter systems which are relevant to the modeling of the response of such systems to simulated and actual aircraft vortex wakes transported through the atmosphere. Some examples of the analysis of the measurements on real and simulated wakes are presented.

Thomson, J. A. L. and Meng, J. C. S.

"LASER DOPPLER VELOCIMETER SYSTEM SIMULATION FOR SENSING AIRCRAFT WAKE VORTICES, PART I: SIMULATION MODEL"

PD-74-058, December 1974, Physical Dynamics Inc., Berkeley, C.

A hydrodynamic model of aircraft vortex wakes moving in a turbulent wind shear field near the ground is developed and used as a basis for modeling the characteristics of a laser Doppler detection and vortex location system. The trailing vortex sheet and the wind shear are represented by discrete free vortices distributed over a two-dimensional grid. The time dependent hydrodynamic equations are solved by direct numerical integration. The effects of buoyant exhaust and atmospheric stratifications are incorporated in the Boussinesq approximation. The ground boundary is simulated by images, and fast Fourier Transform techniques are used to evaluate the vorticity stream function. The

response of a simulated laser Doppler velocimeter is analyzed by simulating the signal return from the flow field as sensed by a simulation of the optical/electronic system.

"MODELING AIRCRAFT PERFORMANCE AND STABILITY ON X-PLANE"

Thesis, 2010, The School of Engineering and Information Technology (SEIT), UNSW Canberra, Campbell, Australia.

Commercial flight simulator software has been long used by the public to hone their piloting skills. X-Plane is the first commercially available flight simulator program which directly outputs mathematical flight data without the need for programming knowledge. This allows the public to readily simulate flight tests on a computer and acquire flight test data. This thesis models the F-15E in X-Plane and compares its performance and handling characteristics to those predicted by theory and flight manual data. These comparisons will be used to determine X-Plane's usefulness as a teaching and analytical tool in the demonstration of how forces and moments affect an aircraft's flight path in flight.

"MEASUREMENT OF UNSTEADY GUSTS IN AN URBAN WIND FIELD USING A UAV-BASED ANEMOMETER"

AIAA Paper 2018-4218, June 2018, Atlanta, GA.

This paper presents the development and testing of an unmanned aerial vehicle (UAV) for measurement of turbulent wind gusts in an urban wind field. This UAV is equipped with a 3-axis sonic anemometer capable of sampling at rates up to 200 Hz. The key advantage of these vehicles is the ability to position the UAV at any desired point in a wind field without the restrictions of fixed towers. The challenge of this configuration is the spatial and temporal integration of a flight controller's attitude data with separate wind speed readings. Furthermore, the measured wind data from the anemometer must be corrected for induced velocities from the vehicle's motion. The focus of this paper is on the development of accurate correction schemes to remove the induced velocity components caused by the rotation and translation of the flight vehicle.

"COMPARISON OF PLENOPTIC PIV AND STEREO PIV MEASUREMENTS IN A WING TIP VORTEX"

17th International Symposium on Application of Laser Techniques to Fluid Mechanics, July 2014, Lisbon, Portugal.

The visibility of a first generation plenoptic PIV system is assessed through comparison with stereo PIV measurements of a wing tip vortex produced by a flat plate at an 8-degree angle of attack. Stereo PIV measurements were acquired in a streamwise plane through the approximate center of the vortex and highlight the presence of the vortex through measurement of the out-of-plane component of

velocity. Instantaneous velocity images indicate that the vortex was interacting with the street like wake produced by the sharp-edged plate. Plenoptic PIV produced instantaneous and average 3D/3C velocity images that clearly show the three-dimensional position of the wing tip vortex along with other features of the flow. The average flow field also displays clear evidence of the interaction between the forming wing tip vortex and the wake. Trends in streamwise averaged velocity profiles were similar between the two systems, although the magnitudes varied with differences attributed to the decreased spatial resolution of the plenoptic camera, the limited number of plenoptic PIV samples and the need for a more robust alignment between the two camera systems. Overall, plenoptic PIV is shown as a viable and convenient method for acquisition of volumetric velocity data. Its primary strength is that it is a single camera technique, which results in a relatively simple experimental arrangement comparable to conventional 2D PIV. Presently, its chief drawback is low spatial resolution and limited dynamic range, although next generation cameras promise significant improvements in both.

"UAV FLIGHT TEST EVALUATION OF FUSION ALGORITHMS FOR ESTIMATION OF ANGLE OF ATTACK AND SIDESLIP ANGLE"

AIAA Paper 2016-0645, January 2016, San Diego, CA.

Angle of attack (AOA) and angle of sideslip (AOS) are critical states for aerodynamic modeling of flight vehicles. They can provide pilots with important safety information for stall avoidance, or serve as feedback for control purposes. More importantly, AOA and AOS are good indications of aircraft encounters with dynamic flow fields, such as thermal, gust, and wake vortices. Such measurements can be used for the detection and identification of the flow model parameters when combined with other onboard sensors. However, it is difficult to get accurate AOA and AOS measurements especially with low-cost small unmanned aerial vehicles (UAVs). This paper provides a thorough evaluation of three commonly used fusion algorithms for AOA and AOS estimation, using UAV flight data in ambient turbulence as well as wake turbulence. The performance of these algorithms is compared both in simulation and through flight test data.

"WAKE ENCOUNTER SIMULATION AND FLIGHT VALIDATION WITH UAV CLOSE FORMATION FLIGHT"

AIAA Paper 2017-1910, January 2017, Grapevine, TX.

In this paper, HawkWakeSim, a novel UAV wake encounter simulation platform, is presented with coupled modeling of aerodynamics and flight dynamics. Unlike conventional aircraft simulation models where aerodynamic coefficients are identified from flight test data, HawkWakeSim uses results from computational fluid dynamics calculations and updates the aerodynamic coefficients at each time step, which eliminates the errors from linearization. Several wake encounter scenarios with different lateral encounter angles and following clearances are simulated and investigated. The aircraft responses in one of the simulated scenarios are compared with experimental data obtained from a UAV close formation flight. Results from HawkWakeSim match the overall trend of flight test results, which show

its effectiveness. Additionally, aircraft responses during wake encounters under different control configurations are simulated and analyzed.

"AN EXPERIMENTAL STUDY ON THE PERFORMANCE OF WIND TURBINES OVER COMPLEX TERRAIN"

AIAA Paper 2013-0612, January 2013, Grapevine, TX.

An experimental study was conducted to investigate the performance of wind turbines over hilly terrains to elucidate the underlying physics to explore/optimize design of wind turbines sitting over complex terrains for higher power yield and better durability. The experiments were conducted in an atmospheric boundary layer wind tunnel with turbines sited over a two-dimensional hill. In addition to measuring dynamic wind loads and the power outputs of the wind turbines, detailed flow field measurements were also made to quantify the flow characteristics of the surface wind and the wake interference among multiple wind turbines over hilly terrain. The detailed flow field measurements were correlated with the wind load and power output measurements of the wind turbine models to explicate the physical mechanisms associated with power generation and fatigue loads acting on the wind turbines for the optimal design of the wind turbine layout over complex terrain.

"SEPARATION DETERMINING METHOD OF CLOSELY SPACED PARALLEL RUNWAYS"

Journal of Traffic and Transportation Engineering, Vol. 13, No. 1, February 2013, pp. 70-76.

By using wake vortex movement characteristics under the most adverse environment, the effects of the slant range and approach glide angles of paired aircrafts and aircraft type combination on runway separation under the dependent parallel approach mode of closely spaced parallel runways were researched, the minimum wake vortex separation standard and crosswind statistical data of NASA were used, and the determination methods of runway centerline distance and threshold offset were put out based on aircraft type parameters. Analysis result shows that when the slant separation standard of paired leading and trailing aircrafts is a certain value, threshold offset decreases with the increases of runway centerline distance and the glide angle of paired trailing aircraft. When the glide angles of paired leading and trailing aircrafts are same, threshold offset decreases with the increases of runway centerline distance and slant separation standard. When runway centerline distance is 380 m, the glide angles of paired leading and trailing aircrafts are both 3 degrees, and slant separation standard is 2 780 m, the threshold offset of Changsha Huanghua International Airport should be more than 1 483 m, which is accord with the runway parameter of foreign authorized airports. [In Chinese].

"AN INSTRUMENTATION SYSTEM FOR THE MEASUREMENT OF ATMOSPHERIC TURBULENCE"

Journal of Industrial Aerodynamics, Vol. 2, 1977, pp. 49-63.

A method is described for the detailed multi-point measurement of the turbulent velocity components and temperature in the atmospheric surface layer. The TSI three-dimensional split-film anemometer system is used as sensor and a special designed data acquisition and data-handling system is used for the sampling, digitizing and storing of the data on digital magnetic tapes. Further processing of the data is performed in a digital computer and programs are developed to allow efficient calculation of the statistical quantities such as, mean values, covariance, power- and cross-spectral density functions. At the present, six anemometer systems have been mounted on the 30-, 50-, 100-, 150-, 200- and 250-foot levels of the 250-foot Meteorological Tower at NASA, Wallops Flight Center. The tower is located at Wallops Island which is one of the barrier islands protecting the so-called 'Delmarva' peninsula from the Atlantic Ocean. The island, which consists of a narrow strip of dunes approximately three meters above sea level, is situated in a northeast-southwest direction and is separated from the mainland by a three-mile-wide tidal swamp.

"PROPAGATION OF SOUND RADIATION THROUGH VORTICES: A CONTRIBUTION TO THE THEORY OF FLOW MEASUREMENT WITH ULTRASOUND"

Report 6/1972, 1972, Max Planck Institut für Stromungsforschung, Göttingen, Germany

The circulation and core diameter of vortices are determined from the frequency distribution of the phase deviations (phase spectra) of an ultrasonic wave propagation through a wake. Theoretical principles are developed which make use of the geometrical acoustic approximation. An exact solution of the canonical equations for the development of acoustic radiation in the potential vortex is presented in integral form, and a closed solution for the corresponding problem in the rigidly rotating vortex core is indicated. A simplified application of these solutions leads to a method for the approximate determination of the vortex core diameter from the phase spectra.

"SURVEY OF EXPERIMENTAL VELOCITY DISTRIBUTIONS IN VORTEX FLOWS WITH BIBLIOGRAPHY"

Report D-82-0683, November 1967, Boeing Scientific Research Labs, Seattle, WA

Vortex flow is basic to and of great importance throughout fluid dynamics. Experimental data on circumferential velocities in real vortices was determined mostly for vortex flows generated by straight wings and delta wings. A literature search was conducted to collect pertinent data and to present a unified picture of present experimental knowledge. Circumferential velocity distributions in using vortices determined in four investigations are set forth in which there was an acceptable degree of confidence in the instrumentation techniques and data analysis. A bibliography on vortex flows is also prescribed.

"NAVIER-STOKES CALCULATION OF AERODYNAMIC CHARACTERISTICS OF WINGS IN VORTEX WAKE ENCOUNTER"

AIAA Paper No. 1997-2267, Atlanta, GA, June 1997

The main purpose of the paper is to use a Navier-Stokes solver to compute the induced aerodynamics on a wing intercepting the vortex wake of a generating wing. Viscosity plays an important role in developing a thick, deflected wake in the in-tunnel simulation. The present investigation is restricted to an axial penetration of the wake by the encountering wing. In addition to the induced rolling moment, the change in longitudinal aerodynamics with respect to the vertical position of the following wing relative to the upstream vortex-generating wing will also be investigated.

Ting, L.

"PERTURBATION PROBLEMS IN FLUID MECHANICS"

Report 92-11-06, November 1992, Courant Institute of Mathematical Sciences, New York NY.

Perturbation methods and numerical methods were employed to study five problem areas. (1) For viscous vortical flows, a complete account of the asymptotic analyses, numerical studies and their physical meaning was presented in Springer-Verlag Lecture Notes in 1991. An extension of the asymptotic analysis for the motion and diffusion of a slender vortex filament to allow for the variation of the core structure along the filament was accomplished in 1992. This extension was needed for the study of the vortex breakdown problem. (2) For shock wave interactions, the locations and the types of singularities in the interaction of semilinear waves in three- and higher dimensional space were identified. (3) For wave propagations in a bubbly liquid, a survey of the linear and nonlinear theories and their limitations was presented in an article in *Advances in Applied Mechanics* in 1991. A system of effective equations uniformly valid at small gas volume fraction and large bubble number density was derived in 1992. (4) For free boundary problems, solutions simulating the breaking up or merging of symmetric slender jets or thin sheets were obtained in 1990. The solution for drop formation after the breaking was formulated recently. (5) In the analysis of structural/acoustic interactions, the solution for the panel oscillation was uncoupled from that for the acoustic field by the recent formulation of the on-surface conditions considering the acoustic effect.

Ting, L.

"STUDIES IN THE MOTION AND DECAY OF VORTICES"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 11-39

Solutions of Navier-Stokes equations are constructed as an asymptotic expansion in terms of a small parameter related to the Reynolds number of the vortex. A general scheme is presented for the matching of the inner viscous core of the vortex to the outer inviscid solution. The singularities in the inviscid theory are removed and the condition of regularity in the flow field defines the velocity of the

vortex line. This general scheme is applied to study vortices in two dimensional, axially symmetric and in three-dimensional flow fields. Results for the outer solution which do or do not require the solution in the viscous core are obtained separately.

Ting, L.

"STUDIES ON THE MOTION AND DECAY OF A VORTEX FILAMENT"

Lecture Notes in Physics, Vol. 148, 1981, pp. 67-105.

A review of asymptotic analyses for the study of the motion and decay of a vortex filament submerged in a background potential flow is presented. Emphasis is placed on physical intuitions motivating the analyses and on the physical interpretation of the asymptotic solutions. The extension of the analyses to a vortex filament submerged in a rotational flow is outlined. The asymptotic analyses identify various canonical problems which require numerical solutions of the Navier-Stokes equations. These numerical studies in turn initiate new theoretical analyses.

Ting, L.

"ON THE MOTION AND DECAY OF A VORTEX IN A NON-UNIFORM STREAM"

PIBAL-851, August 1964, Polytechnic Institute of Brooklyn, Brooklyn, NY

A systematic procedure is presented for the study of the motion of a vortex in a two-dimensional, incompressible, nonuniform stream as a solution of the Navier-Stokes equations by the introduction of a small parameter ϵ , which is inversely proportional to the square root of the Reynolds number of the vortex. Two different sets of length and time scales are introduced. The set with longer length and time scales is identified with the typical scales of the outer nonuniform flow. The ratio of the two length scales and that of the time scales are powers of the small parameter ϵ . By the expansion of the solutions in the power of ϵ with appropriate time and length scales, it is shown that the outer solution of the Navier-Stokes equations will be the same as the inviscid solution, and the leading term in the

inner solution agrees with that of a decaying axially symmetric vortex. The singularity associated with an inviscid vortex is removed.

Ting, L. and Tung, C.

"MOTION AND DECAY OF A VORTEX IN A NONUNIFORM STREAM"

Phys. Fluids, Vol. 8, No. 6, June 1965, pp. 1039-1051

The motion of a vortex in a two-dimensional incompressible nonuniform stream is studied by including the viscous effects in the inner core of the vortex. A systematic procedure is presented by the introduction of two different sets of length and time scales with the larger scales identified with the typical scales of the outer nonuniform flow. The ratios of the scales are powers of the small parameter ϵ which is inversely proportional to the square root of the Reynolds number of the vortex. It is shown that the leading term of the solution to the Navier-Stokes equations is composed of the classical inviscid solution matched with the solution of a decaying axially symmetric vortex. Thus, the singularity in the center of the vortex associated with the classical inviscid theory is removed. The next-order solution shows that the time average of the velocity of the center of the vortex over a period of the order of the larger time scale should agree at least to the order of ϵ^2 with the local space mean of the velocity of the outer inviscid flow which has been assumed to be the velocity of the center of the vortex in the classical inviscid theory of vortex motion.

Ting, L., Klein, R. and Knio, O. M.

"ASYMPTOTIC THEORY OF SLENDER VORTEX FILAMENTS -- OLD AND NEW"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

We give a brief historical account of the asymptotic theories of the motion of slender vortices and the evolution of the core structures. We emphasize the motivations, the choice of length and time scales for a given problem and explain the physical meaning of the asymptotic solutions and the consistency conditions for the core structures. We present some highlights of the extensions of the asymptotic theories in the past decade. They include the use of multiple length scales in the axial variation of the core structure and in the interaction of filaments. The study of the interaction of filaments with a solid body and sound generation, and the applications of asymptotic theory to numerical simulations and experimental investigation of slender vortex dynamics are also presented. We then describe a few vortical flow problems currently under investigation.

Tingey, E. B. and Ning, A.

"PARAMETERIZED VERTICAL-AXIS WIND TURBINE WAKE MODEL USING CFD VORTICITY DATA"

AIAA Paper 2016-1730, January 2016, San Diego, CA.

In order to analyze or optimize a wind farm layout, reduced-order wake models are often used to estimate the interactions between turbines. While many such models exist for horizontal-axis wind turbines, for vertical-axis wind turbines (VAWTs) a simple parametric wake model does not exist. Using computational fluid dynamic (CFD) simulations, we computed vorticity in a VAWT wake, and parameterized the data based on normalized downstream positions, tip-speed ratio, and solidity to predict a normalized wake velocity deficit. When compared to CFD, which takes about a day to run one simulation, the reduced-order model predicts the velocity deficit at any location within 5-6 percent accuracy in a matter of milliseconds. The model was also found to agree well with trends observed in experimental data. Future additions will allow the reduced-order model to be used in wind farm layout analysis and optimization by accounting for multiple wake interactions.

Tinling, B. E.

"ESTIMATION OF VORTEX-INDUCED ROLL EXCURSIONS BASED ON FLIGHT AND SIMULATION RESULTS"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FA-RD-77-68, June 1977, pp. 11-22

The results of flight measurements at altitude were combined with an analytical procedure to estimate the wake vortex roll excursions for aircraft ranging in size from small business jets to jumbo jets. The roll excursion estimates were compared with a bank-angle boundary developed from piloted simulation. The estimates indicate that if the vortex from a jet transport of medium size or larger should be encountered out of ground effect at current separation distance standards, the resulting maximum bank angle exceeds the boundary for all following aircraft except the large heavy transports. The possible bank-angle excursion for small aircraft, even though their separation distances are greater, exceeds the boundary by a large amount. In view of this apparent hazard, it is reasoned that the current extremely low accident rate exists because the specified separation allows sufficient time for the vortices to be removed from the path of following aircraft by winds and by their mutual induction, and because the vortex strength is dissipated at low altitudes by ground effect.

Tinling, B. E.

"ESTIMATES OF THE EFFECTIVENESS OF AUTOMATIC CONTROL IN ALLEVIATING WAKE VORTEX INDUCED ROLL EXCURSIONS"

NASA TM X-73267, August 1977, NASA Ames Research Center, Moffett Field, CA

Estimates of the effectiveness of a model following type control system in reducing the roll excursion due to a wake vortex encounter were obtained from single degree of freedom computations with inputs derived from the results of wind tunnel, flight, and simulation experiments. The analysis indicates that the control power commanded by the automatic system must be roughly equal to the vortex induced roll acceleration if effective limiting of the maximum bank angle is to be achieved.

"FEDERAL AVIATION ADMINISTRATION WAKE TURBULENCE PROGRAM -- RECENT HIGHLIGHTS"

57th Air Traffic Control Association Annual Conference and Exposition, October 2012, Gaylord, MD.

The current paper highlights the recent progress and ongoing development of the Federal Aviation Administration's wake turbulence program activities. The relevance of the topic to NextGen and a brief historical account on the problem is given first. The paper then describes in some detail four specific wake turbulence solutions that are either being developed or implemented, which are (1) FAA Order 7110.308 authorizing simultaneous dependent approaches with 1.5nm diagonal separation to Closely Spaced Parallel Runways, (2) Wake Turbulence Mitigation for Departures (WTMD), (3) Wake Turbulence

Mitigation for Arrivals (WTMA) and (4) Wake Turbulence Recategorization. All of these solutions directly support NextGen's objective for capacity enhancement goals.

Tobin, N., Hamed, A. M. and Chamorro, L. P.

"AN EXPERIMENTAL STUDY ON THE EFFECTS OF WINGLETS ON THE WAKE AND PERFORMANCE OF A MODEL WIND TURBINE"

Energies, Vol. 8, October 2015, pp. 11955-11972.

Wind tunnel experiments were performed to investigate the effects of downstream-facing winglets on the wake dynamics, power and thrust of a model wind turbine. Two similar turbines with and without winglets were operated under the same conditions. Results show an increase in the power and thrust coefficients of 8.2 percent and 15.0 percent for the wingletted case. A simple theoretical treatment of a two-turbine system suggests a possible positive tradeoff between increasing power and thrust coefficients at a wind farm scale. The higher thrust coefficient created a region of enhanced mean shear and turbulence in the outer portion of the wake. The winglets did not significantly change the tip-vortex strength, but higher levels of turbulence in the far wake decreased the tip-vortex strength. Because of the increased mean shear in the wingletted turbine's wake, the Reynolds stresses were higher, potentially leading to a higher energy flux downstream.

Tobin, N., Hamed, A. M. and Chamorro, L. P.

"EXPERIMENTAL STUDY OF THE EFFECTS OF WINGLETS ON THE WAKE OF A MODEL WIND TURBINE"

APS Division of Fluid Dynamics, Abstract D28.002, November 2015, Boston, MA.

Wind tunnel particle image velocimetry was used to investigate the effects of winglets on the wake dynamics of a model wind turbine. The behavior of a turbine with downstream-facing winglets was compared with a turbine without winglets. The turbines were placed in a turbulent boundary layer that reached up to the hub height, allowing for investigation of behavior in both turbulent and uniform flow. The winglets did not significantly change the strength of the tip vortices in the region of uniform flow. The tip vortices in the more turbulent region, however, decayed much faster, diminishing to near-zero within the first about 1.5 rotor diameters, whereas the upper tip vortices persisted potentially up to about 4 rotor diameters. The winglets also increased the power coefficient by 7.5 percent, while increasing the coefficient of thrust by 10.0 percent. The higher coefficient of thrust created a region of enhanced mean shear in the outer portion of the wake, leading to increased turbulence statistics in the far wake. The wingletted turbine had a similar wake deficit at 5 rotor diameters as the base turbine did at 1.5 rotor diameters, with potential implications for using wingletted turbines in wind farms.

Tolhurst, Jr., W. H.

"AN INVESTIGATION OF THE DOWNWASH AND WAKE BEHIND LARGE-SCALE SWEEPED AND UNSWEEPED WINGS"

NACA RM-A7L05, February 1948, Langley Aeronautical Lab., Langley Field, VA

A wind-tunnel investigation has been conducted to determine, at large scale, the downwash angles, dynamic pressure loss, and wake width behind wings having sweep angles of plus/minus 45 degrees, plus/minus 30 degrees, and 0 degree. Data were obtained in a vertical transverse plane located at the probable tail position behind the wings for a region from the plane of symmetry to 0.7 semispan. The results of this investigation indicate that the spanwise distribution of downwash was affected by sweep in a manner like span loading, increased toward the root by sweepforward and toward the tip by sweepback. After the first appearance of stall the downwash near the root of the swept-forward wing decreased markedly, probably because of loss of lift, while the downwash near the root of the swept-back wing increased, probably because of inboard movement of the tip vortices. Sweep in the wing plan form modified the spanwise variation of wake thickness producing a thick wake near the root of swept-forward wings and near the tip of swept-back wings. At moderate to high angles of attack, sweep tends to keep the wake high.

Tomassian, J. D.

"THE MOTION OF A VORTEX PAIR IN A STRATIFIED MEDIUM"

Ph.D. Thesis, 1979, UCLA, Los Angeles, CA

An experiment was constructed to simulate and study the motion of a vortex pair in a stratified atmosphere. The vortex trajectories indicate that the pair initially accelerates and its separation decreases when stratification is dominating, in agreement with Crow's theoretical predictions. However, a short time later, the speed of the pair decreases and its separation increases in the stratified as well as the unstratified cases. A peak in the trajectories is observed to occur at an Nt of 2.4 for all Nb/V , in agreement with observations from real aircraft. The increase in separation is caused by turbulence, and the data agree with recent numerical computations of vortex pair trajectories in a stratified medium with turbulence. As stratification is increased, the separation and the speed of the pair decreases relative to the unstratified case due to counter-sign vorticity at the boundary of the recirculation cell. The vortex pair was unstable even though the tank geometry suppressed the long wave Crow mutual induction instability. The instability disappeared and the lifetime of the pair increased when one vortex interacted with its image across a rigid boundary, indicating a short-wave antisymmetric mode as the mechanism of instability. Core radii appear to be comparable to those of real aircraft. The reduced core size in the image plane experiments is due to the low levels of turbulence which results in reduced mixing.

"DO WIND TURBINES POSE ROLL HAZARDS TO LIGHT AIRCRAFT?"

18th Conference on Aviation, Range, and Aerospace Meteorology, January 2017, Seattle, WA.

Wind energy development has increased rapidly to now account for 4.7 percent of all electricity generation in the United States. Much of this development has occurred in rural locations, where open

spaces are also home to numerous local or 'general aviation' airports. Almost 40 percent of all wind turbines in the US exist within 10 km of a small airport. Wind turbines generate electricity by extracting momentum from the atmosphere, thereby creating wakes characterized by a wind-speed deficit and increased turbulence downwind. Recently, the concern that wind turbine wakes pose hazards for small aircraft has been used to limit wind farm development; however, conflicting estimates on the extent of the wake's hazardous influence still exist. As such, we use large-eddy simulations to examine the wake of a single turbine to assess hazards to small aircraft. Atmospheric measures of rotation (e.g. vorticity) were first examined, followed by wind-generated lift forces and subsequent rolling moments on hypothetical aircraft transecting the wake. Stable, unstable, and neutral cases are explored, with preliminary findings of the neutral case showing that discernible wake characteristics diminish by 10 rotor diameters downstream, and over 99.99 percent of rolling moments experienced by hypothetical planes during through-wake transects are classified as a 'low' roll hazard.

Tomaszewski, J. M., Lundquist, J. K., Churchfield, M. J. and Moriarty, P. J.

"DO WIND TURBINES POSE ROLL HAZARDS TO LIGHT AIRCRAFT?"

Wind Energy Science, Vol. 3, 2018, pp. 833-843.

Wind energy accounted for 5.6% of all electricity generation in the United States in 2016. Much of this development has occurred in rural locations, where open spaces favorable for harnessing wind also serve general aviation airports. As such, nearly 40% of all United States wind turbines exist within 10 km of a small airport. Wind turbines generate electricity by extracting momentum from the atmosphere, creating downwind wakes characterized by wind-speed deficits and increased turbulence. Recently, the concern that turbine wakes pose hazards for small aircraft has been used to limit wind-farm development. Herein, we assess roll hazards to small aircraft using large-eddy simulations (LES) of a utility-scale turbine wake. Wind-generated lift forces and subsequent rolling moments are calculated for hypothetical aircraft transecting the wake in various orientations. Stably and neutrally stratified cases are explored, with the stable case presenting a possible worse-case scenario due to longer-lasting wakes permitted by lower ambient turbulence. In both cases, only 0.001% of rolling moments experienced by hypothetical aircraft during down-wake and cross-wake transects lead to an increased risk of rolling.

"INFLUENCE OF METEOROLOGICAL FACTORS ON THE VORTEX WAKE OF A LIGHT, TWIN-ENGINE AIRCRAFT"

AFOSR-74-1507, March 1974, AeroVironment Inc., Pasadena, C.

The smoke-marked trailing vortex wake generated by a light, twin-engine aircraft (Aero Commander 560F) was probed by another instrumented aircraft and the velocity and temperature fields in the wake were measured. Ground-based cameras recorded overall wake motion and decay due to instabilities. It was determined that wakes descending in a stably stratified atmosphere acquire buoyancy and then

subsequently begin to lose it before they break up. The speed of descent of the wakes decreases with time, and the vortex spacing and the size of the buoyant oval both increase very slightly as the wake descends. A clear correlation between wake tilting and wind shear has been established, and it was determined that shear is one factor which causes the sometimes-observed single persistent vortex.

Tombach, I. H.

"MEASUREMENTS OF THE BEHAVIOR OF VORTEX WAKES OF AIR FORCE TACTICAL AIRCRAFT"

AV FR 654, June 1976, AeroVironment Inc., Pasadena, CA

The velocity fields induced by the trailing vortices generated by T-38, F-4, and A-7 aircraft flying over a 4-meter-high anemometer array were recorded. A total of 163 tests were flown, which encompassed both normal approach and holding configurations of the aircraft. Meteorological conditions were measured simultaneously for correlation with the velocity measurements.

Tombach, I. H.

"TRANSPORT OF A VORTEX WAKE IN A STABLY STRATIFIED ATMOSPHERE"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 41-56

Atmospheric stratification affects the downward motion of an aircraft vortex wake and influences the persistence and stability of the vortex pair configuration. Observations of actual wakes have shown significant variation in the distance to which they descend and in their lifetimes under different degrees of atmospheric stability. This behavior has been modeled analytically as a pair of infinite vortices in an inviscid, compressible, stably stratified atmosphere with entrainment characterized by a single parameter which is related to the difference between the density in a particular region of the wake and that external to the wake. It has been found that the motion of such a vortex system is governed by a parameter Q which depends on the initial circulation and vortex spacing, on the atmospheric stability, and on the entrainment parameter.

Tombach, I. H.

"TRANSPORT AND STABILITY OF A VORTEX WAKE"

MRI 72 FR-1010, April 1972, Meteorology Research Inc., Altadena, CA.

The influence of the atmospheric environment on the transport and decay of a trailing vortex wake has been studied. An analytic model describing the descending motion of an entraining wake in a stably stratified atmosphere has been developed. This model was compared with several other recent theoretical analyses and with limited experimental observations in order to determine the validity.

Tombach, I. H.

"OBSERVATIONS OF ATMOSPHERIC EFFECTS ON VORTEX WAKE BEHAVIOR"

J. Aircraft, Vol. 10, No. 11, November 1973, pp. 641-647

Smoke-marked trailing vortices were generated by a light aircraft under a hierarchy of measured atmospheric stability and turbulence levels and their motion and decay was recorded photographically. Decay from both sinuous vortex interaction and core bursting type instabilities occurred, with bursting being the dominant mode. Turbulence had a strong effect on wake life, with time-to-breakup for both modes varying as $\epsilon^{-1/3}$ to the $1/3$ power, where ϵ is the turbulent dissipation rate. Observed lifetimes ranged from 6 sec in light-to-moderate turbulence to more than 80 sec in calm, stable air. One exceptionally long-lived solitary vortex was observed for more than 3 min. Atmospheric stratification had a weak influence on wake life and its effect on wake descent could not be determined, since descent was often stopped by a rolling of the plane of the vortices. The observed data correlates well with a new theory for time-to-breakup.

Tombach, I. H.

"THE EFFECTS OF ATMOSPHERIC STABILITY, TURBULENCE AND WIND SHEAR ON AIRCRAFT WAKE BEHAVIOR"

Proceedings of the Sixth Conference on Aerospace and Aeronautical Meteorology, American Meteorology Society, 1974, pp. 405-41.

The properties of a smoke-marked wake from a light, twin-engine aircraft were measured experimentally. Correlations were made between wake motion and size and the atmospheric factors of wind, stability, turbulence, and wind shear.

Tombach, I. H. and Bate, Jr., E. R.

"STUDY OF THE MOTION AND PROPERTIES OF THE VORTEX WAKE OF A LIGHT TWIN-ENGINE AIRCRAFT"

AV FR-351, September 1973, AeroVironment Inc., Pasadena, CA.

The smoke-marked trailing vortex wake generated by a light twin-engine aircraft (Aero Commander 560F) was probed by another instrumented aircraft and the velocity and temperature fields in the wake were measured. Ground-based cameras recorded overall wake motion and decay due to instabilities. It was determined that wakes descending in a stably stratified atmosphere acquire buoyancy and then subsequently begin to lose it. The speed of descent of the wakes decreases slightly, and the vortex spacing and the size of the buoyant oval both increase as the wake descends. The tangential velocity around the vortices also decreases slightly as the wake ages. From the various observations it is concluded that representation of wake behavior in terms of an inviscid stage, an entraining stage, and a decaying stage is valid and useful. An experiment was performed to evaluate the effect of the motion of a wing-mounted drag-flap on vortex instabilities. The flap was found to affect vortex-behavior, but a complete assessment of its effectiveness will require further tests.

"INVESTIGATION OF THE MOTION AND DECAY OF THE VORTEX WAKE OF A LIGHT TWIN-ENGINE AIRCRAFT"

AV-FR-439, October 1974, AeroVironment Inc., Pasadena, CA

The properties of the smoke-marked trailing vortex wake generated by a light, twin-engine aircraft (Aerocommander 560F) were investigated experimentally. Velocity and temperature fields in the wake were measured by another instrumented probe aircraft. Ground-based and airborne cameras recorded the motion and decay of the smoke-marked vortices. A clear correlation between wake tilting and wind shear transverse to the wake was observed. The measured descent speed of wakes decreased with time in a stable atmosphere, and the spacing between the vortex pair and the size of the buoyant wake oval both increased slightly as the wake descended. Termination of the organized motion in the wakes was always brought about by vortex instabilities, with vortex breakdown (bursting) predominating for the aircraft scale and flight conditions investigated.

"INVESTIGATION OF VORTEX WAKE STABILITY NEAR THE GROUND"

AFOSR TR-75-1501, July 1975, AeroVironment Inc., Pasadena, CA

The sinuous mutual induction instability of a vortex pair has been investigated theoretically and experimentally in atmospheric conditions which prevail near the aground. Two theoretical models were developed - one for a vortex pair in the constant stress layer of the atmospheric boundary layer, and the second for a vortex interacting with its image when in ground effect. The theoretical results show that the proximity of the ground shortens wake lifetime by up to 10% compared to the results aloft. The experimental data agrees satisfactorily with the theoretical predictions.

Tombach, I. H., Lissaman, P. B. S. and Mullen, J. B.

"AIRCRAFT VORTEX WAKE BEHAVIOR AND DECAY NEAR THE GROUND"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 297-309

One of the apparent modes of decay of aircraft wake vortices has been variously described as vortex breakdown or vortex bursting, the latter because of the visual appearance of this decay mode when the vortices are marked with smoke. A multi-faceted experimental and analytical research program was carried out to explore the details of vortex breakdown under conditions representative of those which would prevail at low altitudes in the vicinity of airports. Three separate approaches were taken simultaneously. Flight tests with Lockheed L-18 Lodestar and Boeing 747 aircraft flying over an array of ground-based cameras and instrumentation provided data on overall vortex behavior, on the vortex

ages at the time of onset of instabilities, and on the changes in the vortex velocity fields which resulted from vortex breakdowns. Analytical work on stability theories identified conditions under which vortices could undergo unstable decay. Experimental tests in a water tank looked at the internal instability of vortices, and also shed light on vortex motion near the ground. Finally, a heuristic modeling approach consolidated the results of these programs into a simple representation of the relationship between the times of vortex breakdowns and the ambient turbulence levels.

"IMPACT OF DIFFERENT WAKE MODELS ON THE ESTIMATION OF WIND FARM POWER GENERATION"

AIAA Paper 2012-5430, September 2012, Indianapolis, Indiana.

The power generation of a wind farm is significantly less than the summation of the power generated by each turbine when operating as a standalone entity. This power reduction can be attributed to the energy loss due to the wake effects -- the resulting velocity deficit in the wind downstream of a turbine. In the case of wind farm design, the wake losses are generally quantified using wake models. The effectiveness of wind farm design (seeking to maximize the farm output) therefore depends on the accuracy and the reliability of the wake models. This paper compares the impact of the following four analytical wake models on the wind farm power generation: (i) the Jensen model, (ii) the Larson model, (iii) the Frandsen model, and (iv) the Ishihara model. The sensitivity of this impact to the Land Area per Turbine and the incoming wind speed is also investigated. The wind farm power generation model used in this paper is adopted from the Unrestricted Wind Farm Layout Optimization methodology. Single wake case studies show that the velocity deficit and the wake diameter estimated by the different analytical wake models can be significantly different. A maximum difference of 70 percent was also observed for the wind farm capacity factor values estimated using different wake models.

"CHAOTIC SCATTERING OF TWO IDENTICAL POINT VORTEX PAIRS REVISITED"

Physics of Fluids, Vol. 20, 2008, pp. 093605-1 - 093605-10.

A new numerical exploration suggests that the motion of two vortex pairs, with constituent vortices all the same absolute circulation, displays chaotic scattering regimes. The mechanisms leading to chaotic scattering are different from the slingshot effect identified by Price and occur in a different region of the four-vortex phase space. They may, in many cases, be understood by appealing to the solutions of the three-vortex problem obtained by merging two like-signed vortices into one of twice the strength and by assuming that the four-vortex problem has unstable periodic solutions like those seen in the thereby associated three-vortex problems. The integrals of motion, linear impulse and Hamiltonian are recast in a form appropriate for vortex pair scattering interactions that provides constraints on the parameters characterizing the outgoing vortex pairs in terms of the initial conditions.

"MERGING OPTIMIZATION METHOD CONSIDERING MINIMUM TIME SEPARATION BASED ON WAKE VORTEX CATEGORY"

AIAA Paper 2018-1596, January 2018, Kissimmee, FL.

To advance air traffic control, the merging optimization method has been studied. This method simultaneously optimizes the trajectory and sequence of the arrival aircraft while maintaining a sufficient time separation at the merging point to avoid wake turbulence. In this study, the minimum time separation based on the wake turbulence category is applied to the merging optimization method. The separation standards are stipulated by the wake turbulence category based on the sizes of the leading and following aircraft. Considering the wake turbulence category is one of the key techniques for implementing the merging optimization method in practical air traffic control. Numerical simulations are performed to show the validity of the proposed method. The simulation results are compared with those of the merging optimization method with a specified sequence to review the optimality of the proposed method. The simulation results show that the merging optimization method can optimize the merging trajectories considering the minimum time separation based on the wake turbulence category.

"WAKE VORTEX ENCOUNTER LOADS. FLIGHT TESTS AND NUMERICAL SIMULATIONS"

ICAS 2014, September 2014, St. Petersburg, Russia.

The paper will present the wake vortex encounter (WVE) problem from a dynamic loads standpoint. The numerical simulation methodology and assumptions for loads calculation will be explained, as well

as the models and tools used for that purpose. An extensive Flight Test campaign has been dedicated to study the phenomenon and validate the overall loads calculation process. Some parametric studies, devoted to a better understanding of the phenomenon and its sensitivities to some geometrical parameters will also be presented. Finally, a stochastic approach to the loads calculation has been performed to link the loads levels with their probabilities. This kind of approach will permit to assess the definition of wake vortex scenarios for future regulations.

"IMPROVED UNSTEADY FAR-FIELD DRAG BREAKDOWN METHOD AND APPLICATION TO COMPLEX CASES"

AIAA Journal, Vol. 54, No. 6, June 2016, pp. 1907-1921.

Far-field drag extraction has the advantage over near-field integration of providing a phenomenological breakdown of drag. A decomposition into components linked to shock waves, viscous interactions, and lift-induced vortices is straightforward for steady flows. A formulation based on thermodynamic considerations is used at ONERA - The French Aerospace Lab and by its partners, but it is restricted to steady cases. A generalization to unsteady flows of the Van der Vooren formulation has been developed and tested on three unsteady cases previously. The proposed method allowed the breakdown of drag into the three usual components only; however, the induced drag coefficient remained ill-defined. This unsteady formulation is here modified to better express the induced drag. A new drag component is identified as a propagation and acoustic contribution. The new formulation is then applied to complex cases: two-dimensional and three-dimensional pitching cases, and an OAT15A profile subject to buffet simulated by zonal detached-eddy simulation computations.

"THE EFFECTS OF INSTALLING VORTEX ATTENUATING DEVICES ON THE DESIGN, PERFORMANCE, AND OPERATIONS OF A HEAVY COMMERCIAL JET TRANSPORT"

D6-34174, October 1975, Boeing Commercial Airplane Company, Seattle, W.

The effect of two trailing vortex attenuation concepts on the design, performance, and operations of an existing heavy jet transport have been investigated. The two concepts studied are the trailing-edge spline and high thrust on the outboard engines. Losses in takeoff, landing, and mission performance, along with potential operational problems, have been identified and feasibility recommendations have been made.

Traub, L. W.

"EFFECTS OF TAPER RATIO ON TRAILING VORTEX STRUCTURE"

Aero. J., Vol. 100, No. 996, June/July 1996, pp. 252-254

A theoretical study was undertaken to determine the effect of taper ratio on the trailing vortex structure of a high aspect ratio unswept wing. The wing was modelled using lifting line theory, and the vortex was assumed to have a Rankine distribution of circulation. The results show that reducing the taper ratio of the wing decreases the maximum tangential velocity of the vortex as well as the vortex span while the core's diameter increases. Data is also presented showing the sensitivity of induced drag to wake vortex parameters.

Traub, L. W. and Agarwal, G.

"AERODYNAMIC CHARACTERISTICS OF A GURNEY/JET FLAP AT LOW REYNOLDS NUMBERS"

J. Aircraft, Vol. 45, No. 2, March-April 2008, pp. 424-429

A low-speed wind-tunnel investigation has been undertaken to establish the effect of a Gurney flap used in conjunction with a jet flap at low Reynolds numbers. The characteristics of the combination were explored as a potential control effector for small unmanned aerial vehicles. Measurements included force balance, wake survey, and flow visualization. The results indicate that the jet flap maintains a theoretically determined dependence on the jet momentum coefficient, even at a low Reynolds number (160,000). A numerical lifting-line program was modified to allow estimate of the rolling moment that may be generated by ailerons composed of a Gurney/jet flap. The numerical data suggest that the jet flap can generate significant rolling moments with realistic jet momentum coefficients.

Traub, L. W. and Nurick, A.

"EFFECTS OF WING-TIP VORTEX FLAPS"

J. Aircraft, Vol. 30, No. 4, July-August 1993, pp. 557-560

The trailing vortex system of a finite lifting wing induces a downwash, and consequently a rotation of the freestream velocity vector giving rise to vortex drag. The importance of wing tip geometry in the generation of vortex drag has propagated several tip-mounted drag reducing devices aimed at improving wing efficiency. Successful concepts include winglets and tip sails.

"APPLICATION OF THE VORTEX BREAKDOWN PHENOMENON IN THE ATTENUATION OF TRAILING VORTICES"

Aeronautical Journal, Vol. 102, No. 1018, October-December 1998, pp. 439-444

An experimental investigation to determine the effectiveness of a wing-tip device designed to attenuate the trailing vortex of a lifting, flat-plate wing is detailed. The induced-breakdown vortex

attenuation device (IBVAD) is essentially a toed-in, vertically-oriented sheared tip. Results are presented comprising force-balance, water tunnel flow visualization, and wake studies using a seven-hole probe. The data show that compared with an equal-span rectangular wing, variations of the IBVAD device can reduce drag at moderate-to-high lift coefficients, as well as reduce the maximum rotary velocity of the trailing vortex by 28 percent. Axial vorticity in the wake vortex was significantly attenuated compared with the rectangular wing, with a 52.6 percent reduction in the magnitude of the maximum vorticity. The vortex core radius was also seen to be larger than the rectangular wing. However, even substantial attenuation and redistribution of trailing vorticity may be insufficient to reduce the wake hazard.

"INTERNAL GRAVITY WAVE GENERATION BY VORTEX WAKES"

AFOSR-TR-77-1309, December 1977, Martin Marietta Corp., Baltimore, MD.

The investigation focused on various details relating to the numerical prediction of vortex wakes. Contributions are described to the reduction of false transport effects and the prediction of the descent velocity of an unsteady, viscous strongly interacting vortex distribution.

Traugott, S. C.

"VISCOUS DECAY OF A TWO-DIMENSIONAL INTERACTING VORTEX PAIR"

Bull. Am. Physical Society, Vol. 20, No. 11, November 1975, p. 1428

The far downstream stage of decay of a stable vortex wake behind an aircraft is simulated by a rectilinear counter-rotating vortex pair. A numerical finite difference calculation is used to follow the evolution of an initially prescribed vorticity distribution under the action of viscosity. The initial vorticity distribution is not concentrated in cores but is continuously distributed according to an analytical steady inviscid solution which represents the two-dimensional analog of Hill's spherical vortex. There is initially no jump in vorticity at the boundary between inner and outer flow, and the numerical results then describe distortion and decay as the vortices annihilate each other.

"AERIAL SPRAYING: A SIMULATION OF FACTORS INFLUENCING THE DISTRIBUTION AND RECOVERY OF LIQUID DROPLETS"

Journal of Agricultural Engineering Research, Vol. 22, Issue 2, June 1977, pp. 183-196.

A computer model has been developed and used to assess the effects of wing tip vortices, crosswind, height, evaporation, and propeller swirl on the trajectories of droplets emitted from an agricultural

aircraft. The ground deposits resulting from the simulation suggest restraints on the design of an aircraft nozzle layout. The results and their method of presentation are discussed.

Trieling, R. R., Dam, C. E. C. and van Heijst, G. J. F.

"DYNAMICS OF TWO IDENTICAL VORTICES IN LINEAR SHEAR"

Physics of Fluids, Vol. 22, 2010, pp. 117104-1 - 117104-13.

The dynamics of two identical vortices in linear shear was studied both numerically and experimentally. Numerical simulations based on the technique of contour dynamics reveal that the vortex evolution in adverse shear is significantly different from that in cooperative shear. Vortices in adverse shear predominantly separate, whereas vortices in cooperative shear predominantly merge. In addition, adverse shear may destruct the vortices much in the same way as a single vortex in adverse shear, whereas cooperative shear stabilizes the vortices and thus enhances the possibility of vortex merger. The critical distance for vortex merger depends strongly on both the sign and the

"INTERACTION OF TWO UNEQUAL COROTATING VORTICES"

Physics of Fluids, Vol. 17, 2005, 087103-1 to 087103-17

Previous high-resolution contour dynamics calculations [Dritschell and Waugh, Phys. Fluids A 4, 1737 (1992)] have shown that in two-dimensional inviscid flow the interaction of two unequal corotating vortices with uniform vorticity is not always associated with vortex growth and may lead to vortices smaller than the original vortices. In the present study, we investigate whether these results also hold for two-dimensional vortices with continuous vorticity distributions. Similar flow regimes are found as for uniform vorticity patches, but the variation of the flow regimes with the initial vortex radii and peak vortices is more complicated and strongly dependent on the initial shape of the vorticity profile. It is found that the 'halo' of low-value vorticity, which surrounds the cores of continuous vortices, significantly increases the critical distance at which the weaker vortex is destroyed. The halo also promotes the vortex cores to merge more efficiently, since it accounts for a substantial part of the loss of circulation into filaments. Simple transformation rules and merger criteria are derived for the inviscid interaction between two Gaussian vortices. The strong dependence of the flow regimes on the initial vorticity distribution partly explains why previous laboratory experiments in an electron plasma [Mitchell and Driscoll, Phys. Fluids 8, 1828 (1996)] show complete merger of two unequal vortices in a range of parameter space where contour dynamics simulations with uniform vorticity patches predict partial merger or partial straining-out of the smaller vortex. It is shown that the measured times for complete merger are in reasonable agreement with inviscid dynamics when the vortices are very similar. For more distinct vortices the weaker vortex is often observed to be destroyed on a time scale much smaller than expected from inviscid numerical simulations. An explanation for this discrepancy is given by the combined effects of vortex stripping and viscous diffusion, which leads to an enhanced

erosion of the weaker vortex. These results are verified by laboratory experiments in a conventional (rotating) fluid.

Trier, S. B.

"MODELING STUDIES OF TURBULENCE MECHANISMS ASSOCIATED WITH MESOSCALE CONVECTIVE SYSTEMS"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 17, 2016, Springer International Publishing Switzerland, pp. 335-356.

High-resolution numerical simulations have aided recent understanding of mechanisms responsible for convectively induced aviation turbulence (CIT) spatially removed from its parent moist convection. Anticyclonic jets occurring near the tropopause, which are often significantly enhanced by mesoscale convective systems or other forms of organized convection, influence a variety of different mechanisms of turbulence at commercial aviation cruising altitudes. Herein, we describe different CIT mechanisms that are possible near these anticyclonic outflow jets and illustrate them with examples from recent simulations.

"THE ASYMPTOTIC STUDY OF DISSIPATION AND BREAKDOWN OF A WING-TIP VORTEX"

J. Fluid Mech., Vol. 274, 1994, pp. 293-337

The steady axisymmetrical wing-tip vortex is studied in this paper by means of asymptotic methods within the limit of high Reynolds numbers. The smooth regrouping of the vortex under the action of viscous forces is described by a quasi-cylindrical approximation. The solutions of the quasi-cylindrical approximation are thoroughly analyzed numerically and it is shown that a saddle-point bifurcation appears at certain critical values of circulation. At these values the solution may be continued in two ways: as a supercritical branch which approaches the Batchelor limit far downstream; and a subcritical one, which passes the second, nodal-point bifurcation. The parabolic quasi-cylindrical equations past this point allow the downstream disturbances to propagate upstream, like for example, boundary-layer equations in the regime of strong hypersonic interaction. The flow past the second bifurcation point was studied numerically and it was shown that solutions of the quasi-cylindrical approximation with large reversed-flow regions exist. An asymptotic expansion of such solutions far downstream was constructed, and it turned out that the reversed-flow region expands exponentially. This process is halted by elliptical effects in the external flow. An asymptotic theory of large reversed-flow regions is suggested including viscosity and elliptical effects. Numerical solutions for unbounded vortex breakdown parabolically expanding far downstream are presented. Then the general asymptotic problem statement which describes the flow near the bifurcation points is used to study the asymptotic solutions near the first bifurcation point. The problem is investigated numerically and two kinds of solution, which may be treated as transcritical jumps and marginal vortex breakdown, are found and discussed.

"METHODOLOGY FOR ROTORCRAFT BROWNOUT MITIGATION THROUGH FLIGHT PATH OPTIMIZATION"

Journal of Guidance, Control and Dynamics, Vol. 37, No. 5, September-October 2014, pp. 1524-1538.

A methodology is presented for the selection of approach-to-landing maneuvers that may result in improved brownout characteristics. The methodology is based upon a brownout metric that assesses the relative brownout cloud volume densities in critical regions of the pilot's field of view. The metric becomes the objective function of a procedure in which a typical visual approach profile is parameterized and optimized to minimize brownout in a representative landing maneuver. The optimization is constrained to avoid maneuvers that would be conducive to the onset of vortex ring state or would result in flight within the 'avoid' regions of a typical helicopter height-velocity diagram. The analysis uses a free-vortex wake model and simulates the dynamics of the dust particles immersed in the rotor downwash. The results show that the optimal approach trajectories affect the resulting flowfield, particularly the development of a ground vortex ahead of the rotor disk, which influences the rate of development, size, and volume density of the brownout cloud. The results are compared with prior experimental results, and potential operational interpretations of the outcomes are examined.

"AIR AND SEA SURFACE TEMPERATURE MEASUREMENTS USING A 60-GHZ MICROWAVE ROTATING RADIOMETER"

IEEE Transactions on Geoscience and Remote Sensing, Vol. 36, No. 1, January 1998, pp. 3-15.

Data obtained from a single-channel scanning 5-mm radiometer on a research vessel were used for the study of sea surface temperature and lower-atmospheric temperature profiles under neutral, weakly stable, and unstable conditions. Comparisons with in situ air and water temperature measurements, dropsonde temperature data, radiosonde data, and VV Ku-band side-looking radar images are presented. The technique based on 5-mm measurements determines the air-skin water (skin depth of 0.3 mm) temperature difference with an accuracy of the order of 0.1 K. Analysis of the experimental data suggests that the air-skin water temperature difference depends weakly on solar heating and wind speed V for $2.5 < V < 9$ m/s.

"COMPARISON OF THE WAKE OF DIFFERENT TYPES OF WIND TURBINE CFD MODELS"

AIAA Paper No. 2012-0237, January 2012, Nashville, TN.

The wake of the NREL 5MW wind turbine was simulated using CFD with a fully resolved rotor geometry, an actuator line method and actuator disc method, respectively. Simulations were carried out prescribing both uniform and turbulent inflow and the wake properties predicted by the three models were compared. The actuator disc and line methods were in very close agreement for uniform inflow using RANS, whereas the gradients were smeared more rapidly in the fully resolved rotor wake. In uniform inflow using DES the fully resolved rotor wake broke up approximately 1D downstream, where the actuator disc and line wakes remained stable. In the simulations with turbulent inflow the wakes behind the actuator line and fully resolved rotor were in very close agreement, indicating that the differences observed in uniform inflow do not play an important role if the inflow is turbulent.

"NUMERICAL SIMULATION OF NORMAL- AND OBLIQUE-SHOCK VORTEX INTENSITIES"

Journal of Applied Mathematics & Mechanics, Vol. 80, Supplement 1, 2000, pp. S181-S182.

The dependence of the breakdown topology on the shock-vortex interaction conditions is numerically investigated. Based on solutions of the Euler equations the unsteady three-dimensional flow field is studied at several freestream Mach numbers and for normal and oblique shocks. The results of the finite-volume method using the AUSM approach indicate a strong dependence of the recirculation region downstream of the shock on the shock induced pressure gradient and on the vortex strength.

"WAKE TURBULENCE AND THE JUMBO JETS - WHOSE RESPONSIBILITY, PILOT OR CONTROLLER"

Annals of Air and Space Law, Vol. 3, 1978, pp. 269-28.

Case law regarding the wake turbulence danger for small aircraft operating near jumbo jets is reviewed. One of the questions arising in the cases studied is whether the controller has a duty to provide wake turbulence warnings, or whether it is the pilot's duty to avoid the vortices. A finding of wake turbulence does not necessarily mean that the Government bears responsibility for negligence; the determination of duty and proximate cause is essential to the resolution of the cases.

"TURBULENT VELOCITY SPECTRA FROM LASER DOPPLER DATA"

3rd ONERA-DLR Aerospace Symposium, June 2001, Paris, pp. S4-3/1-13.

This contribution reviews the estimation of spectra from laser Doppler data and provides some recommended guidelines. It is shown that reliable spectral estimates can be achieved for frequencies well beyond the mean data rate. The estimators discussed here exhibit some further advantages when used for processing data from multi-point measurements, used for spatial correlations. Some final remarks are directed towards the ramifications of these procedures on the optical system design.

Tsirkunov, Y. M., Lobanova, M. A., Tsvetkov, A. I. and Schepanyuk, B. A.

"LARGE-SCALE VORTEX STRUCTURE OF FLOW IN THE NEAR WAKE BEHIND AN AIRLINER DURING TAKEOFF AND LANDING"

ICAS-2016-0666, September 2016, Daejeon, Korea.

The large-scale flow vortex structure in the near-field wake of airliner moving on the runway during its takeoff and landing was investigated numerically based on a RANS approach with the SST turbulence model using ANSYS soft. Numerical results are compared with the ones obtained earlier for a cruising flight, and they are added by experimental data in the wind tunnel.

"EFFECT OF THE WING TRAILING-EDGE FLAPS AND SPOILERS POSITION ON THE JET-VORTEX WAKE BEHIND AN AIRCRAFT DURING TAKEOFF AND LANDING RUN"

7th European Conference for Aeronautics and Space Sciences (EUCASS 2017), July 2017, Milan, Italy.

The large-scale vortex structure of flow in the near wake behind an aircraft during its run on a runway is investigated numerically. The geometrical aircraft configuration was taken close to a mid-range commercial aircraft like Boeing 737-300. It included all essential elements: a body (fuselage), wings with winglets, horizontal and vertical stabilizers, engine nacelles, nacelle pylons, inboard flap track fairings, leading-edge and trailing-edge flaps, and spoilers. Flaps and spoilers position corresponded to the takeoff and landing run condition. Computational simulation was based on solving the Reynolds averaged Navier-Stokes equations closed with the Menter SST turbulence model. Patterns of streamlines, fields of the axial vorticity and the turbulent intensity, vertical and horizontal velocity profiles in the wake are compared and discussed for both run regimes. The flow model was preliminary tested for validity by comparison of the calculated velocity profiles behind a small-scaled aircraft model with those obtained in special wind tunnel experiments.

"FLOW VISUALIZATION ABOUT WAKE VORTEX CAVITATION WITH PIV SYSTEM"

Nihon Kikai Gakkai Nenji Taikai Koen Ronbunshu, Vol. 2, 2001, pp. 255-256 (In Japanese).

It is well known that the regular vortex shedding process named Karman vortex streets always occurs in the wake behind bluff bodies under high Reynolds number. The wake flow with cavitation has the same process and the Strouhal number depends on the cavitation number. But, the interference mechanism between the vortex shedding process and cavitation scale has not been clarified. This study investigated the flow visualization about wake vortex cavitation behind a wedge at several cavitation numbers by using PIV and LDV systems. The vortex shedding process had two modes corresponding to

the cavitation number. To examine this mechanism, the flow visualization was executed by using the method which lays the vector map on top of the image map.

Tucker, H. G.

"DIRECTIONAL ANEMOMETER FOR NEAR-GROUND AIRCRAFT VORTEX WAKE DETECTION"

National Research Council Canada Bulletin, Vol. 8, No. 2, July 1976

The Control Systems and Human Engineering Laboratory in the Division of Mechanical Engineering is currently developing a specialized anemometer which is based on the deflection of a turbulent air jet and is capable of simultaneously measuring the direction and mean magnitude of the horizontal wind velocity component as well as the fluctuations of the vertical wind velocity component. This instrument has potential application in increasing the utilization rate of airfield landing strips by detecting and monitoring vortex wakes generated during landings and take-offs. In particular, the instrument may be readily designed to exceed the reliability, sensitivity and dynamic response requirements while being cost effective relative to other anemometers of at least comparable performance.

Tucker, V. A.

"GLIDING BIRDS: REDUCTION OF INDUCED DRAG BY WING TIP SLOTS BETWEEN THE PRIMARY FEATHERS"

Journal of Experimental Biology, Vol. 180, July 1993, pp. 285-310.

The feathers at the wing tips of most birds that soar over land separate both horizontally and vertically in flight to form slotted tips. The individual feathers in the slotted tips resemble the winglets used on the wing tips of some aircraft to reduce induced drag. A wing that produces lift leaves a pair of vortex sheets in its wake. Wing theory shows that winglets can reduce the kinetic energy left in the vortex sheets, and hence the induced drag, by spreading vorticity both horizontally and vertically. This paper describes the aerodynamic forces on a wing made of a base wing and different wing tips. The feathered wing tip was slotted and was made of four primary feathers from a Harris' hawk (*Parabuteo unicinctus*). The Clark Y tip was unslotted and was made of balsa wood shaped to a Clark Y airfoil. The balsa feather tip was slotted and was made of three balsa wood wings shaped like feathers.

"BEHAVIOR OF WAKE VORTICES NEAR THE GROUND OVER A LARGE RANGE OF REYNOLDS NUMBERS"

Aerospace Science and Tech., Vol. 3, No. 2, February 1999, pp. 71-81

Recent numerical simulations of the wake vortex behavior close to the ground cover a Reynolds number range that is far below the realistic value of 10×10^7 - 10×10^8 . Therefore, one goal of the study was the expansion of the range of simulated cases to Reynolds numbers up to 3.33×10^6 . Another goal was the prediction of the maximum altitude the vortices reach during and after their various rebounds. It is shown that the strength of the wake vortex flow behind large aircraft is not reduced by the wake vortex ground interaction and that the vortex aging is extremely slow, at least if a laminar and two-dimensional flow is assumed. The high Reynolds number wakes of big aircraft show a conservation of the primary vortex circulation and a negligible growth rate of the vortex core radii.

Tulin, M. P. and Schwartz, J.

"THE MOTION OF TURBULENT VORTEX-PAIRS IN HOMOGENEOUS AND DENSITY STRATIFIED MEDIA"

TR-231-15, April 1971, Hydronautics Inc., Laurel, MD

A theory for the motion of two-dimensional turbulent vortex pairs in homogeneous media has been developed based on separate velocity scaling of the internal and external flow fields involved in the motion and considering variations in volume, circulation, momentum, and energy. Based on the results obtained from this theory a simplified theory is derived to deal with the rising motion of turbulent vortex pairs in stratified media. The theoretical results are compared with systematic experimental observations.

Tung, C. and Lim, J.

"ANALYSIS OF ROTOR VORTREX WAKE STRUCTURE USING 3-C PIV MEASUREMENTS"

In Vortex Dominated Flows, edited by D. Blackmore, E. Krause and C. Tung, 2005, World Scientific, New Jersey, Chapter 13, pp. 229-249.

Three-component (3-C) PIV measurements of a model rotor wake in descent flight are analyzed. The measuring PIV plane is always cutting the vortex with an angle. Another difficulty is the convective velocity of the vortex wake is not known accurately either. The measured vortex wake geometry has been used to determine the convection velocity. For three closely adjacent points along the curved vortex, one may fit a circular arc. The orientation of the PIV measuring plane to the plane that is normal to the curved vortex at the middle point can be easily determined by the geometry of these three points. Both vortex core radius and peak swirl velocity are smaller in the resolved normal plane than the one obtained in the measuring plane. Vortex formation, structure and decay are also discussed.

"PREDICTION AND MEASUREMENT OF BLADE-VORTEX INTERACTION LOADING"

1st Joint CEAS/AIAA Aeroacoustics Conf., June 1995, Munich, Germany.

An extensive quantity of airload measurements was obtained for a pressure-instrumented model of the BO-105 main rotor for many higher-harmonic control settings at Duits-Nederlandse Wind Tunnel. The wake geometry, vortex strength, and vortex core size were also measured through a laser light sheet technique and LDV. These results are used to verify the BVI airload prediction methodologies developed by AFDD, DLR, NASA Langley, and ONERA. The comparisons show that an accurate prediction of the blade motion and the wake geometry is the most important aspect of the BVI airload predictions.

Tung, C., Pucci, S. L., Caradonna, F. X. and Morse, H. A.

"THE STRUCTURE OF TRAILING VORTICES GENERATED BY MODEL ROTOR BLADES"

Vertica, Vol. 7, No. 1, 1983, pp. 33-43

The present study is one of a series of tests employing hot-wire anemometry to investigate the effects of blade geometry on vortex structure. These tests cover a range of aspect ratios and blade twist. For all configurations, measured vortex strength correlates well with maximum blade-bound circulation. Measurements of wake geometry agree with classical data for high aspect ratios. The detailed vortex structure is like that found for fixed wings and consists of four well-defined regions - a viscous core, a turbulent mixing region, a merging region, and an inviscid outer region. All high aspect ratio data are described by a single set of empirical formulas.

Tung, C., Russell, J. W. and Sankar, L. N.

"MODIFICATIONS OF THE TIP VORTEX STRUCTURE FROM A HOVERING ROTOR USING SPOILERS"

IUTAM Symposium on Dynamics of Slender Vortices, Aachen, Germany, August 31-September 3, 1997

Numerical studies of the tip vortex structure from a hovering rotor with and without various spoilers are presented. A general multizone unsteady three-dimensional Navier-Stokes solver is developed to determine the flowfield. A scheme that is fifth-order accurate in space and first-order accurate in time is used to improve the capturing of the tip vortex. Velocity data from the core of the vortex is studied at various planes behind the blade trailing edge. Computations of this velocity data for a clean rotor are first compared with experimental results obtained for the same rotor test case. Three different trailing edge spoiler configurations are then investigated to see if the tip vortex structure can be favorably altered.

Tung, C., Yu, Y. H. and Low, S. L.

"AERODYNAMIC ASPECTS OF BLADE-VORTEX INTERACTION (BVI)"

AIAA Paper No. 1996-2010, New Orleans, June 199.

This paper presents a review of the blade-vortex interaction (BVI) phenomenon. Both analytical and experimental studies of two-dimensional parallel airfoil-vortex interaction, three-dimensional BVIs, and helicopter rotor BVIs are covered. The important parameters that affect the BVI airloads are discussed.

Tur, A. and Yanovsky, V.

"POINT VORTICES WITH A RATIONAL NECKLACE: NEW EXACT STATIONARY SOLUTIONS OF THE TWO-DIMENSIONAL EULER EQUATION"

Physics of Fluids, Vol. 16, No. 8, August 2004, pp. 2877-2885

In this paper we find a new class of explicit exact stationary solutions of the two-dimensional (2D) Euler equation which describe vortex patterns of necklace type with $N + 1$ -fold symmetry in rotational shear flow. The point vortex with a strength equal to plus/minus $4\pi N$ (where N -integer number) is situated in the center of the vortex structure. The vorticity distribution outside of the center is smooth and is described by a two-parametric family of rational functions which are known in explicit form for any N . In the centers of vortex satellites the vorticity does not have any singularity and remains of finite value. When N is increasing, the solutions describe the transition layer in 2D-rotational shear flow.

Turchak, L. I.

"VORTEX SAFETY IN AVIATION"

Application of Mathematics in Technical and Natural Sciences, AIP Conference Proceedings 1487, 2012, pp. 49-62.

The objective is the general review of impact of aircraft wake vortices on the follower aircraft encountering the wake. Currently, the presence of wake vortices past aircraft limits the airspace capacity and flight safety level for aircraft of different purposes. However, wake vortex nature and evolution have not been studied in full measure. A mathematical model simulating the process of near wake generation past bodies of different shapes, as well as the wake evolution after rolling-up into wake vortices (far wake) is developed. The processes are suggested to be modeled by means of the Method of Discrete Vortices. Far wake evolution is determined by its complex interaction with the atmosphere and ground boundary layer. The main factors that should be considered are: wind and ambient turbulence 3D-distributions, temperature stratification of the atmosphere, wind shear, as well as some others which effects will be manifested as considerable during the investigation. The ground boundary layer effects on wake vortex evolution are substantial at low flight altitudes and are determined through the boundary layer separation.

Turkgeldi, I. E. and Kandil, O. A.

"DEVELOPMENT AND APPLICATION OF ADAPTIVE DYNAMIC GRID FOR WAKE-VORTEX/GROUND INTERACTION"

AIAA Paper No. 2000-0789, Reno, NV, January 2000.

An adaptive dynamic grid method for wake vortex/ground interaction problems is developed and its effects on the solution accuracy have been investigated. The unsteady full Navier-Stokes equations are solved by using three different grids. The first grid is a single-zone and fixed-size grid. The second grid is also a single-zone grid but its fine core region is split into two parts whenever the separation distance of the vortices exceeds a certain length. The third grid uses a multizone technique by means of two embedded grids placed at vortex cores to alleviate excess numerical dissipation. These grids are applied to the same initial-condition case with a linear crosswind shear and a prescribed temperature distribution due to the engine exhaust plume. The results are compared with the measurements taken at Idaho Falls in 1990. It has been conclusively demonstrated that an adaptive dynamic grid combined with a multizone approach is necessary to obtain accurate results.

Turner, G. P., Padfield, G. D. and Harris, M.

"ENCOUNTERS WITH AIRCRAFT VORTEX WAKES: THE IMPACT ON HELICOPTER HANDLING QUALITIES"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 839-849

A study concerning the risks associated with locating a helicopter final approach and takeoff area alongside an active runway at a busy international airport is documented. Specifically, using desktop simulation, the problem is addressed of an in-flight helicopter encountering the shed wing tip vortex from a large transport aircraft. Measurements are reviewed of vortices taken using coherent laser radar equipment located under the final approach path to London Heathrow Airport to establish a model of the vortex velocity profile. The simulations have shown the helicopter can experience transient pitch attitude changes of up to 40 deg and accumulated descent rates of 1500 ft/min (457 m/min) during the encounter, assuming that no pilot intervention is made. Established handling qualities metrics have been adapted and suggest that these responses may produce handling difficulties. The simulations were also broadened to consider a range of helicopter designs and the effects of shed vortices from a number of large transport aircraft. It is concluded that under particular circumstances a helicopter can experience significant transient motions on encountering a shed wing tip vortex, although no attempt has been made to estimate the probability of this occurrence.

Turner, H. L.

"MEASUREMENT OF THE MOMENTS OF INERTIA OF AN AIRPLANE BY A SIMPLIFIED METHOD"

NACA Technical Note No. 2201, October 1950, Ames Aeronautical Lab., Moffett Field, CA.

A simplified method for the experimental determination of the moments of inertia, product of inertia, and inclination of the principal axes; the associated equipment and techniques; and the application of this method to a conventional 13,000-pound airplane are described. Measurements were made with the landing gear retracted for full and empty fuel conditions. The equipment, which consisted primarily of knife-edge supports and restraining springs for the pitch and roll axes and a single-shaft torsional pendulum for the yaw axis, was designed for increased accuracy as well as for simplicity of operation

and ease of handling as compared with previous methods. At no time was it necessary to hoist or jack the airplane in an abnormal fashion.

Turner, J.

"ETWIRL - A EUROPEAN WAKE VORTEX INCIDENT REPORTING SYSTEM AND DATABASE"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 119-123.

ETWIRL (European Turbulent Wake Incident Reporting Log) is a European Commission funded project to establish a pan-European wake vortex incident reporting system and database. The database will hold details of actual incidents and associated meteorological data for use in model validation, safety studies and by aviation organizations worldwide. The project is being implemented jointly by the UK Met. Office and RED Scientific Ltd. At this stage, the database contents and products have still to be finalized, subject to users' requirements.

Turner, J.

"ETWIRL: A NEW PAN-EUROPEAN WAKE VORTEX REPORTING SYSTEM AND DATABASE"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998.

Increasing demands on European airport capacity has recently brought the issue of wake vortex hazards to the forefront of aviation research. However, current wake vortex separation rules take no account of the effects of meteorological conditions. With sufficient understanding of these effects, the potential to decrease separations under favorable meteorological conditions could be realized without compromising safety standards. The European Commission has recently contracted with aviation specialists RED Scientific Ltd. along with the UK Met. Office to implement a Europe-wide wake vortex incident reporting system, utilizing both automatic and human data sources. The project, named ETWIRL (European Turbulent Wake Incident Reporting Log), will run for two years, and will develop a database of wake vortex encounters at European terminals along with comprehensive meteorological data. This paper describes the expected content of the database together with a discussion about potential methods of data dissemination to interested parties. Confidentiality issues and the future role of the database will also be discussed.

Turner, J.

"DEVELOPMENT OF A WAKE VORTEX INCIDENT REPORTING SYSTEM AND DATABASE"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 571-581

In planning for increased capacity in aviation transport in the next century, changes in procedure must be based not only on the results of research, but on a sound assessment of current practices.

There is currently no source of objective and comprehensive data on wake vortex incidents which may be used in safety assessments and research. The European Turbulent Wake Incident Reporting Log is a European Commission funded project to establish a pan-European wake vortex incident reporting system and database. The database will hold details of actual incidents and associated meteorological data for use in model validation, safety studies and by aviation organizations worldwide. At this stage, the database contents and products have still to be finalized, subject to users' requirements. An Internet site has been launched inviting feedback from all parties on the database content and proposed products.

Turner, J. A., Halsey, N. G. J. and Cole, G.

"A EUROPEAN WAKE VORTEX ENCOUNTER REPORTING SYSTEM AND DATABASE"

Proceedings of the 8th Conference on Aviation, Range, and Aerospace Meteorology, Dallas, TX, January 1999

In response to the growing pressure of increased air traffic on terminal capacity, changes in wake vortex separation procedures must be based not only on the results of theoretical research, but on a sound assessment of current practices. Hence there is a requirement for an objective system for recording wake vortex encounters and the conditions leading to them. ETWIRL (European Turbulent Wake Incident Reporting Log) is a European project to establish a fully comprehensive pan-European wake vortex incident reporting system and database. The database holds details of actual incidents and associated meteorological data for use in model validation, safety studies and by aviation organizations worldwide. The reporting system began operations in early 1998, and data became available to aviation organizations and researchers during summer 1998. The system currently involves the participation of several major European airlines and air traffic services. The success of the project so far has generated much interest in the US, and it is hoped that a similar system could be implemented to address the increasing capacity problem at many US airports.

Turner, J. S.

"A COMPARISON BETWEEN BUOYANT VORTEX RINGS AND VORTEX PAIRS"

J. Fluid Mech., Vol. 7, June 1960, pp. 419-432

In this paper it is shown how earlier results for buoyant vortex rings may be extended to describe the corresponding two-dimensional case, which arises in the theory of bent-over plumes. It is again assumed that in uniform surroundings the circulation remains constant while the buoyancy acts to increase the momentum of the pair. The behavior in two dimensions is quite different from that in three, however; a buoyant vortex ring spreads linearly with height, whereas a buoyant pair spreads exponentially with height, or linearly with time (and therefore, in a bent-over plume, linearly with distance downward). The theory has been extended to describe the rise of buoyant rings and pairs through stably stratified surroundings having a linear density gradient. The behavior near the maximum height reached is found to depend critically in both cases on the relative rates at which the

circulation and the momentum fall to zero. If these reach zero together, the rings or pairs will steadily increase in size and come to rest at a finite height and with a finite radius. If the circulation is non-zero when the momentum vanishes, the radius begins to decrease soon after the buoyancy becomes zero, and the vortices will therefore tend to break up suddenly and mix into their surroundings. There is a considerable increase in the final height which should be attained by vortex rings or bent-over plumes if the initial circulation is increased; it is suggested that releasing smoke intermittently, rather than continuously, at high velocity might be a means of increasing the effective height of chimneys in calm conditions. When the circulation reaches zero before the momentum does, the solutions indicate that the radius becomes very large near the level of zero buoyancy.

Turner, J. S.

"BUOYANT VORTEX RINGS"

Proc. Royal Soc. London A, Mat. 239, 1957, pp. 61-75

It is pointed out that there is a fundamental difference in the behavior of vortex rings projected upwards, according as they do or do not contain fluid which is lighter than the surroundings. A theory based on the perfect fluid approximation is developed to describe the motion of buoyant rings in a uniform fluid. The essential assumption is that the circulation remains constant with time while the buoyancy force acts to increase the impulse of a ring. This leads to the prediction that increasing the buoyancy will give a greater rate of expansion and a lower velocity of rise. The theory is extended to the case of a ring rising through a stably stratified fluid having a constant density gradient; in this case increasing the buoyancy should lead to a lower final height. The predictions of the theory have been verified by carrying out experiments in the laboratory with small vortex rings formed in water, using methylated spirits and salt to produce the density differences. The observations suggest that substantially the same analysis may be applicable to phenomena on a larger scale in the atmosphere; the velocity and final height of an explosion cloud should be determined by the buoyancy and circulation generated near the ground and the stability conditions of the atmosphere.

Tymczyszyn, J. J.

"SUMMARY OF PANEL STATEMENT REGARDING WAKE TURBULENCE"

FAA Symposium on Turbulence, Federal Aviation Administration, Washington, DC, March 1971, p. 21

The highlights of the Wake Turbulence Program at Edwards Air Force Base, Seattle, and Idaho Falls were presented. The principal results included: that flap extension on the generating airplane always resulted in a reduction of apparent vortex strength and persistence, the influence of span ratios of the following aircraft was dominant, and that general aviation airplanes sometimes experienced violent vertical acceleration at distances greater than that which would produce uncontrollable roll.

Tymczyszyn, J. J. and Barber, M. R.

"RECENT WAKE TURBULENCE FLIGHT TEST PROGRAMS"

Soc. Exp. Test Pilots 1974 Report to the Aerospace Profession, Eighteenth Symposium Proceedings, Vol. 12, No. 2, 1974, pp. 52-67

The introduction of wide-bodied jumbo jet transports into commercial and military service in the last 5 years has prompted four major wake vortex flight tests which involved having various instrumented probe aircraft fly behind jumbo jets. The early test programs, which were conducted by NASA/FAA/USAF/industry/airline teams, were intended primarily to determine separation distance requirements. More recently they have also been made to demonstrate the potential of wake vortex alleviation configurations. These tests were made using the B-747 airplane.

Tymczyszyn, J. J. and Barber, M. R.

"TECHNIQUES FOR EARLY DEMISE OF VORTICES - A PILOT'S VIEW"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 247-263.

The emphasis on full-scale airborne flight testing of wake vortex turbulence has naturally phased into a systematic evaluation of methods for attenuating vortex strength rather than concentrating primarily on the basic consideration of determining separation distances required for safe control of the following aircraft. A brief review of several techniques is provided with emphasis on the most successful configuration explored to date. This configuration change has been the extension of the two most outboard spoiler segments during the landing approach of the B-747. Similar configurations have been successfully tested in wind tunnels by NASA-LRC for the DC-10 and L-1011 and flight tests of the L-1011 are scheduled for the immediate future. An attempt is made to predict the operational environmental and certification problems which would have to be considered if reduced spacing is dictated by the need to improve airport capacity and general arguments are presented in favor of wake vortex alleviation.

Tymczyszyn, J. J., Biehl, K. J. and Teager, S. A.

"FLIGHT TEST INVESTIGATION OF THE WAKE VORTICES GENERATED BY ROTORCRAFT"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 13-1 - 13-27

Helicopter wake vortices were probed by small airplanes to obtain a direct assessment of vortex hazard as a function of distance behind the generating helicopter. These tests were designed to provide data for establishing Air Traffic Control separation criteria and for comparison with theoretical calculations. The obvious lack of flight test measurements of helicopter wake turbulence prompted the FAA to undertake a helicopter wake turbulence program in the late 1980's. The result was a flight test program that was a combination of ground based and airborne experimentation, though only the airborne results are presented here. This study is especially timely due to the preponderance of

theoretical calculations based on ground tests that preceded these flights. These ground-based tests suggest a high wake vortex hazard from rotorcraft and consequently imply large separation distances for safe IFR flight behind rotorcraft.

Uberoi, M.

"MECHANISMS OF DECAY OF LAMINAR AND TURBULENT VORTICES"

Project SQUID Technical Report UC-1-PU, Purdue University, December 1977

Dynamics of an infinitely long one-dimensional vortex and a swirl are compared with dynamics of a semi-infinitely long trailing vortex and trailing swirl. With increasing distance, the change in axial velocity difference between the core of the trailing vortex and the surrounding region causes radial convection and some associated axial convection of angular momentum. In laminar or turbulent trailing vortices, this is the dominant mechanism for decrease in velocities of swirl in the core and corresponding growth of the core. Axial velocity difference between the core of the trailing vortex and the surrounding region is necessary for the sustenance of turbulence in the vortex core. A theory of turbulent trailing vortex is developed based on these mechanisms and the results are compared with experimental observations.

Uberoi, M. S.

"MECHANISMS OF DECAY OF LAMINAR AND TURBULENT VORTICES"

J. Fluid Mech., Vol. 90, Part 2, 1979, pp. 241-256

The dynamics of an infinitely long one-dimensional vortex and a swirl are compared with the dynamics of a semi-infinitely long trailing vortex and trailing swirl. With increasing distance, the change in the axial velocity difference between the core of the trailing vortex and the surrounding region causes radial convection and some associated axial convection of angular momentum. In laminar or turbulent trailing vortices, we show that under most conditions of interest this is the dominant mechanism for the decrease in the velocities of swirl in the core and corresponding growth of the core. Based on theoretical considerations and experimental observations, we show that the axial velocity difference between the core of the trailing vortex and the surrounding region is necessary for the sustenance of turbulence in the vortex core. A theory of the turbulent trailing vortex is developed based on these mechanisms and the results are compared with our experimental observations.

Uberoi, M., Shivamoggi, B. K. and Chen, S.-S.

"AXIAL FLOW IN TRAILING LINE VORTICES"

Project SQUID Technical Report UC-2-PU, Purdue University, June 1978

Axial flow in the core of laminar steady trailing vortex from the tip of a semi-infinite lifting wing is analyzed, assuming that the pressure gradient is determined by the swirl velocities of an ideal infinite

line vortex. The axial and lateral variations of the axial velocity depend on the strength of the vortex and initial axial velocity distribution which must be specified at some station behind the wing.

Uhlman Jr, J. S.

"AN INTEGRAL EQUATION FORMULATION OF THE EQUATIONS OF MOTION OF AN INCOMPRESSIBLE FLUID"

TR 10,086, July 1992, Naval Undersea Warfare Center, Newport, RI.

A set of coupled integral equations is derived from the incompressible Navier-Stokes equations and the continuity equation. These equations are based on a vorticity-velocity-enthalpy formulation and are exact. The equations consist of a generalization of the Biot-Savart law for determining the velocity, an integral expression of the momentum equation for determining the vorticity, and a boundary integral equation for determining the stagnation enthalpy. The equations are linear in each independent variable, with the nonlinearities entering only through the cross terms of the vorticity and velocity. They possess several interesting properties, including the total absence of spatial derivatives and the fact that the stagnation enthalpy, or pressure, is required only on the boundary of the fluid domain. In addition, since the vorticity is present in all volume integrals, the domain of integration in this case is restricted to the region of nonzero vorticity. All boundary conditions, and particularly the far field boundary condition, are naturally incorporated in the formulation.

Uhlman, J., Grant, J., Fine, N. and Rees, F.

"ON THE SOUND GENERATED BY AIRCRAFT TRAILING VORTICES: A DESCRIPTION OF THE PROJECT SOCRATES THEORY AND MODELING EFFORT"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

Results are presented of the Project SOCRATES Theory and Modeling study concerning the acoustic signature of aircraft wake vortices. The paper, which is an account of a work in progress, will focus on the examination of the physical mechanisms responsible for low frequency vortex-generated sound using a combination of analytical, computational, and experimental methods. A Lagrangian vorticity collocation method is used to compute the dynamics of columnar trailing vortices and Powell's form of Lighthill's acoustic analogy is used to compute the resulting sound field. Analytical results for a few canonical problems, such as the sound radiated by small amplitude core vibrations of infinite columnar vortices and vortex rings, are used to validate the numerical calculation of the acoustic field. Results of computational simulations will be shown for several model problems. Of particular interest for the wake-vortex problem is the sound field radiated by columnar vortices with periodic wrapped vortex rings which are known to form when strong coherent vortex structures interact with the relatively weak small-scale structures embedded in the ambient turbulence. That interaction is expected to be a dominant sound radiating mechanism for trailing wake vortices. Computational and measured sound field characteristics will be compared in an attempt to support or refute that supposition.

Ulken, R.

"INVESTIGATION OF WAKE VORTICES OF LANDING AIRCRAFT AT FRANKFURT AIRPORT"

DFVLR MITT-88-15, May 1988, DFVLR, Braunschweig, Germany

At Frankfurt Airport investigations of wake vortices were carried out. It should be discovered whether and under which meteorological conditions landing aircraft could be endangered by wake vortices generated by leading large transport aircraft on a parallel glide path. The crosswind shows an evident influence on the horizontal motion of a vortex. But its velocity during 56% of the time of the main air traffic is so slow that a vortex cannot reach the parallel glide path with dangerous intensity due to its limited life-span. Within the remaining time the danger to a following aircraft depends very strongly on the meteorological conditions of the vicinity.

Unterstrasser, S.

"LARGE-EDDY SIMULATION STUDY OF CONTRAIL MICROPHYSICS AND GEOMETRY DURING THE VORTEX PHASE AND CONSEQUENCES ON CONTRAIL-TO-CIRRUS TRANSITION"

Journal of Geophysical Research: Atmospheres, Vol. 119, 2014, pp. 7537-7555.

Large-eddy simulations with Lagrangian ice microphysics were used to study the early contrail evolution during the vortex phase. Micro physical and geometrical properties of a contrail produced by a large-sized aircraft (type B777/A340) were investigated systematically for a large parameter range. Crystal loss due to adiabatic heating in the downward moving vortices was found to depend strongly on relative humidity and temperature, qualitatively like previous 2-D simulation results. Contrail depth is as large as 450 m for the investigated parameter range and was found to be underestimated in a previous 2-D study. Further sensitivity studies show a nonnegligible effect of the initial ice crystal size distribution and the initial ice crystal number on the crystal loss, whereas the contrail structure and ice mass evolution is only barely affected by these variations. Variation of fuel flow has the smallest effect on crystal loss. At high supersaturations, our choice of contrail spatial initialization may underestimate the ice crystal loss. The set of presented sensitivity studies is a first step toward a quantitative description of young contrails in terms of vertical extent and crystal loss. Concluding contrail-to-cirrus simulations demonstrate the relevance of vortex phase processes and its three-dimensional modeling on the later contrail-cirrus properties.

Unterstrasser, S. and Solch, L.

"STUDY OF CONTRAIL MICROPHYSICS IN THE VORTEX PHASE WITH A LAGRANGIAN PARTICLE TRACKING MODEL"

Atmos. Chem. and Physics, Vol. 10, 2010, pp. 10003-10015.

Crystal sublimation/loss is a dominant feature of the contrail evolution during the vortex phase and has a substantial impact on the later contrail-to-cirrus transition. Previous studies showed that the fraction of crystals surviving the vortex phase depends primarily on relative humidity, temperature, and

the aircraft type. An existing model for contrail vortex phase simulations (with a 2-moment bulk microphysics scheme) was upgraded with a newly developed state-of-the-art microphysics module (LCM) which uses Lagrangian particle tracking. This allows for explicit process-oriented modeling of the ice crystal size distribution in contrast to the bulk approach. We show that it is of great importance to employ an advanced microphysics scheme to determine the crystal loss during the vortex phase. The LCM-model shows even larger sensitivities to the above-mentioned key parameters than previously estimated with the bulk model. The impact of the initial crystal number is studied and for the first time also the initial width of the crystal size distribution. Both are shown to be relevant. This corroborates the need for a realistic representation of microphysical processes and knowledge of the ice phase characteristics.

"FAR FIELD WAKE VORTEX EVOLUTION OF TWO AIRCRAFT FORMATION FLIGHT AND IMPLICATIONS ON YOUNG CONTRAILS"

The Aeronautical Journal, Vol. 124, No. 1275, May 2020, pp. 667-702.

Large-eddy simulations (LES) have been employed to investigate the far-field four-vortex wake vortex evolution over 10min behind an aircraft formation. In formation flight scenarios, the wake vortex behavior was found to be much more complex, chaotic, and diverse than in the classical single aircraft case, depending very sensitively on the formation geometry, i.e. the lateral and vertical offset of the two involved aircraft. Even though the case-by-case variability of the wake vortex behavior across the various formation flight scenarios is large, the final plume dimensions after vortex dissolution are in general substantially different from those of single aircraft scenarios. The plumes are around 170 to 250m deep and 400m to 680m broad, whereas a single A350/B777 aircraft would produce a 480m deep and 330m broad plume. Formation flight plumes are thus not as deep, yet they are broader, as the vortices do not only propagate vertically but also in span-wise direction. Two different LES models have been employed independently and show consistent results suggesting the robustness of the findings. Notably, CO₂ emissions are only one contribution to the aviation climate impact among several others like contrails and emission of water vapor and nitrogen oxides, which would be all affected by the implementation of formation flight. Thus, we also highlight the differences in ice microphysical and geometrical properties of young formation flight contrails relative to the classical single aircraft case.

Unterstrasser, S., Gierens, K. and Spichtinger, P.

"THE EVOLUTION OF CONTRAIL MICROPHYSICS IN THE VORTEX PHASE"

Meteorologische Zeitschrift, Vol. 17, No., April 2008, pp. 145-156.

We investigate the evolution of contrails during the vortex phase using numerical simulations. Emphasis is placed on microphysical properties and on the vertical distribution of ice mass and number concentration at the end of the vortex phase. Instead of using a 3D model which would be preferable

but computationally too costly, we use a 2D model equipped with a special tool for controlling vortex decay. We conduct a great number of sensitivity studies for one aircraft type. It turns out that atmospheric parameters, namely supersaturation, temperature, stability and turbulence level have the biggest impact on the number of ice crystals and on the ice mass that survives until vortex breakup and that therefore makes up the persistent contrail in supersaturated air. The initial ice crystal number density and its distribution in the vortex, are of minor importance.

"DIMENSION OF AIRCRAFT EXHAUST PLUMES AT CRUISE CONDITIONS: EFFECT OF WAKE VORTICES"

Atmospheric Chemistry and Physics, Vol. 14, 2014, pp. 2713-2733.

The dispersion of aircraft emissions during the vortex phase is studied using a 3-D LES model with Lagrangian particle tracking. The simulations start with a fully rolled-up vortex pair of a type B747/A340 airplane and the tracer centered around the vortex cores. The tracer dilution and plume extent is studied for a variety of ambient and aircraft parameters until aircraft-induced effects have ceased. For typical upper tropospheric conditions, the impact of stratification is more dominant compared to turbulence intensity or vertical wind shear. Moreover, the sensitivity to the initial tracer distribution was found to be weak. Along the transverse direction, the tracer concentration can be well approximated by a Gaussian distribution, along the vertical a superposition of three Gaussian distributions is adequate. For the studied parameter range, the vertical plume expansion ranges from 400 m to 500 m and cross-sectional area from 40,000 square meters to 60,000 square meters after six minutes. for validation, selected simulations were compared to an alternative LES model and to in-situ NO-measurements.

"THE CREDOS PROJECT: MADRID BARAJAS CASE STUDY"

D5-7, December 2009.

This report is aimed at analyzing CREDOS Concept implementation in Madrid Barajas airport (LEMD), with reliable and real data as far as possible taking the current level of development of the project, through expert experience, fast time simulations and data offered from other similar studies. This deliverable provides a specific case study of the CREDOS implementation from the point of view of Operation, Human Factor and Cost Benefit Analysis. The Operational study analyses the scenario at LEMD, including current traffic, wind, and operational restrictions. A set of Fast Time Simulations were performed to provide an estimation of the improvement in reduction of delay that the use of CREDOS separations could bring to Madris-Barajas. The main conclusion is that current traffic figures do not account for a large improvement due to CREDOS as the target runway is not saturated, although the reduction of delay during peak periods could be enough to justify its implementation. The methodology used in the case study is summarized to serve as guidelines for other possible case studies of the implementation of CREDOS at other airports who would wish to follow.

"THE EFFECT OF WING-TIP MODIFICATIONS ON AIRCRAFT WAKE TURBULENCE"

VPI-E-72-8, July 1972, Virginia Polytechnic Institute and State University, Blacksburg, VA

Several different wing-tip modifications were used to alter the characteristics of an airfoil trailing vortex. Preliminary photographs were taken using a tuft-grid to visually determine the effects of the various tip configurations. Detailed mean flow measurements were then made at ten and thirty chord lengths downstream of the wing. As a first approximation, the static pressure was assumed to be constant. The results show a definite decrease in the tangential velocity of the vortex and a spreading out of the core for all modifications tested.

Uzun, A. and Hussaini, M. Y.

"A COMPUTATIONAL STUDY ON TIP VORTEX NOISE"

AIAA Paper No. 2008-2913, Vancouver, Canada, May 2008

Tip vortex noise is an important component of aircraft high-lift device noise. It is imperative to gain a better understanding of this problem before appropriate noise reduction technologies can be developed and implemented effectively. This paper reports results from our ongoing work on tip vortex simulations. The simulations are performed using a high-order accurate, multi-block, large eddy simulation (LES) code with overset grid capability. The main emphasis of the present simulations is to simulate the formation of a tip vortex around a wing with a blunt tip and its interaction with the wing surface. The blunt tip geometry actually gives rise to the formation of two vortices. The primary vortex forms over the upper surface of the wing, while the secondary vortex forms off the side edge. These two vortices merge to form the tip vortex. Comparisons of the simulation results with available experimental data are shown. Some of the observed differences between the LES and the experiment are believed to be due to the Reynolds number differences between them.

Uzun, A. and Hussaini, M. Y.

"SIMULATIONS OF VORTEX FORMATION AROUND A BLUNT WING TIP"

AIAA Journal, Vol. 48, No. 6, June 2010, pp. 1221-1234.

We report our findings from a computational study on wing-tip vortices. The main emphasis of the simulations is to compute the formation of a tip vortex around a blunt wing tip and its interaction with the wing and tip side-edge surfaces. Comparisons of simulation results with available experimental data are done to assess the prediction capability of the simulations. The simulations are performed on a computational grid containing 110 million points total. The blunt tip geometry gives rise to the formation of two vortices. The primary vortex forms over the upper surface of the wing, and the secondary vortex forms off the side edge. These two vortices merge around the tip trailing edge to

form the tip vortex. Simulations at the experimental Reynolds number of 1,800,000 are performed using several sub-grid scale models. It is shown that the simulation performed without an explicit sub-grid scale model, also known as implicit large eddy simulation, produces the best agreement with the experimental measurements. Although some differences between the simulation results and experimental data still exist, the overall agreement between the experiment and simulation is found to be satisfactory.

"TOWARDS TIP VORTEX NOISE PREDICTION BY HIGH-ORDER LES ON OVERSET GRIDS"

AIAA Paper No. 2005-2865, Monterey, CA, May 2005

This paper reports on a multi-block large eddy simulation (LES) code with overset grid capability which has been developed to primarily study the tip vortex noise problem arising on rotating wind turbine blades. The LES code can also be used to simulate the tip vortices around stationary wing geometries typically found in aeronautical applications. It employs state-of-the-art compact finite differencing, implicit spatial filtering, and non-reflecting boundary conditions on free boundaries, as well as characteristic-type boundary conditions on solid walls. High-order accurate interpolation is used for the transfer of information among the individual component grids that make up the overset grid topology. The multi-block nature and the overset grid capability of the code allow high-order accurate numerical solutions in complex domains. Results for the tip vortex around a stationary wing with a rounded tip are presented to demonstrate the capability of the code. Comparisons of the numerical results with experimental data are also carried out for the validation of the computational methodology.

Uzun, A., Hussaini, M. Y. and Streett, C. L.

"LARGE-EDDY SIMULATION OF A WING TIP VORTEX ON OVERSET GRIDS"

AIAA Journal, Vol. 44, No. 6, 2006, pp. 1229-1242.

This paper reports on a multi-block large eddy simulation (LES) code with overset grid capability which has been developed to primarily study the tip vortex noise problem arising on rotating wind turbine blades. The LES code can also be used to simulate the tip vortices around stationary wing geometries typically found in aeronautical applications. It employs state-of-the-art compact finite differencing, implicit spatial filtering, and non-reflecting boundary conditions on free boundaries, as well as characteristic-type boundary conditions on solid walls. High-order accurate interpolation is used for the transfer of information among the individual component grids that make up the overset grid topology. The multi-block nature and the overset grid capability of the code allow high-order accurate numerical solutions in complex domains. Results for the tip vortex around a stationary wing with a rounded tip are presented to demonstrate the capability of the code. Comparisons of the numerical results with experimental data are also carried out for the validation of the computational methodology.

"CONTROL OF VORTEX PAIR USING A WEAK EXTERNAL FLOW"

Journal of Turbulence, Vol. 3, Paper 051, October 2002, pp. 1-7

The problem of controlling the position of a pair of point vortices using a strain field or the field of a single source/sink is considered using singular control methods and dynamical system perturbation theory. We show that averaging over the fast rotation of the vortices around the center of vorticity reduces the order of the system of evolution equations and allows one to achieve the desired control using a single control field.

"PRELIMINARY STUDY OF SINGLE PARTICLE LIDAR FOR WING WAKE SURVEY"

16th Coherent Laser Conference, June 2011, Long Beach, CA.

In this paper we assess the feasibility of an airborne lidar dedicated to wing wake survey, an application that would be of real interest for applied aerodynamics research. In flight wing wake survey could lead to non-intrusive global drag estimation under realistic conditions. Single particle coherent Doppler lidar has proved to be efficient for measurements at high altitude, and thus, seems to be a good candidate to meet this challenge. The feasibility study focused on two main issues: (1) Since wind speed is retrieved from the Doppler frequency shift of natural aerosol crossing the laser beam, the lidar introduces a bias in the measurement of the wing wake profile. (2) Since the flow to be analyzed is turbulent, we must evaluate the impact of aero optical effects upon lidar performance.

Valla, M., Dolfi-Bouteyre, A., Cariou, J. P. and Lawson, J.

"WAKE VORTEX MONITORING OF DEPARTING AIRCRAFT WITH 1.5 MICRON ALL-FIBER PULSED LIDAR"

ODAS 2007, Gottingen, Germany, Oct. 2007

A new 1.5-micron pulsed lidar using an all-fiber laser source has been developed by ONERA in cooperation with Leosphere, for wake vortex and wind field measurements. The lidar has been designed for medium range detection (50 to 400 m). This system is based on telecom fiber technology which offers low cost and reliable components. The system has been tested on an airport field and has demonstrated to be well suitable for wake vortex monitoring.

"VORTICAL FLOW PREDICTION VALIDATION FOR AN UNMANNED COMBAT AIR VEHICLE MODEL"

Journal of Aircraft, Vol. 48, No. 6, November-December 2011, pp. 1948-1959.

As part of the NATO Applied Vehicle Technology 161 technical group, a study of the aerodynamic behavior of the stability and control configuration wind-tunnel model is presented. Sharp and round leading-edge versions of the model are computed. A validation of Reynolds-averaged Navier-Stokes predictions obtained using two block structured codes are made. Static cases are analyzed and compared with wind-tunnel measurements. The vortical flow features are described in detail for a range of angles of attack. The predictions are in good agreement with the experiments at low angles of attack, whereas for higher angles of incidence (greater than 15 degrees), some discrepancies are seen. A dual vortex structure is present in this region for both leading-edge configurations, resulting in highly nonlinear aerodynamic behavior.

"WAKE VORTEX SAFETY EVALUATION OF SINGLE RUNWAY APPROACHES UNDER DIFFERENT WEATHER AND OPERATIONAL CONDITIONS"

NLR-TP-2002-077, February 2002, National Aerospace Laboratory, and PSAM 6 Conf., June 2002, San Juan, PR

The steady increase in air traffic imposes a need for enhanced airport capacity, and the desire to safely reduce existing separation minima. An important capacity constraint factor is the risk imposed by wake vortices. In view of the uncertainties and the difficulties in understanding the wake vortex phenomena, a novel WAKE Vortex Induced Risk assessment (WAVIR) model has been developed to evaluate wake vortex induced risk. The probabilistic model incorporates sub-models for wake vortex evolution, wake vortex encounter, and flight path evolution, and relates the severity of wake vortex encounters to incident/accident risk probability. The model is applied to evaluate the risk related to different separation distances between aircraft landing on a single runway. An extensive initial risk assessment is carried out to evaluate the impact of weather and wind conditions and procedural aspects on incident/accident risk. The risk assessment results are compared with proposed risk requirements to assess safe and appropriate separation distances. It is shown that a reduction of the current separation minima - and consequently an increase of capacity - might be possible under most operational and weather conditions. However, it is also shown that the separation distances might need to be increased under some particular weather conditions (e.g. low atmospheric turbulence).

"THE CURRENT PRACTICE OF SEPARATION DELIVERY AT MAJOR EUROPEAN AIRPORTS"

Eleventh USA/Europe Air Traffic Management Research and Development Seminar (ATM2015), June 2015, Lisbon, Portugal.

Separation minima are or can become a key bottleneck for the runway throughput at major airports. Therefore, in the context of SESAR Project 6.8.1, EUROCONTROL is investigating concepts for flexible and dynamic use of wake turbulence separations. To successfully develop such concepts and optimize the benefits, it is important that current practices and lessons learnt from today's operations are

understood and considered. The aim of the study presented in this paper is therefore to baseline the current practices for separation delivery on final approach at major European airports. For this, site visits to European ATC units in combination with analysis of radar data have been conducted. Statistical characteristics on speed, distance and time spacing as observed in today's operations depending on e.g., airport, headwind, and distance to threshold are determined. Distance spacing close to the threshold as observed in the data satisfies the minimum radar or wake turbulence separation minima with a buffer that is on average in between 0.5 and 1.0 NM and has a standard deviation of about 0.5 NM. The mean compression of distance spacing on the last 10 NM of the final approach is approximately 1 NM. About half of this compression occurs when the leader aircraft is beyond 4 DME when aircraft adapt to their final approach speed. It is shown that there are considerable differences per airport, and this illustrates that it is important to consider local conditions in the assessment of benefits for a certain airport. Furthermore, the observed mean and variation of spacing buffers may suggest that for optimized runway throughput, new concepts should not only focus on reduction of minima but also on the management of distance spacing compression variation, e.g. better understanding and predicting aircraft speed performance, such that buffers can be optimized. The results of this study are used by SESAR and EUROCONTROL in the development of a new ATC tool to predict aircraft speed performance. This Leading Optimized Runway Delivery (LORD) tool supports Air Traffic Controllers to optimize the separation buffer and more efficiently and easily deal with the compression effect on the last part of the final approach.

van Baren, G., Speijker, L. and Frech, M.

"INCREASED ARRIVAL CAPACITY THROUGH THE USE OF THE ATC-WAKE SEPARATION MODE PLANNER"

AIAA Paper No. 2006-7745, Wichita, KS, September 2006

Today's wake vortex separation rules tend to become capacity bottlenecks at busy airports. Within the ATC-Wake project for the European Commission, an integrated Air Traffic Control (ATC) wake vortex safety and capacity system has been designed to provide the means to significantly enhance airport capacity. The system will enable Air Traffic Controllers to apply new weather based dynamic aircraft separation. One of the components of the ATC-Wake system is the Separation Mode Planner (SMP) that advises the ATC supervisor about safe and adequate separation. The SMP is used in the planning phase where weather and wake vortex forecast information is used together with aircraft separation rules to establish the arrival and/or departure sequence. Weather nowcasting and wake vortex prediction and detection information is used in the tactical phase to monitor and control safe separation. Wind forecast data along the flight path is used in the proposed methodology of the SMP to determine time frames suitable for reduced separation. Criteria on crosswind and associated safe separation minima are derived from safety assessment results. The methodology is illustrated using Nowcasting Wake Vortex Impact Variables (NOWWIV) wind forecast data and WAKE Vortex Induced Risk assessment (WAVIR) results for Single Runway Arrivals. Analysis of a crosswind climatology provides insight in the potential benefits in terms of runway throughput or delay reduction.

van Baren, G., Treve, V., Rooseleer, F., van der Geest, P. and Heesbeen, B.

"ASSESSING THE SEVERITY OF WAKE ENCOUNTERS IN VARIOUS AIRCRAFT TYPES IN PILOTED FLIGHT SIMULATIONS"

AIAA Paper 2017-1084, January 2017, Grapevine, TX.

The ICAO wake turbulence separation standards for approaching and departing aircraft are considered safe and to some extent over-conservative for certain pairs of aircraft and in certain conditions. With the need to improve efficiency and capacity at the larger busy airports, research has been ongoing to come up with concepts aiming at optimized, weather dependent and pair-wise separation minima. The safety analysis of the European pair-wise concept (RECAT-PWS-EU) as developed by EUROCONTROL Agency is based on a relative assessment using the dimensionless Roll Control Coefficient (RMC) as the metric expressing wake encounter severity. Separation design is based on the principle that the worst-case RMC value that an aircraft type is exposed to, will be less than or equal to the worst-case RMC that a smaller reference aircraft is exposed to. The applicability of this alignment principle may be limited to aircraft within a certain category, because other factors than RMC may play a role in the experienced severity for aircraft that differ significantly in size and maneuverability. With the objective to create additional assurance that the estimated severity levels at the defined separations are comparable and acceptable, EUROCONTROL, in collaboration with the Netherlands Aerospace Centre NLR have conducted a campaign with realistic piloted flight simulations in the framework of the SESAR program. A range of aircraft types has been simulated in NLR's GRACE research simulator facility. More than 700 wake encounters have been flown in realistic level flight and final approach scenarios. Pilot ratings of the severity and flight data have been analyzed in combination. The results show that the RMC is a good metric for wake encounter severity. The pilot ratings for the various aircraft types correlate well with RMC values, especially in level flight. In approach, closer to ground at around 200-100 ft, pilot rating also correlates with deviations from the stabilized approach and go-around intentions. The results support the alignment as applied in the RECAT-PWS-EU Safety Case..

van Dam, C. P.

"EFFICIENCY CHARACTERISTICS OF CRESCENT-SHAPED WINGS AND CAUDAL FINNS"

Nature, Vol. 325, January 1987, pp. 435-437.

Caudal (tail) fins of fish and aquatic mammals that cruise long distances, and wings of certain birds, often have the shape of a crescent moon. This study investigates how the crescent shape contributes to the traveling performance of these animals. A steady-flow theory that correctly models the trailing wake was used to analyze lifting surface efficiency, which is dependent on the level of induced (or vortex) drag for a given lift and span of the lifting surface. This analysis shows that backward curvature of a wing improves induced efficiency to a value greater than that of the flat untwisted wing of elliptical shape considered optimal in classical wing theory. This increase of induced efficiency results from the nonplanar trailing vortex sheet produced by the crescent-shaped wing at a given angle of attack.

"SHEAR-FLOW INSTABILITY IN A ROTATING FLUID"

J. Fluid Mechanics, Vol. 387, 1999, pp. 177-204.

The instability of a forced, circular shear layer in a rotating fluid has been studied experimentally and numerically. The experiments were performed with a shallow layer of water in a parabolic tank, in which it is possible to apply radial pumping and to model a geophysical beta-effect. A shear layer was produced by a secondary rotation of the central part of the parabolic vessel. In most experiments, the shear layer takes on the appearance of a sequence of vortices, the number of which decreases with increasing strength of the shear. A beta-effect may prevent the formation of a steady vortex chain. Continuous pumping of fluid from the periphery to the center or vice versa leads to an azimuthal velocity field corresponding to a point vortex. This azimuthal flow appears to stabilize the shear flow if it is opposite to the inner rotation, and to be destabilizing otherwise. The numerical investigations consist of the solution of the quasi-geostrophic equation in a geometry like the experimental situation and with a term modeling the experimental forcing. Though the numerical computations are based on a two-dimensional model, they capture the essential features of the instability and the resulting vortex structures.

van den Berg, L.

"TOPOLOGICAL AND NUMERICAL ASPECTS OF AXISYMMETRIC VORTEX BREAKDOWN"

M-741, December 1996, Technische Univ. Delft (Netherlands), Faculty of Aerospace Engineering, Delft, The Netherlands

The emphasis of this work lies on the topological and numerical aspects of axisymmetric vortex breakdown. First, a literature survey is given of the theoretical, experimental, and numerical results concerning breakdown that could be obtained. Furthermore, the qualitative theory of dynamical systems is applied to steady axisymmetric flows. The topology of steady viscous flows is studied based on the axisymmetric Navier-Stokes equations governing incompressible laminar flow. Special attention is given to flow patterns that are concerned with the genesis of vortex breakdown bubbles. The behavior of some physical parameters, such as the kinematic pressure, the three vorticity components and the vortex stretching and tilting terms near the breakdown bubbles is investigated. Finally, numerical calculations concerning the vortical flow in a tube with convergent-divergent dimensions are performed with the help of a Navier-Stokes/Euler code.

van der Laan, J. M.

"EXPERIMENTAL VORTEX ANALYZER"

NLR MP 82006 U, January 1982, National Aerospace Laboratory, Amsterdam, The Netherlands

A measuring system is described for detection and analyses of aircraft wake vortices in the approach zone of a runway. This system consists of propeller anemometers, a data-acquisition unit, a quick-look

monitor and a NOVA minicomputer with a real-time vortex detection program. A short description of aircraft wake vortices is also given. Some results of the measuring program are discussed. [In Dutch.]

van der Laan, J. M., van den Dam, R. F., van der Weijde, H., and Aardoom, W.

"RESULTS FROM THE RLD/NLR AIRCRAFT WAKE VORTEX MEASUREMENT PROGRAM (DATA COLLECTION PERIOD APRIL - OCTOBER 1980)"

NLR TR 81067 L, June 1981, National Aerospace Laboratory, Amsterdam, The Netherlands

The results are given of an aircraft wake vortex measurement program. A Vortex Detection System is used, based on propeller anemometers. This system as well as the vortex detection software is described. Several observed weather and vortex phenomena are discussed. Cumulative distributions of vortex residence time are given, for several combinations of aircraft and windspeeds. Some aspects of the feasibility of a Vortex Advisory System, based on a wind criterion, are discussed.

"FLEXIBLE RUNWAY USE MODELING USING PAIRWISE RECAT-EU SEPARATION MINIMA"

AIAA Paper 2018-3840, June 2018, Atlanta, GA.

If we would take fuel consumption and noise annoyance into account in the runway allocation process, runway allocation can take place more efficiently, both in terms of fuel cost as well as noise annoyance. In this research, the focus is on the further development of a model to make the calculations more refined. Moreover, the improvements conducted in this research relate to the methodologies to compute the cost of the decision variables and the level of complexity of specific linear programming constraints in the optimization model. Consequently, the aim of this research is to answer the following research question: Can the performance of Standard Flex be further optimized by applying pairwise flight dependencies, while ensuring and contributing to a valid trade-off between runway capacity, noise emission, fuel burn and safety. By means of this research, the flexible runway allocation model has been improved on many aspects. The computation strategy of both objectives has moved from a reference aircraft-based computation strategy to an analysis based on each unique aircraft on its own. This refined computational approach has resulted in a better understanding and modeling strategy of the operations that take place at an airport. Finally, the implementation of RECAT-EU separation minima has resulted in a reduction of 5-10 percent in overall separation times with respect to the regular ICAO WTC strategy, based on multiple air traffic demand mixture scenarios, based on a specific demand of flights.

"WIND MEASUREMENTS: POTENTIAL WIND SPEED DERIVED FROM WIND SPEED FLUCTUATIONS MEASUREMENTS, AND THE REPRESENTATIVITY OF WIND STATIONS"

WMO Instruments and Observing Methods Reports, No. 74 (WMO/TD - No. 1028), October 2000, pp. 72.

Turbulence measurements as part of operational meteorological observations for synoptical purposes provide direct information of terrain roughness. The method using standard deviations is a simple tool for the calculation of the potential wind speed providing a higher degree of representativity.

van der Meulen, J. P.

"WAKE VORTEX INDUCED WIND MEASUREMENTS AT AIRFIELDS: - A SIMPLE ALGORITHM TO REDUCE THE VORTEX IMPACT"

WMO Instruments and Observing Methods Reports, No. 70 (WMO/TD - No. 877), May 1998, pp. 139.

The surface wind measurements at an airport is intended to provide the representative condition, particularly of 6-10 m above the runway. The sensor location is such that the site should not be by affected by the flow from buildings, etc., or by aircraft operations. In practice, the final choice of the site is a compromise of many factors and as such, the sensor location may still be at times impacted by the surrounding objects and aircraft operations. In this paper, the impact of aircraft wake turbulence on the determination of wind gust is explored. A simple algorithm to detect the artificial wind guest caused by wake vortices was implemented, and was found to improve the meteorological characterization of the wind guest.

van der Vegt, J. J. W.

"FUNDAMENTALS OF THREE-DIMENSIONAL VORTEX MOTION AROUND SOLID BODIES"

Fluid Dynamics Research, Vol. 3, Issues 1-4, Sept. 1988, pp. 179-182

An Action Principle describing the evolution of a 3-D inviscid vorticity field around a solid body is presented. This variational principle is used for the construction of a numerical algorithm. A formal solution of the inviscid vorticity transport equation is given by means of a Lie transform using a Dirac bracket and Hamiltonian functional. This solution is used in a stochastic algorithm for the simulation of the evolution of a viscous vorticity field around a body.

van der Wall, B. G.

"WIND TURBINE WAKE VORTEX INFLUENCE ON SAFETY OF SMALL ROTORCRAFT"

The Aeronautical Journal, Vol. 123, No. 1267, September 2019, pp. 1374 1395.

The wake vortex of lifting surfaces such as wind turbine blades or fixed-wing aircraft can heavily affect the blade aerodynamics of rotorcraft. Using blade element theory, the pilot control inputs required to mitigate such vortex effects are estimated and compared to the available control margin at the operating condition of interest. In contrast, when no pilot action is performed, the rotor blade flapping

caused by the vortex is evaluated and compared to available margins. It is a safety concern when the remaining margins become zero. The influence of the vortex strength, its core radius and orientation to the rotor disk are evaluated and the effect of rotor blade characteristics (Lock number, natural frequency) is investigated.

"ANALYSIS METHODOLOGY FOR 3C-PIV DATA OF ROTARY WING VORTICES"

Experiments in Fluids, Vol. 40, 2006, pp. 798-812

3C-PIV data from tip vortices of either fixed-wing or rotating wing experiments are challenging from an analysis point of view. Model motion, vortex wander, spurious vectors, periodic and aperiodic effects, turbulence, and other disturbing effects are all present in the data. In most cases the vortices are not measured perpendicular to their axis as well. Engineers need time-averaged properties from the vortex in the vortex axis system for a proper modeling approach within simulation codes. This article describes the methods needed to deal with all the mentioned problem areas, including the conditional averaging and rotation into the vortex axis system. The methods are validated by using numerically generated vortex vector fields, and finally applied to experimental data from a hover condition of a model rotor.

"THE HART II TEST - MEASUREMENT OF HELICOPTER ROTOR WAKES"

Aerospace Science and Tech., Vol. 8, No. 2004, pp. 273-284

A key parameter to reduce rotor noise is a wake location relative to a blade. During the data analysis in the years after the HART test of 1994 it was found that comprehensive wake data are needed to understand wake development, vortex creation and aging, their motion, and their re-development after an interaction with a rotor blade. Therefore, DLR, ONERA, NASA Langley, US Army AFDD and DNW again came together and generated a follow-on program named HART II. In this program the rotor wake was intensively measured with a novel double-stereo PIV (Particle Image Velocimetry) system. This provides instantaneous flow field data in both a large observation area and in a smaller close-up view to the vortex core. Additionally, rotor blade deformation, airloads, and noise radiation were measured to form a complete, consistent, and comprehensive data base. Another 'first time' was the application of the blade position measurement technique SPR (Stereo Pattern Recognition), which provided instantaneous optical measurement of the blade bending in flap, lead-lag and torsion. In this paper, the HART II test is described in detail, including a description of all measurement techniques applied and with some results from each of them.

"RUNWAY WAKE VORTEX, CROSSWIND, AND VISIBILITY DETECTION WITH A SCINTILLOMETER AT SCHIPHOL AIRPORT"

Boundary-Layer Meteorology, Vol. 157, 2015, pp. 481-499.

We evaluate the performance and investigate the capability of a scintillometer to detect wake vortices, crosswind, and visibility near an airport runway. An experiment is carried out at Schiphol airport (Amsterdam, The Netherlands), where an optical scintillometer is positioned alongside a runway. An algorithm is developed to detect wake vortices, and also the strength of the wake vortex, from the variance in the scintillation signal. The algorithm shows promising results in detecting wake vortices and their strengths during the night. During the day, the scintillometer signal is dominated by environmental turbulence and wake vortices are no longer detectable. The crosswind measured by the scintillometer is compared with wind-speed and wind-direction data at the airport. Our results show that, after applying an outlier filter, the scintillometer can measure the crosswind over the short time period of 3s required for aviation applications. The outlier filter does not compromise the capability of the scintillometer to obtain the maximum 3s crosswind over a 10-min time frame correctly. Finally, a transmission method is used to obtain the visibility from the scintillometer signal, which is then compared with that obtained from a visibility sensor. The scintillometer can identify periods of low visibility correctly, although it shows a high amount of scatter around the exact visibility value.

"STATISTICS OF WIND DIRECTION AND ITS INCREMENTS"

Physics of Fluids, Vol. 12, No. 6, June 2000, pp. 1529-1534.

We study some elementary statistics of wind direction fluctuations in the atmosphere for a wide range of time scales (0.0001 sec to 1 hr), and in both vertical and horizontal planes. In the plane parallel to the ground surface, the direction time series consists of two parts: a constant drift due to large weather systems moving with the mean wind speed, and fluctuations about this drift. The statistics of the direction fluctuations show a rough similarity to Brownian motion but depend, in detail, on the wind speed. This dependence manifests itself quite clearly in the statistics of wind-direction increments over various intervals of time. These increments are intermittent during periods of low wind speeds but Gaussian-like during periods of high wind speeds.

"A REVIEW OF CIVIL AVIATION ACCIDENTS, AIR TRAFFIC MANAGEMENT RELATED ACCIDENTS: 1980-1999"

4th International Air Traffic Management R&D Seminar, December 2001, Santa Fe, NM.

The National Aerospace Laboratory NLR was contracted by the Air Traffic Control the Netherlands (LVNL) to collect and analyze a selected several air traffic management (ATM) related accidents. The objective of the present study was to quantify the historical safety performance in terms of accident

rates of a selected number of ATM related accident types. This information can assist in the determination of target levels of safety. This paper presents an analysis of ATM related accidents involving commercial civil transport aircraft which occurred worldwide during the period 1980-1999. ATM related accident rates by event type, flight phase and world region are presented and discussed.

"SAFETY ASPECTS OF TAILWIND OPERATIONS"

NLR TR-2001-003, January 2001, National Aerospace Lab., Amsterdam, The Netherlands

In the present study the safety aspects of aircraft takeoff and landing operations in tailwinds are explored. The study covers a description of legislative instruments that influence preferential runway selection in relation to the maximum tailwind component applied; tailwind certification issues; and relevant safety issues concerning tailwind operations in general. Also, a systematic analysis of historical tailwind related overrun accidents and incidents is presented.

"A STUDY OF NORMAL OPERATIONAL LANDING PERFORMANCE ON SUBSONIC CIVIL NARROW BODY JET AIRCRAFT DURING ILS APPROACHES"

NLR-CR-2006-048, December 2006, National Aerospace Laboratory, Amsterdam, The Netherlands.

The need for improved capacity at airports to accommodate the rapid growth of domestic air traffic in the United States has led to the investigation of Landing and Hold Short Operations (LAHSO) as a safe and feasible means to increase the traffic flow. While the capacity issue becomes important, it is imperative that the increase in capacity does not lead to a safety decline. A key task is to investigate the aircraft landing performance as to provide operations safety guidelines for reducing the risks of incidents and accidents associated with LAHSO. For this a clear knowledge of the day-to-day landing operation is required. The present study is conducted using in-flight recorded data collected from day-to-day landing operations. These data were obtained from the quick access recorder for two types of narrow body aircraft, the B737-400 and the A319/A320/A321. Data from quick access recorders can be used to analyze aircraft performance. Aircraft landing field performance is influenced by many variables. Some variables have a more dominating influence than others. Some variables that have a strong influence are height above the threshold, speed loss from flare initiation to touchdown, and the available runway length for landing. However, there is not one single factor that really dominates the landing field performance.

"WIND TURBINE AERODYNAMICS FROM AN AEROSPACE PERSPECTIVE"

AIAA Paper 2018-0991, January 2018, Kissimmee, FL.

The current challenges in wind turbine aerodynamics simulations share a number of similarities with the challenges that the aerospace industry has faced in the past. Some of the current challenges in the aerospace aerodynamics community are also relevant for today's wind turbine aerodynamics community and vice versa. This paper sketches these similarities in broad strokes and points out the possibilities to revive solutions from the aerospace aerodynamics community from the 1960's onward that, with some modifications, can be applied to wind turbine aerodynamics problems. Opportunities are indicated where both the wind turbine and the aerospace aerodynamics communities can benefit from collaborative research.

"AIRCRAFT RESPONSES TO ATMOSPHERIC TURBULENCE. A COMPARATIVE STUDY"

Report LR-778, December 1994, Technical University of Delft, Delft, The Netherlands.

A comparison is made between the methods as presented in references (Etkin, 1972), (Etkin, 1980), (Robinson, 1991) and (Mulder & van der Vaart, 1993). Both the Delft University of Technology (DUT) and Etkin's Four Point Aircraft (FPA) models presented herein simplify the characteristics of atmospheric turbulence greatly. The differences between the two methods appear to be small in output power spectral densities results. The aircraft models, for both the DUT and FPA theory, are equal for most turbulence inputs. However, the approach in calculating the input power spectral densities differs considerably. The results, described by output power spectral densities, coincide over a wide frequency range.

"THROTTLING A LAVAL NOZZLE BY A VORTEX: AN ANALYTICAL THEORY"

AIAA Paper No. 2007-1282, Reno, NV, January 2007

This paper presents an analytical theory for a vortex flow through a Laval nozzle. It will demonstrate that when a vortex is present the total velocity reaches sonic conditions upstream of the nozzle throat, that the axial velocity in the nozzle throat is equal to the local speed of sound and that the mass flow through the Laval nozzle depends on the vortex strength in such a way that the mass flow decreases with increasing vortex strength. The predictions of the analytical theory have been compared to the results of experiments and a numerical simulation, and it can be concluded that the analytical theory describes the characteristics of the flow very well.

"A REVIEW OF ROTORCRAFT WAKE MODELING METHODS FOR FLIGHT DYNAMICS APPLICATIONS"

35th European Rotorcraft Forum, Paper 101221, September 2009, Hamburg, Germany.

In this paper, the results of a brief survey in the field of rotorcraft inflow and wake modeling developments are presented. For many years, inflow models have been augmented with (semi-) empirical and analytical models to remove restrictions present in dynamic inflow models. In the meantime, significant algorithmic advances have been made in the field of Lagrangian free wake methods. This review summarizes the state of the art in rotor wake and inflow modeling for flight dynamics applications, and outlines benefits and limitations of both methods. As a result of this survey, our future research will focus on the development of a simplified free wake model where all vorticity is located on a continuous, truncated cylinder that can deform freely under its own influence.

"WIND TUNNEL EXPERIMENTS ON WAKE VORTEX DECAY IN EXTERNAL TURBULENCE"

AST4-CT-2005-012238, May 2007, Technical University Eindhoven, Eindhoven, The Netherlands.

In this study we present an experimental investigation of the evolution of both single and double wing-tip vortices in a wind tunnel with and without a turbulence generating grid, where $R = 40,000$ typically. Cross sectional velocity fields were obtained by means of particle image velocimetry at several locations downstream of the airfoil. Special attention was given to resolve the vortex core, since this has often been a region of difficulty in most experimental investigations. The single vortex was found to exist of a small viscous core and an outer region with nonzero vorticity. The decay of the maximum azimuthal velocity is close to laminar, both with and without grid. The main effect of the grid turbulence is to increase the diffusion of vorticity in the outer region and to enhance the wandering of the vortex center. The wandering amplitude is inversely proportional to the strength of the vortex, indicating mutual interaction between the vortex and external turbulence. For the double wing tip vortices, a split wing configuration was used with three different tip spacings. The vorticity distribution of the double vortices is more compact than that of the single vortex but decays due to cross-diffusion. The cross-diffusion is without grid significantly larger than viscous diffusion and enhanced by grid turbulence. Grid turbulence is also found to promote the onset of the Crow instability. The instability causes the vortex centers to oscillate with an angle of approximately 33 degrees to the horizontal. The growth rate of the oscillation amplitude is approximately half the growth rate predicted by inviscid theory. The Crow instability is followed by the phenomenon of vortex linking, which results in a rapid destruction of the vortices. At very strong turbulence levels, core oscillations and decay of circulation are significantly present, though the Crow instability is no longer observed.

"AN EXPERIMENTAL STUDY OF THE EFFECT OF EXTERNAL TURBULENCE ON THE DECAY OF A SINGLE VORTEX AND A VORTEX PAIR"

Journal of Fluid Mechanics, Vol. 670, 2011, pp. 214-239.

This study is concerned with the effect of external turbulence on the decay of vortices. Single vortices and vortex pairs were generated with wing(s) mounted in the sidewalls of a wind tunnel. The distance

between the two vortices could be adjusted such that they just touched each other or overlapped. The intensity of the turbulence could be controlled with a turbulence grid. The development of the vortex was measured at several downstream stations with particle image velocimetry for a range of wing settings. The results indicate that the single vortex can be described by the 'two length scales' model of Jacquin, Fabre and Geffroy. A vortex core, which decays like a Lamb-Oseen vortex, is embedded in a region with an almost constant radius and a much lower azimuthal velocity that obeys a r to the minus beta power law, with r being the radius measured from the vortex center. For the turbulence levels and the test section length used in this study, the single-vortex behavior is independent of the external turbulence and in contrast with the decay of the vortex pair that strongly depends on the external turbulence. In the initial stages of the vortex pair evolution, the vortices decay due to cancellation of vorticity at the symmetry plane. At a later stage, Crow oscillations are observed, followed by a breakdown of the vortices. This vortex breakdown might be due to direct turbulent action. The observed behavior is in agreement with the theoretical model of Crow and Bate..

"WIND TUNNEL EXPERIMENTS ON WAKE-VORTEX DECAY IN EXTERNAL TURBULENCE"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

It is well known from numerical studies that external turbulence promotes the decay of wake vortices, either by increased vorticity diffusion or by triggering 3D instabilities that lead to their destruction. So far, however, very few quantitative laboratory studies have been devoted to the issue of wake-vortex decay. In this study, we present an experimental investigation of the evolution of both single and double wing-tip vortices in a wind tunnel with and without a turbulence generating grid, where the Reynolds number is typically 40000. Particle image velocimetry measurements of the cross-sectional velocity field at several locations downstream of the airfoil show that for a single vortex the decay of the maximum azimuthal velocity is close to laminar, both with and without grid. The main effect of the grid turbulence is to enhance the wandering of the vortex center. Special attention was given to resolve the vortex core, since this has often been a region of difficulty in most experimental investigations. For the double wing-tip vortices a split wing configuration was used with three different tip spacings. External turbulence is found to promote the onset of the Crow instability and to enhance cross diffusion of vorticity. The Crow instability is followed by the phenomenon of vortex linking, which results in a rapid destruction of the vortices. At very strong turbulence levels, core oscillations and decay of circulation are significantly present, though Crow instability is no longer observed.

"NUMERICAL INVESTIGATION OF VORTEX BREAKDOWN"

AIAA Paper 2016-4174, June 2016, Washington, DC.

The computational prediction of maximum lift for a high-lift configuration of transport aircraft still poses a challenge. The accurate computational prediction depends on the ability to accurately represent the physical flow features involved in high-lift flow. For a transport aircraft with wing mounted engines the breakdown of vortices from the nacelle strakes can be a dominant flow feature determining maximum lift. In this paper a study is presented that focusses on investigating vortex breakdown numerically. Effort has been spent to find an experiment in which vortex breakdown can be investigated independently of major interaction of surrounding physical flow features as is the case in the flow over high-lift configurations. Aim of the study is to identify practices in current available Computational Fluid Dynamics (CFD) capabilities that are necessary to accurately represent vortex breakdown and understand why. Furthermore, it is assessed whether further validation data is required. In particular, the focus is on the level of physical modelling (turbulence model) and the computational strategy (executing steady or unsteady flow computations) needed to adequately predict vortex breakdown. One of the main conclusions of the study is that basic physical features of vortex breakdown can be captured in a turbulent flow computation, provided that in the numerical method the Reynolds stresses are considered.

"ROTOR THEORIES BY PROFESSOR JOUKOWSKY: MOMENTUM THEORIES"

Progress in Aerospace Sciences, Vol. 73, 2015, pp. 1-18.

This paper is the first of two papers on the history of rotor aerodynamics with special emphasis on the role of Joukowski. The present one focuses on the development of the momentum theory while the second one surveys the development of vortex theory for rotors. Joukowski has played a major role in these developments. Although he cooperated with other famous aerodynamicists like Prandtl, his contribution is not well recognized as most of his publications are in Russian. The paper discusses the role of the English, Russian and German research schools of the Twentieth Century, and the contributions by individual researchers like Lanchester, Prandtl, Betz and Joukowski himself. After the one-dimensional momentum theory was well established, the introduction of torque and angular momentum was the next step. Joukowski has led the basis for this next step, but Glauert's Blade Element Momentum still is the basis of current rotor design codes. He applied some assumptions limiting the validity to moderate and high tip speed ratios. Sorensen and van Kuik published a solution for wind turbines with very low tip speed ratios, which is now expanded to propellers as well, with one remaining assumption of inviscid flow. For very low tip speed ratios the general momentum theory gives unphysical results which disappear after applying a perturbation parameter representing phenomena not captured by the Euler equations.

van Staveren, W. H. J. J.

"ANALYSES OF AIRCRAFT RESPONSES TO ATMOSPHERIC TURBULENCE"

PhD Thesis, Dec. 2003, Delft University of Technology, Delft, The Netherlands.

The response of aircraft to stochastic atmospheric turbulence are studied in the framework of three mathematical models, (1) the classical Delft University of Technology (DUT) model and (2) the classical Four Point Aircraft (FPA) model, and (3) a newly developed Parametric Computational Aerodynamic (PCA) model. From the results presented, it is concluded that the introduced PCA-model is the most accurate for all considered gust fields. Compared to the Linearized Potential Flow solution (which is assumed to be the benchmark, or the model that approximates reality closest) the new parametric model shows increased accuracy over the classical parametric models (the DUT- and FPA-model), especially for the aircraft responses to 2D gust fields. Furthermore, it shows more accuracy in the aircraft responses to 1D longitudinal gust fields. Although results will be presented for a Cessna Ce550 Citation II aircraft only, the theory and methods are applicable to a wide variety of fixed-wing aircraft, that is from the smallest UAV to the largest aircraft (such as the Boeing B747 and the Airbus A380).

Van Woortman, H. J. B. and Polak, F. R.

"A VORTEX ADVISORY SYSTEM AT SCHIPHOL/AMSTERDAM AIRPORT: FEASIBLE AND MEANINGFUL?"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 5-1 - 5-15

The results are given of an aircraft wake vortex measurement program. A wind criterion for a future Vortex Advisory System has been established. Actual wind data for Schiphol Airport, the Netherlands, concerning 11 months in 1980/81 have been analyzed with respect to the feasibility of a VAS-ellipse criterion (semi-axes 7 x 13 kts). The results are based on the peak hours for inbound traffic for runway 06. On average the wind vector lies within the ellipse criterion during more than half the total time a runway can be used. In case the wind vector lies within the ellipse, it takes generally not long in succession: in 70% it takes less than 4 minutes. Although a low number of ellipse transitions per hour prevails, transitions of higher frequency (> 5 per hour) do occur often enough (30% of total time) to cause problems for the controller to determine whether separations must be changed or not. The effect of the above-mentioned frequent ellipse transitions can be reduced using a buffer zone. By using a 3kts buffer zone around the ellipse criterion and keeping the 'red light' on if this zone is not exceeded, about 60% of the highly frequent transitions will be eliminated. These are the transitions which exceed the ellipse boundary with less than 3 kts. The 'attention time' are generally very short (< 5 min. in 90% of the cases). The 'warning times' are even shorter. It is a general feeling that the present results indicate that the operational benefit of a VAS for Schiphol Airport will be very limited. The main reason for this opinion is that, although the ellipse criterion as such is reliable, due to the rapid and almost unpredictable wind variations which do often occur at Schiphol, the operationally acceptable buffer zone or time lag will probably be so large that, effectively the controller will have to apply large separations almost all the time.

van Zyl, I.

"EXTREMUM-SEEKING CONTROL FOR CONSTRAINED OPTIMAL FORMATION FLIGHT OF COMMERCIAL AIRLINERS"

MS Thesis, March 2018, Stellenbosch University, Matieland, South Africa.

Formation flight of commercial airliners has become a topic of interest due to the possibility of significant fuel savings. With air traffic rapidly increasing, the aeronautical industry recognizes the necessity to improve fuel efficiency of long-distance flights. Previous studies have shown that extended formation flight of existing commercial aircraft is plausible, but have not dedicated much attention to fully utilizing the wingtip generated wakes. This study presents the design, implementation, and verification of a perturbation-based extremum-seeking controller that enables follower aircraft to locate and maintain optimal formation separations in a practical formation flight scenario. Typically, the trailing vortices of the leader aircraft are displaced due to atmospheric disturbances, such as static winds and turbulence, and models of the vortex positions are not exact. Due to the dangers related to flight deep in the leader's wake, a novel constrained objective function is proposed that prevents the extremum-seeking controller from guiding the follower aircraft too close to the vortex core. In this constrained objective function, the extremum is represented by a constrained extremum contour instead of a single point. A novel extremum-seeking state machine is proposed that controls the different modes of operation that the follower aircraft transitions through as it approaches the constrained extremum. The states and the state transition boundaries are defined as functions of the objective function, which allow them to follow the displaced trailing vortex, instead of remaining static relative to the leader aircraft. This also enables the extremum-seeking control to not only track a static trailing vortex, but also a constrained extremum for a dynamic trailing vortex. It is also shown that by approaching the constrained extremum at a constant approach rate, rather than the classical proportional approach rate, the effects of the non-linear wake on the seeking performance may be mitigated. The extremum-seeking controller was verified in simulation on a formation flight model of two Boeing 747 aircraft in right echelon formation. The formation is subjected to realistic atmospheric disturbances and sensor noise. The simulation results show that the extremum-seeking controller is able to successfully guide the follower to the constrained extremum, even in the presence of varying static wind and light turbulence, and that thrust reduction of up to 23 percent may be achieved.

Vancassel, X.

"SIMULATION OF AEROSOLS IN NEAR-FIELD AIRCRAFT PLUMES: APPLICATION TO MESO-SCALE MODELS INITIALISATION"

9th ONERA-DLR Aerospace Symposium, October 2008, Chatillon, France.

One of the challenges in assessing the aviation impact on the atmosphere lies in the correct consideration of the various processes involved. These have to be captured for very different time and spatial scales, from molecular to the earth's size. The global impact of aviation on the atmosphere is generally determined using the total amount of gas and particulate matter emitted by aircraft, as a function of the flight routes used. But the results of their interaction with the background species obtained from CTM (Chemistry Transport Model) generally ignore some of the physical and chemical transformations occurring at much smaller scales in the aircraft plume. Microphysical and chemistry models have been developed to take the plume chemistry and microphysics into account. They are most of the time trajectory box models which are run along an average plume. They can also be coupled online with aerodynamics models but in that case, they must be simplified to minimize

computation costs. In the paper, we present an offline alternative method based on the use of an ensemble of OD boxes and a detailed plume aerosol model. The results show the different particles properties, especially volatile but also ice (size distribution, composition, etc.) and emphasize the influence of mixing.

Vancassel, X., Mirabel, P. and Francois, G.

"NUMERICAL SIMULATION OF AEROSOLS IN AN AIRCRAFT WAKE USING A 3d LES SOLVER AND A DETAILED MICROPHYSICAL MODEL"

International Journal of Sustainable Aviation, Vol. 1, No. 2, 2014, pp. 139-159.

The global impact of aviation on the atmosphere is generally determined using the total amount of gas and particulate matter emitted at the aircraft engine exit but generally ignore some of the physical transformations occurring at much smaller scales in the aircraft wake. In this work, we present an offline alternative method based on the use of a detailed plume aerosol model combined to fluid trajectories calculated from 3D large-eddy simulations (LESs). The study has been limited to the first 10 s behind a type Airbus 340 aircraft. The results have been compared to those obtained from a one-way coupling approach including a simple microphysics water vapor deposition model on soot cores. The respective evolutions of average ice particles radius are in good agreement. Furthermore, different types of aerosol properties are examined including the charged volatile particles, the dry and activated soot, and the ice crystals from homogeneous and heterogeneous freezing. The variability of the aerosol size distribution clearly illustrates the influence of the mixing, as a function of the position in the aircraft plume. Finally, the volatile particles distribution exhibits a bimodal shape resulting from the presence of charges, in agreement with that observed experimentally.

vanDam, C. P.

"INDUCED-DRAG CHARACTERISTICS OF CRESCENT-MOON-SHAPED WINGS"

Journal of Aircraft, Vol. 24, No. 2, February 1987, pp. 115-119.

Results are presented of a theoretical study conducted to analyze the potential drag reduction characteristics of wings with highly tapered aft-swept tips at subsonic speeds. These planar wings, also named crescent-moon-shaped wings or wings with curved planform, can produce induced drag less than the minimal value obtained with the classical unswept elliptical wing for a constant lift and wing span. The induced-drag reduction is the result of the nonplanar wing and wake shape at the angle of attack. For an example wing of aspect ratio 7, the crescent-moon shape provides a reduction in cruise induced drag of 8.0 percent as compared to an unswept elliptical wing.

Vandernoot, F.-X., Barricau, P., Bezard, H. and Boisson, H.-C.

"MEAN AND TURBULENCE MEASUREMENTS OF WAKE VORTICES. WANDERING EFFECTS."

14th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, July 2008.

Experiments have been performed in a hydrodynamic tunnel behind a generic half-wing equipped with an inboard flap, up to 9 wingspans downstream using two-component Laser Doppler Velocimetry and three-component Particle Image Velocimetry. A half wing model of constant chord, full aspect ratio equal to 4, rounded wingtip and NACA0012 wing section has been used. The inboard flap which allows to get two co-rotating vortices extends over 80 percent of the half-span and 30 percent of the chord. The deflection angle can be set to 0 degrees (clean case), 4, 6 or 8 degrees. The upstream velocity is equal to 4 m/s which corresponds to a Reynolds number based on chord of about 300,000. The LDV campaign has provided a characterization of the near wake in cross planes at 0.1 and 0.25 wingspans downstream the trailing edge. Besides, the spanwise load distribution has been estimated by measurements along closed path around the wing sections. The PIV campaign, during which the setting of the coplanarity of the laser sheet and the calibration plate was revealed of first importance, has supplied the complete velocity and turbulence fields in cross planes scattered in the extended near wake between 1.27 and 8.74 wingspans downstream the wing. Furthermore, the wandering phenomenon, i.e. the slow side-to-side vortex motion which strongly alters the measurements, has been considered carefully. A procedure was implemented to delete the over diffusion and the overwhelming excess of turbulence artificially induced by this phenomenon in the vortex core.

Vandernoot, F.-X., Bezard, H., Barricau, P. and Boisson, H.-C.

"MEAN AND TURBULENCE MEASUREMENTS OF WAKE VORTICES, WANDERING EFFECTS"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 200.

The aim of the present study is to accurately characterize the rollup behind a generic wing equipped with an inboard flap deflected at different angles. The wandering effects are clearly identified and corrected. A half wing model of 75 mm chord, 150 mm half-span (aspect ratio equal to 4), rounded wingtip and NACA0012 wing section was used. The flap extends over 80 percent of the half-span and 30 percent of the chord. The flap angle can be set to 0 degrees (clean case), 4, 6 or 8 degrees. The experiments were carried out in the hydrodynamic tunnel THALES of the ONERA/DMAE (upstream velocity, 4 m/s; Reynolds number based on chord, around 300,000). To quantify the aerodynamics of the wing, a LDV system was used to measure the velocity along closed paths around the wing profile in different sections to estimate the spanwise load distribution and to connect it to the circulation of the wake vortices thanks to Betz's theory. To quantify the rollup for the different configurations of the wing, a stereoscopic PIV system was used to measure cross planes until almost 9 wingspans downstream. The angles of attack were chosen so that comparisons between the flap angles could be made at the same angle of attack or at the same lift. The mean fields of the three velocity components, the axial vorticity, and the six Reynolds stresses were measured with success. Classical phenomena, such as the diffusion of a single vortex or the behavior of a two-vortex system, were clearly identified from one cross plane to another.

"SIMULATION OF THE RADAR CROSS-SECTION OF WAKE VORTICES IN CLEAR AIR"

ERAD 2012, 7th Conf. on Radar in Meteorology and Hydrology, June 2012, Toulouse, France.

Real-time sensing of Wake Vortices at take-off and landing is a key issue for the implementation of new air traffic management systems for reduced aircraft separation in favorable weather conditions and for increased air safety. In the framework of SESAR P12.2.2 project, a model has been developed at UCL for the calculation of the radar cross-section of the wake vortices, in a wide frequency range. The first step is the simulation of the evolution of pressure, temperature, and humidity versus time, during the landing phase of the aircraft. These parameters are calculated using a pseudo-spectral code developed at UCL and then used for the calculation of the refractive index of the atmosphere under stratified conditions. They are represented in a plane perpendicular to the airplane velocity and evolving with time. The next step is the calculation of the radar cross-section of the various elements of the 3D-grid. The integrand is composed of a rapidly oscillating function in the frequency range of interest. The method of Li has been implemented for the resolution of the integral. The integration method necessitates interpolation between the elements of the grid. Simulations can be calculated for various airplanes weight and span, various speeds, various stratifications of the atmosphere, represented by Brunt-Vaisala constant.

"MODEL FOR THE CALCULATION OF THE RADAR CROSS SECTION OF WAKE VORTICES OF TAKE-OFF AND LANDING AIRPLANES"

ERAD 2012, 7th Conf. on Radar in Meteorology and Hydrology, June 2012, Toulouse, France.

A new model has been developed for the calculation of the radar cross section and the power backscattered by wake vortices of take-off and landing airplanes to better understand the physical mechanisms involved, to compare with the measurements that will be performed in X-band by Thales during the SESAR P12.2.2 project and to prepare inputs for testing a Wake Vortex Advisory System. The model contains a first part that simulates the evolution of the vortex in stratified atmosphere, using simplified 2D fluid mechanics equations and uses the pressure, temperature and humidity for the calculation of the difference between the dielectric permittivity of the clear air and of the wake vortex. The second part calculates the power backscattered by the dielectric permittivity gradients in the vortex. The input parameters describe the atmosphere as well as the airplane of interest. Simulation results have been compared with results published in the literature, when all the input parameters are available.

Vanierschot, M.

"ON THE DYNAMICS OF THE TRANSITION TO VORTEX BREAKDOWN IN AXISYMMETRIC INVISCID SWIRLING FLOWS"

European Journal of Mechanics B/Fluids, Vol. 65, 2017, pp. 65-69.

This paper reports on novel features found in the dynamics of the transition to vortex breakdown in inviscid axisymmetric flows with swirl. These features are revealed by a transient simulation of an open-ended pipe flow where the inlet swirl is suddenly increased from a swirl number just below the onset of vortex breakdown to a swirl number just above the onset of vortex breakdown. To eliminate the numerous parameters influencing breakdown, the axisymmetric Euler equations with swirl are used as a fluid flow model and solutions are obtained by means of numerical simulation. It is shown that as the step response has died out, the flow evolves to a quasi-static state where time derivatives of variables are negligible small. Stability analysis of this state shows that it can support standing waves in a small region of the flow domain. These standing waves are observed in the simulations as an imbalance in the axial momentum equation which slows down the flow near the central axis. The amplitude of this imbalance grows exponentially in time with a dimensionless growth rate of 0.83 scaled with the flowthrough time. Eventually, the axial velocity along the central axis becomes negative in a small part of the flow, leading to an axisymmetric recirculation zone, called vortex breakdown. To the authors knowledge, this study would be the first to reveal these features prior to breakdown and the results may help in understanding of the physical mechanisms leading to it as this is still a controversial issue in literature.

"ON THE ENERGY OF ELLIPTICAL VORTICES"

Physics of Fluids, Vol. 22, 2010, pp. 081701-1 - 081701-4.

Consider a two-dimensional axisymmetric vortex with circulation G . Suppose that this vortex is isovortically deformed into an elliptical vortex. We show that the reduction in energy is $-(G^2) \ln[(q + 1/q)/2]/(4\pi)$, where q^2 is the ratio of the major to the minor axis of any elliptical vorticity contour. It is notable that the reduction in energy is independent of the details of vorticity profile of the axisymmetric vortex and independent of its average radius. The implications of this result for the two-dimensional inverse cascade are briefly discussed.

vanZyl, L. H.

"UNSTEADY PANEL METHOD FOR COMPLEX CONFIGURATIONS INCLUDING WAKE MODELING"

Journal of Aircraft, Vol. 45, No. 1, January-February 2008, pp. 276-285

The calculation of unsteady air loads is an essential step in any aeroelastic analysis. The subsonic doublet lattice method is used extensively for this purpose because of its simplicity and reliability. The body models available with the popular implementations of the doublet lattice method are, however, not very versatile in terms of geometries that can be modeled. The ZONA6 code offers a versatile surface panel body model including a separated wake model, but uses a pressure panel method for lifting surfaces. This paper describes the development of an unsteady subsonic wing-body code based on the doublet lattice method, with a source panel representation of bodies, a separated wake flow

model based on the ZONA6 approach, and an approximate method of images to model wing-body interference. This approach provides greater flexibility in body shapes that can be modeled while retaining the reliability of the doublet lattice method for lifting surfaces.

"FLIGHT LOAD ASSESSMENT FOR LIGHT AIRCRAFT LANDING TRAJECTORIES IN WINDY ATMOSPHERE AND NEAR WIND FARMS"

Aerospace, Vol. 5, No. 2, 2018, pp. 42-1 to 42-22.

This work focuses on the wake encounter problem occurring when a light, or very light, aircraft flies through or nearby a wind turbine wake. The dependency of the aircraft normal load factor on the distance from the turbine rotor in various flight and environmental conditions is quantified. For this research, a framework of software applications has been developed for generating and controlling a population of flight simulation scenarios in presence of assigned wind and turbulence fields. The JSBSim flight dynamics model makes use of several autopilot systems for simulating a realistic pilot behavior during navigation. The wind distribution, calculated with OpenFOAM, is a separate input for the dynamic model and is considered frozen during each flight simulation. The aircraft normal load factor during wake encounters is monitored at different distances from the rotor, aircraft speeds, rates of descent and crossing angles. Based on these figures, some preliminary guidelines and recommendations on safe encounter distances are provided for general aviation aircraft with considerations on pilot comfort and flight safety. These are needed, for instance, when an accident risk assessment study is required for flight in proximity of Aeolic parks. A link to the GitHub code repository is provided.

Varshney, K.

"UNSTEADY DYNAMICS OF WIND TURBINE WAKE, OSCILLATING BUBBLE AND FALLING CARD"

PhD Thesis, January 2009, University of Massachusetts, Amherst, MA.

Helical tip vortices in the wake of a wind turbine, dynamics of a rising and oscillating bubble and trajectories of cards falling under gravity have been investigated here. The near wake flow field of the wind turbine in the Reynolds number range 1000 to 5000 has been explored using qualitative dye flow visualization and quantitative digital particle image velocimetry (DPIV) techniques. Flow visualization studies showed the dye getting trapped in the shape of spirals surrounding the helical vortex cores. It was found that the helical vortex core size was increasing with downstream distance. It was also found that the normalized stream-wise component of the wake velocity decreased with increasing tip-speed ratios. The pitch of the tip vortex monotonically decreased with increasing tip-speed ratios. The evolution of the global wake vorticity field with time has been studied in detail, for the first time. The results indicated that vorticity peaks at the center of the core, as one would expect. The vorticity at the center of the core was also found to decay as the vortex moved downstream, implying that the viscous

dissipation was active even at length scales of few diameters. Power spectrum of the stream-wise velocity field at a point showed a distinctive peak at a frequency of 0.5 Hz.

Vasatka, J. E.

"THE DYNAMIC RESPONSE OF A TWIN-ENGINE, COMMERCIAL JET TRANSPORT TO WAKE VORTEX ENCOUNTERS"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 14-1 to 14-1.

To refine existing wake-vortex separation distances through the application of technology, the issues associated with defining the basis for separation criteria must be addressed. This includes understanding the significance of a wake vortex encounter. To further the process of understanding the significance of such encounters, a flight simulator was used to evaluate the response of a jet-transport aircraft to wake-vortex encounters. The objective was to evaluate the response of a twin-engine, commercial jet transport to a variety of wake characteristics and operational assumptions. The study was conducted using a modified simulation of a twin-engine, commercial jet transport. The simulations included: (1) the free response of a trimmed airplane encountering a wake; (2) the response of an airplane controlled by only the autopilot; and (3) the response of an airplane controlled by a 'math pilot' designed to maintain wings level. The latter two modes of airplane control were chosen in order that the airplane response could be evaluated without incurring the variation associated with pilot-in-the-loop simulations. The results from this study suggest that the airplane's response is dependent on the flight path through the wake.

Vasatka, J. E.

"AN OVERVIEW OF WAKE VORTEX ISSUES AND THE ACTIVITIES OF THE GOVERNMENT/INDUSTRY TEAM"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Quebec, Canada, December 1997, pp. 41-42

The continuing growth of air travel and the increasing application of technology for managing air traffic is changing the environment of the air traffic system. Maintaining or enhancing the existing level of safety while improving productivity in this changing environment will require careful consideration to the underlying assumptions incorporated into the existing system. Research efforts presently under way around the world are addressing many aspects of the wake turbulence issue. However, no single organization has the breadth of expertise or the resources required to address the issues associated with developing and implementing solutions for wake-turbulence related issues. Therefore, to enhance safety and mitigate unnecessary capacity limitations placed on the system, the Government/Industry Team is identifying how to combine the efforts of many organizations to ensure that a focused, coordinated wake-turbulence plan is implemented and that it has constancy of purpose, clear and obtainable goals, strong leadership, and adequate resources.

Vasile, J. D.

"EFFECT OF A PITCH-OSCILLATING CANARD ON LIFT ENHANCEMENT AND TIP VORTEX MITIGATION"

AIAA Paper 2017-0717, January 2017, Grapevine, TX.

A two-dimensional NACA 0012 airfoil and three-dimensional NACA 0015 canard undergoing a dynamic ramp pitch-oscillating motion was investigated computationally. The effect of amplitude and reduced frequency on augmenting lift for both configurations was considered. The study showed lift enhancement for both configurations at freestream Mach number = 0.5 and = 0.2 for all amplitudes and reduced frequencies at angles of attack post stall. Furthermore, the effect of the dynamic motion on the development of the tip vortex was explored. The time-averaged flow solution for the pitch-oscillating canard revealed lower vorticity magnitude and less coherence of the tip vortex downstream. For the parameters investigated, increasing the amplitude of the oscillation proved to be the most effective in enhancing lift as well as reducing the strength of the tip vortex. The encouraging results indicate that further research in unsteady aerodynamics to increase the control authority of canard-controlled projectiles is necessary.

Vasilescu, R.

"HELICOPTER BLADE TIP VORTEX MODIFICATIONS IN HOVER USING PIEZOELECTRICALLY MODULATED BLOWING"

PhD Thesis, November 2004, Georgia Institute of Technology, Atlanta, GA.

In this thesis, piezoelectrically modulated and/or vectored blowing at the rotor blade tip is theoretically investigated as an active technique for modifying the structure of the tip vortex core as well as for increasing blade vortex miss distance. The mechanisms of formation and convection of rotor blade tip vortices up to and beyond 360 degrees wake age are described based on the CFD results for the baseline cases of a hovering rotor with rounded and square tips. A methodology combining electromechanical and CFD modeling is developed and applied to the study of a piezoelectrically modulated and vectored blowing two-dimensional wing section. The thesis is focused on the CFD analysis of rotor flow with modulated tangential blowing over a rounded blade tip, and with steady mid-plane blade tip blowing, respectively. Computational results obtained for steady tangential blowing indicate that the miss distance can be doubled compared to the baseline case, which may lead to a significant reduction in BVI noise level if this trend shown in hover can be replicated in low-speed forward flight. Results also show that through modulated blowing a higher dissipation of vorticity can be obtained.

Vasilescu, R. and Dancila, D. S.

"ROTOR WAKE MODIFICATIONS IN HOVER USING UNSTEADY SPANWISE BLOWING"

AIAA Paper No. 2006-1065, Reno, NV, January 2006

2200

A Computational Fluid Dynamics (CFD) study investigating the effects of unsteady spanwise rotor blade tip blowing on the formation and evolution mechanisms of blade tip vortices shed during hover is presented in this paper. The specific blowing configuration consists of a single jet sheet with modulated mass flow rate controlled through slot area variation, ejected tangentially over a rounded blade tip cap. By using the beneficial Coanda effect of jet attachment to the curved wall of the blade tip cap a downward deflection of the jet sheet direction is obtained. As a consequence the location and formation of the tip vortices are modified in a time dependent manner with reference to a baseline, no-blowing case investigated for the same rotor and flight conditions.

Vasilescu, R., Ganesh, B., Dancila, D. S., Komerath, N. M. and Sankar, L. N.

"GEOMETRY TIP CAP EFFECTS ON FORMATION AND NEAR WAKE EVOLUTION OF THE ROTOR TIP VORTICES"

AIAA Paper No. 2006-3376, San Francisco, CA, June 2006.

A combined numerical and experimental investigation is performed on the fundamental aspects of tip vortex formation and convection mechanisms for a two bladed rotor. The paper is focused on identifying similarities and differences in the near wake fields caused by blade tip geometry modification. Two different configurations are investigated. The first one corresponds to a square blade tip while the second one corresponds to a rounded blade tip cap. PIV measurements of the crossflow velocities around the forming tip vortex were performed for a forward flight regime characterized by a 0.1 advance ratio. RANS simulations of the rotor flow were conducted for the same rotor configurations as used in the experimental tests but considering only the hover regime. Both experimental and numerical tests confirm that there is a qualitative difference in the tip vortex formation and evolution between the square blade tip and rounded blade tip configurations. This qualitative change is shown in the velocity distributions measured and computed around and downstream of the tip. It is explained by the differences in the flow separation identified for the two configurations.

Vatistas, G. H.

"NEW MODEL FOR INTENSE SELF-SIMILAR VORTICES"

Journal of Propulsion and Power, Vol. 14, No. 4, July-August 1998, pp. 462-469

A new model that can generate single- or double-celled steady, incompressible, intense vortices is proposed. As was evident in earlier experiments, depending on the values of scaling constants, it is shown that the axial-velocity component may attain profiles ranging from jet-like to wake-like. In general, the radial-velocity profile has a similar shape as the tangential velocity, developing a direction reversal near the axis of rotation when the two-celled vortex appears. For the case of a one-celled vortex, the tangential velocity behaves like that of Rankine's vortex with viscous smoothing near the core. However, as the reverse flow inside the core matures the tangential velocity reduces gradually from the forced-vortex profile while its maximum value is augmented. The evolution from a one-celled

to a two-celled vortex is also characterized by a migration of the vorticity peak from the central axis toward the core. The present theory suggests that the implementation of the experimental data for the tangential velocity near the core depends on the quality of the secondary flow.

Vatistas, G. H.

"SIMPLE MODEL FOR TURBULENT TIP VORTICES"

Journal of Aircraft, Vol. 43, No. 5, September-October 2006, pp. 1577-1579

Fifteen years ago, a family of laminar vortices was proposed by Vatistas et al. The most widely used member of the set is the $n=2$. Recently, the basic model was transformed to account for vortex decay. The formulation was further enlarged to include the effects of density variations. The present paper represents the first attempt toward capturing the overall effects of turbulence via a mathematically simple model. A probable reason for the historical preference to Scully's formulation in modeling tip vortices is also identified.

Vatistas, G. H. and Aboelkassem, Y.

"EXTENSION OF THE INCOMPRESSIBLE $n=2$ VORTEX INTO COMPRESSIBLE"

AIAA Journal, Vol. 44, No. 8, August 2006, pp. 1912-1915

The incompressible $n=2$ vortex model formulation has been extended to account for density variation via the use of energy equation and perfect gas law. The basic elements of the approach are anticipated to be applicable to examine phenomena such as vortex stability, compressible flow aeroacoustics, compressible vortex visualizations via shadowgraphs, and several others.

Vatistas, G. H. and Aboelkassem, Y.

"SPACE-TIME ANALOGY OF SELF-SIMILAR INTENSE VORTICES"

AIAA Journal, Vol. 44, No. 4, April 2006, pp. 912-917.

The theoretical development presented here provides a space-time duality for self-similar intense vortices. The methodology was first derived and then its validity was tested using several known classical vortices. In this Note, we have examined the similarity properties of a group of intense vortices. The system of equations that describes the general problem was condensed using a similarity variable that combines space and time. The revealed duality among the vortex decay and the steady-state subset made possible the transformation of various known vortex models from decaying to steady state and vice versa. Vortices of this type were found to remain concentrated and intense throughout the decay phase. In the presence of a meridional flow, the simplified problem is underdetermined, which explained the reason behind the emergence of a multitude of past solutions. The main characteristics of the analogy were justified by the data of various experimental studies.

Vatistas, G. H., Aboelkassem, Y. and Kamran Siddiqui, M. H.

"TIME DECAY OF n FAMILY OF VORTICES"

AIAA Journal, Vol. 43, No. 6, June 2005, pp. 1389-1391

The steady state vortex model of Vatistas, et. al, is further developed into a high Reynolds number time decaying model. Following the classical order-of-magnitude analysis and similarity transformation analogous to those in the development of boundary layer flow theory, a generalized transformation between a family of steady state vortices and their time varying counterparts are established. The well-known vortex profiles such as Lamb, Burgers and Survillan models can be seen as specialized cases of the generalized formulation described in this work.

Vatistas, G. H., Aboelkassem, Y. and Siddiqui, M. H. K.

"ON THE SPACE-TIME DUALITY OF INTENSE VORTICES"

AIAA Paper No. 2005-5159, Toronto, Canada, June 2005

In this paper, we present a general methodology whereby steady intense vortices are transformed into time decaying via an independent variable that combined space and time. The fundamental principle was then employed to extend the desingularized n - family of steady state vortices to become time dependent. Limited experimental data confirms the validity of the approach. The method is sufficiently general as to allow the conversion of any known vortex model of the same kind from steady to time decaying and visa versa.

"THERMAL PROPERTIES OF COMPRESSIBLE LINE VORTICES"

Journal of Aircraft, Vol. 54, No. 4, July-August 2017, pp. 1407-1414.

A simple mathematical model to simulate the temperature, pressure, and density distributions in intense turbulent compressible line vortices is reported. Based on the previous $n = 2$ member of the n family of vortices, a wider-range model that includes the rudimentary combined features of turbulence and compressibility is built. In antithesis to the previous laminar theoretical approaches, where the converging flow cooled down monotonically with decreasing radius, it is now discovered that, far from the axis of rotation, the gas is first heated up, reaching a static temperature maximum that is higher than the ambient value; then, it chills down to a subambient minimum at the vortex center. The cause of this effect is recognized to be the outcome of competition between two fundamental mechanisms: gas heating because of mechanical dissipation, and cooling due to mainly fluid parcel's dilation. Thus, the present investigation identifies the cause of the Ranque-Hilsch-like thermal effect observed in unconfined compressible vortices. In comparison to laminar vortices, the center of a turbulent gaseous

vortex is found to be cooler, thinner, and under lower-pressure conditions. All thermodynamic properties are shown to be functions of the vortex Mach number and level of turbulence.

Vatistas, G. H., Kozel, V. and Mih, W. C.

"A SIMPLER MODEL FOR CONCENTRATED VORTICES"

Experiments in Fluids, Vol. 11, 1991, pp. 73-76

A simple vortex model based on an empirical formula for the tangential velocity component was presented. A closed form solution for the static pressure which agrees well with the observed values was obtained. The model produced a radial velocity component which is bounded over the whole domain.

Vatistas, G. H., Lin, S. and Li, P. M.

"A SIMILAR PROFILE FOR THE TANGENTIAL VELOCITY IN VORTEX CHAMBERS"

Experiments in Fluids, Vol. 6, 1988, pp. 135-137

Forcing a fluid into a cylindrical chamber through either a series of tangential inlets, or a rotating porous circumferential wall will generate a strong confined vortex. In both cases a Rankine-like tangential velocity profile, with a viscous smoothening in the region where the vortex changes modes, will be produced. Recent experiments by Vatistas (1984) have shown the velocity to strongly depend on several flow parameters, and not to vary significantly along the height of the chamber. The latter observation is true for most of the vortex chamber flow except inside Ekman's boundary layers, at the top and bottom plates, where the tangential velocity is first expected to peak, and then reduce to zero. In the present note a similarity relationship for the radial profile of the tangential velocity is reported. Experimental data confirm the results of the analysis. Oseen's equation for an unconfined vortex is found to adequately approximate the confined vortex.

Vatistas, G. H., Panagiotakakos, G. D. and Manikis, F. I.

"EXTENSION OF THE n -VORTEX MODEL TO APPROXIMATE THE EFFECTS OF TURBULENCE"

Journal of Aircraft, Vol. 52, No. 5, September-October 2015, pp. 1721-1725.

The present work is an extension of the previous contribution of Vatistas on simple model for turbulent tip vortices. A generalized formula that encapsulates both the laminar and turbulent members of the n family of vortices that could also produce the turbulent equivalent of the Rankine and Kaufmann-Scully vortices was presented. The best correlation for the tangential velocity with the experimental tangential velocity data is shown to occur when n is equal to two. An approximate link of the turbulent parameter to the effective vortex Reynolds number was made. The present formulation was shown to perform better in approximating the wake of both laboratory and full-scale vortices than the traditional approaches.

Vaucher, G. T., Creegan, E. and Yarbrough, J.

"924-MHZ WIND PROFILING RADAR ACCEPTANCE TESTS"

ARL-TR-1815, November 1998, U.S. Army Research Laboratory, White Sands Missile Range, NM.

In March of 1998, the Artillery Branch of the Army Research Laboratory received a Reconstructed 924 MHz Wind Profiling Radar System. Over the subsequent months, several hardware tests were conducted to verify the successful functioning of the radar components and integrated system. In this technical publication, seven radar evaluation tests are documented. The first two radar evaluation tests, the Frequency Survey, and the Local Site and Internal Radar System Noise Tests, examine the non-operational environments for possible radar signal corruption sources. The radar signal itself is reviewed in the Radar Signal Analysis Test. Finally, the radar's components are isolated and evaluated in the 'I' and 'Q', Opposing Beams, System Noise Test: Pre-Amplifier, and System Noise Test: Distributed Amplifier Tests. Each Test explanation includes: (1) the Radar Test Purpose, (2) the Hardware/Test Setup and Materials, (3) the Test Description, and (4) the Results and Result Interpretation. Figures displaying specific hardware setup, or test results are included, as appropriate. Appended to the text are results from the initial radar verification exercise. Brief excerpts from the Radar Test logbook are included, to enhance the reader's understanding.

Vaughan, J. M.

"COHERENT LASER SPECTROSCOPY AND DOPPLER LIDAR SENSING IN THE ATMOSPHERE"

Physica Scripta, Vol. T78, 1998, pp. 73-81

The principles of coherent laser spectroscopy are briefly reviewed in which a signal beam is heterodyned with an optical local oscillator beam. The frequency and single mode selectivity this provides is shown to be very advantageous. This is illustrated by recent work on the properties of different classes of light held including the fractal character of Gaussian-Lorentzian light, and by several aspects of laser physics. In equivalent practical applications to remote sensing in the atmosphere, coherent Doppler lidar provides a powerful technique. This is illustrated by measurements of wind fields and aircraft wake vortices. Airborne equipment have been used for measurements of true airspeed, wind shear warning and atmospheric backscatter levels. Future space-borne lidars could potentially measure the global wind field – which would be of great benefit for numerical weather forecasting and climate studies.

Vaughan, J. M.

"WAKE VORTEX INVESTIGATIONS AT HEATHROW AIRPORT, LONDON"

Proceedings of 3rd Aero Days Post-Conference, Nouvelle Revue D'Aeronautique et D'Astronautique, No. 2, 1998, pp. 116-12.

Measurements of aircraft wake vortices by Laser Doppler Velocimetry (LDV) can provide unique, full-scale information on vortex generation, evolution, trajectory, and decay in the real atmosphere. During

trials at Heathrow nearly 3000 records of vortices from landing aircraft were made over 25 days between December 1994 and September 1995. Examples of some of the initial results are presented, including characteristic vortex signatures and profiles from different aircraft and analyses of vortex strength and trajectory. Because of their fine resolution, LDV measurements should enhance the understanding of the structure of vortices and the mechanisms, including meteorological conditions, governing their behavior. Vortex bursting for example is poorly understood but is likely to be the limiting factor in determining acceptable separation minima at airports. Application to airport operation is briefly discussed and the possible contribution to strategic and tactical decision making.

Vaughan, J. M. and Harris, M.

"LIDAR MEASUREMENT OF B747 WAKES: OBSERVATION OF A VORTEX WITHIN A VORTEX"

Aerospace Science and Tech., Vol. 5, August 2001, pp. 409-411.

Measurements of aircraft wake vortices obtained by laser radar techniques at London Heathrow Airport have revealed many interesting features of vortex structure. Notably, the vortices from Boeing 747 aircraft are shown to contain an intense, narrow-core vortex embedded within a larger co-rotating diffuse vortex. We propose an empirical 'double-dispersion' model consisting of the linear superposition of two concentric dispersion functions. This new model provides a good description of the B747 vortex, and should therefore be applicable in simulations of aircraft encounters with B747 vortices.

Vaughan, J. M., Brown, D. W., Constant, G., Eacock, J. R. and Foord, R.

"STRUCTURE, TRAJECTORY AND STRENGTH OF B747 AIRCRAFT WAKE VORTICES MEASURED BY LASER"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 10-1 to 10-1.

Wake vortices of aircraft landing at Heathrow have been measured with a coherent laser radar. Analysis of the vortex velocity profiles from B747 aircraft shows a series of symmetrical dips or inversions on approach to the central core. Such inversions are not predicted theoretically and contrast with the uniformly increasing velocity profiles observed from other aircraft. Vortex trajectories may also be reconstructed; in one case a B747 vortex, after initial descent, returned to the glideslope with undiminished strength over a minute later.

Vaughan, J. M., Steinvall, K. O., Werner, C. and Flamant, P. H.

"COHERENT LASER RADAR IN EUROPE"

IEEE Proceedings, Vol. 84, No. 2, February 1996, pp. 205-226

European work in coherent laser radar with 10 micron and shorter wavelength lasers is reviewed. Fundamental aspects include heterodyne studies of signal statistics and fluctuations, and detailed

experimental and theoretical work on signal amplification and autodyne arrangements with light reinjected into the laser cavity. Progress with lasers, detectors, and modulators has led to the development of several compact robust field systems both continuous-wave and pulsed. Various ground-based programs are described including local wind field measurement and wake vortex investigation at airfields, and study of range, image, and Doppler shift of hard targets. Airborne systems have investigated avionics problems of true airspeed, pressure error, and wind shear warning. Other airborne studies include ground imaging, obstacle warning, terrain following, and a compendium of atmospheric backscattering over the North and South Atlantic. In recent years, the European Space Agency has supported studies and technology development for a space-borne wind lidar in the Atmospheric Laser Doppler Instrument (ALADIN) program.

Vechtel, D.

"FLIGHT SIMULATOR STUDY ON THE INFLUENCE OF VORTEX CURVATURE ON WAKE ENCOUNTER HAZARD USING LES WIND FIELDS"

The Aeronautical Journal, Vol. 116, No. 1177, March 2012, pp. 287-302.

A flight simulator study has been carried out to evaluate the performance of modern flight control systems encountering curved wake vortices. During the decay process the shape of wake vortices alters significantly which has an influence on the encounter characteristics and thus on the encounter hazard. To analyze most realistic wake encounters, flow fields of matured vortices have been generated with large-eddy-simulations. These were used for the determination of induced force and moment histories during the encounter. The force and moment histories have been implemented into the equations of motions of a 6 DoF flight simulation. For the sake of comparison encounters have also been simulated with straight vortices as they were mostly used for many other investigations. The most important goal of the study was to analyze the difference between these ideally straight vortices and vortices with a more realistic shape regarding encounter acceptance. The simulator study was conducted in an A330 motion-based full-flight simulator with pilots-in-the-loop. The analyzed scenario was a wake encounter during final approach. The encounter conditions corresponded to a heavy-behind-heavy situation for IFR operations. The aircraft was flown either manually (in normal law) or with autopilot engaged. Altogether 93 encounters have been simulated, 38 with straight and 55 encounters with curved vortices. For encounters under manual control the simulator study revealed a potential risk of pilot induced oscillations during encounters with curved vortices. With autopilot engaged not even one encounter with curved vortices was classified to be unacceptable. Although significant aircraft response was experienced the autopilot never disengaged automatically in any encounter. Altogether about 12 percent of the encounters were not accepted by the pilots. This is indeed a significant number, especially as the analyzed scenarios can be regarded to be realistic situations which can occur in reality even if the applicable separation distances are applied.

Vechtel, D.

"SIMULATION STUDY OF WAKE ENCOUNTERS WITH STRAIGHT AND DEFORMED VORTICES"

The Aeronautical Journal, Vol. 120, No. 1226, April 2016, pp. 651-674.

A simulation study was conducted to investigate the influence of vortex deformation on wake encounter characteristics. Wake vortices tend to be strongly deformed during the decay process, depending on the atmospheric conditions in terms of turbulence and thermal stratification. For quantification of the influence of vortex deformation, encounters of an aircraft of the 'Medium' category behind a generator aircraft of the 'Heavy' category were simulated with straight vortices and with realistically deformed vortices derived from large-eddy simulations. All relevant parameters that influence the encounter characteristics, such as encounter angles and positions, were varied within a wide range. In order to cover all kinds of vortex deformation, encounters with different vortex ages from 16-136 seconds were simulated. Hence, all relevant phases during the vortex decay from nearly straight and wavy vortices to vortex rings were considered. The parameter variation study revealed that on average the impact on the encountering aircraft is less with deformed vortices than with straight vortices of comparable strength. Especially with vortex rings, the encountering aircraft is exposed to a much smaller impact. However, the results also show a larger aircraft response during encounters with wavy vortices just prior to vortex linking. The maximum aircraft response with wavy vortices is stronger than with straight vortices of comparable strength. Also, the strongest encounters occur under greater encounter angles with deformed vortices than with straight ones.

Vechtel, D.

"IN-FLIGHT SIMULATION OF WAKE ENCOUNTERS USING DEFORMED VORTICES"

Aeronautical Journal, Vol. 117, No. 1196, October 2013, pp. 997-1018.

During the decay process the shape of wake vortices changes significantly which has an influence on the encounter characteristics, hence on the encounter hazard. To evaluate the influence of vortex deformation on the wake encounter hazard, in-flight simulations with the DLR research aircraft ATTAS were carried out. For a realistic analysis of wake encounters flow fields of matured vortices were generated with large eddy simulations. These flow fields were used for the determination of histories of induced forces and moments acting on the wake encountering aircraft. The force and moment histories were then fed into the equations of motions of the non-linear six degree-of-freedom in-flight simulation of the DLR research aircraft ATTAS. To compare different stages of vortex deformation, encounters were simulated in flight with wavy vortices and vortex rings. The most important benefit of the in-flight simulation is the realistic environment, which enables a realistic assessment of pilots' encounter acceptance. The analyzed scenario was of a wake encounter during final approach. The encounter conditions correspond to separation distances of about 4nm and 5nm behind an aircraft of the 'heavy' category. During the encounters the ATTAS was flown under manual control. Altogether 31 encounters were simulated in flight, 9 with wavy vortices and 22 with vortex rings. The analysis of the results shows that with increasing vortex deformation the encounter impact acts increasingly in all degrees of freedom. Apparently, pilots assess roll-dominated encounters as more dangerous, which is why the unacceptability threshold is higher for encounters with vortex rings than for those with wavy vortices. Besides this unacceptability boundary, a harmlessness boundary can be determined, which seems to be independent from the degree of vortex deformation. This is an important outcome of the flight test described in this paper. Although, due to the very limited number of flight tests performed,

no clear correlation between the pilot ratings and objective measures could be assessed, an acceptance boundary for the roll control ratio could be determined below which the effects of vortex deformation seem to be negligible.

"SIMULATION STUDY OF SEVERITY AND MITIGATION OF WAKE-VORTEX ENCOUNTERS IN GROUND PROXIMITY"

Journal of Aircraft, Vol. 54, No. 5, September-October 2017, pp. 1802-1813.

Wake-vortex encounter reports as well as simulations show a significantly higher encounter probability during landing shortly before touchdown in comparison to other flight phases. This is caused, among other factors, by the special behavior of wake vortices in ground effect. Nevertheless, hazardous wake encounters with adverse consequences are rarely reported. To gain more insight in the mechanisms of wake encounters close to ground, encounter simulations were performed with realistic vortex flowfields. These were generated using coupled Reynolds-averaged Navier-Stokes and large-eddy simulations covering the whole vortex evolution in ground effect from generation until decay and were used for a hazard analysis. Encounter simulations were performed with a simulation model of an A320-size aircraft with autopilot engaged following an A340-size aircraft. Different wind conditions and vortex ages were considered as well as a so-called plate line. Recent studies showed increased vortex decay when a series of plates is positioned in front of the runway threshold. The results of the study reveal a significant reduction of the maximal vortex impact on the encountering aircraft due to the plate line. This effect is more pronounced for younger vortices, but also for operationally relevant vortex ages, a considerable effect of the plate lines in reducing the maximum aircraft reaction due to a wake encounter close to the ground can be observed.

Veerman, H. C. M.

"PRELIMINARY MULTI-MISSION UAS DESIGN"

MS Thesis, August 2012, Delft University of Technology, Delft, Netherlands.

Unmanned vehicles are important when it comes to performing a desired task in a dangerous or inaccessible environment. Unmanned robots, have been successfully used for many years. More recently, a growing interest in Unmanned Aircraft Systems (UASs) has arisen. In the past few years, the development of sensors, microprocessors and propulsion systems resulted in UASs that are smaller, lighter, and more capable than ever before. This leads to endurance, efficiency and autonomy levels that exceed the capabilities of manned flight. Many successful designs have been created by several universities, commercial companies, and research agencies. Due to the wide variety of applications, several configurational concepts have been developed. As a result, most UAS designs are optimized for a dedicated task. To perform different tasks, users need to have access to multiple UASs. This means that manufacturers and users must maintain production and support lines for multiple UASs. The goal of this thesis was to create a preliminary design of a multi-mission UAS by using off-the-shelf systems.

This UAS must be able to perform both low and high-speed missions. To reach the stated goal a clear overview of all requirements had to be created first. This was followed by extensive market research to get an overview of the performance of current UAS designs. This market research was captured in a database. Based on the requirements in combination with the obtained database, all UAS classes and configurational options have been evaluated. The evaluation revealed that a new fixed wing electrically powered mini UAS design may be able to comply with the all UAS requirements. Based on the UAS database, weight estimation relationships for preliminary mini UAS design were derived. These relationships were used for the preliminary UAS performance and weight estimation. After investigating the technical and operational feasibility, the compliance with respect to the requirements was checked. This resulted in a new UAS design point. Subsequently, the UAS design was analyzed in more detail. Optimization of the wing was performed by using a quasi-3D optimizer. This was followed by a tail design that was based on UAS reference data and volume coefficients. The resulting wing and tail design were evaluated by investigating the wing-tail effects and the primary static & dynamic stability derivatives. This was followed by an evaluation of the material options for the structure. During this evaluation a new manufacturing technique, 3D printing, was tested. Subsequently, the propulsion system design was performed by using a UAV Propulsion Development Kit (UPDK). This UPDK can estimate the performance of multiple engine-propeller combinations. Based on the evaluation of the top five combinations, a combination was selected. Finally, the additional UAS subsystems were selected. After the preliminary UAS design was completed, the effectiveness of the design was evaluated. Together with off-the-shelf systems it was possible to create a design that is able to comply with most requirements. The WER for the payload weight was found to be inaccurate. This was caused by the fact that current UASs are equipped with heavier or additional payloads. The WER for the empty weight slightly underestimated the structural weight of the UAS. Overall, it can be concluded that it is possible to create a preliminary mini UAS design capable of performing both low and high speed missions using off-the-shelf systems.

Veillette, P. and Decker, R.

"BEWARE OF THE HORIZONTAL TORNADO! WAKE VORTEX, PART I"

Air Line Pilot, Vol. 63, No. 1, February 1994, pp. 26-3.

This paper reviews the state of the art of wake vortex behavior based on the 1991 Wake Vortices Conference in Washington, DC. Accident statistics are reviewed and it was noted that air carrier aircraft are often involved both as vortex generators and encounters. Vortex motion in five stages of development is reviewed: vortex formation, vortex effect on the other vortex (sink rates), growth of the vortex rotational axis and wavelength disturbances, core growth and vortex distortion, and distorted vortex rings.

Veillette, P. and Decker, R.

"BEWARE OF THE HORIZONTAL TORNADO! WAKE VORTEX, PART II"

Air Line Pilot, Vol. 63, No. 2, February 1994, pp. 24-2.

This paper reviews aircraft configuration effects (aircraft speed, wingspan, weight, flap deflection, engine replacement, etc.) on vortex movement and decay. Effects on aircraft motion are described based on how an aircraft encounters a vortex: flying right into the vortex itself (along track), flying in between a vortex pair, and flying perpendicular to a pair of vortices (cross track).

Veillette, P. R.

"DATA SHOWS THAT U.S. WAKE-TURBULENCE ACCIDENTS ARE MOST FREQUENT AT LOW ALTITUDE AND DURING APPROACH AND LANDING"

Flight Safety Digest, Vol. 21, No. 3-4, March-April 2002, pp. 1-47

In wake-turbulence accidents and incidents from 1983 through 2000, about 10 percent of the aircraft weighed more than 30,000 pounds/13,600 kilograms, and two-thirds of the pilots held commercial pilot certificates or airline transport pilot certificates.

Veillette, P. R. and Decker, R.

"HANDLING HORIZONTAL TORNADOES"

FAA Aviation Safety Journal., Vol. 13, Nos. 13 and 14, July 1993, pp. 3-9.

Wake vortices do not always behave in the orderly manner prescribed in the AIM, and what we have been told about avoiding them could actually get us into trouble. This report is an up-to-date briefing on the invisible menace.

"EXPERIMENTAL CHARACTERIZATION OF UAS FLOW FIELDS THROUGH HOTWIRE ANEMOMETRY AND PIV"

AIAA Paper 2018-4121, June 2018, Atlanta, GA.

The velocity flow field around a small unmanned air system (UAS), specifically the DJI Phantom 3, is investigated in a series of experiments at Syracuse University. Experiments were conducted in the 15'x10'x18' room herein referred to as the Indoor Flow Lab. The goal of these experiments was to gain a better understanding of the rich, turbulent flow field that a typical UAS creates. Characterization of the flow using hotwire anemometry and stereo particle image velocimetry (PIV) has been conducted. Regions of investigation include the downwash, above the vehicle, and far downstream. Investigation of several locations around the UAS show that dominant frequencies exist within the flow field. Analysis of the flow field includes calculation of mean velocities, turbulence intensities, mean-square velocity, and turbulent kinetic energy at several downstream locations. The spectral content of the flow field is analyzed and presented using power spectral density. Discussion and comparison of the applicability of hotwire anemometry and stereo-PIV to this flow will be made.

"VORTEX WAKE INVESTIGATION BEHIND A WING-FLAP MODEL WITH JET SIMULATION"

ICAS 2008, Anchorage, AK, Sept. 2008.

To get a better insight in the effect of jets on vortex development and decay, stereo-PIV measurements were performed in a towing tank behind a flapped aircraft model. The experimental data set yields the wake vortex behavior in a range that extends from the vortex formation stage up to the mid-field (approximately $t=2$ corresponding to 100 wingspans for angle of attack of 0 degrees and 60 wingspans for angle of attack of 6 degrees). Although the jet does not affect the overall circulation strength, it has a significant effect on the velocity distribution in the wake. A new Double Gaussian vortex model is introduced that perfectly fits the measurement data.

Veldhuis, L. L. M. and de Kat, R.

"VORTEX WAKE INVESTIGATION BEHIND A WING-FLAP MODEL WITH JET SIMULATION"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

In the current research we focus on the effect of jets on the development and decay of the vortices produced by a wing with flaps deployed, as typically found during take-off and landing. For this purpose wake vortex flow experiments were performed behind a generic aircraft model using the Stereo-PIV measurement technique in a towing tank.

Veldhuis, L. L. M. and Rentema, D. W. E.

"EXPERIMENTAL ANALYSIS OF THE VORTEX WAKE STRUCTURE BEHIND A PROPELLER-WING CONFIGURATION"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 15-1 to 15-17.

A flow field survey was performed with a 5-hole pressure probe at 1 chord length behind a propeller-wing configuration revealing important qualitative and quantitative information on the propeller dominated interactive flow field. The model, that consists of a low aspect ratio semi-span wing model combined with a 4 bladed tractor propeller, was tested at several low subsonic flow conditions in the Delft University Low Speed Windtunnel. The distribution of total pressure and axial vorticity show, besides the well-known spiral tip vortex, a strong deformation of the slipstream structure. The deformation of the vortex wake is strongly related to the spanwise lift distribution of the propeller/wing configuration which might be used as a starting point for prediction of vortex formation and decay. It also determines the magnitude of the overall induced drag and the deformation process therefore has implications for the proper modeling of slipstreams used within theoretical prediction

codes for the analysis of airplane performance. To obtain quantitative information from the field data the theory of Betz and Maskell was applied to determine the lift, the profile drag and the induced drag for both the model with and without running propeller. Comparison of these results with external balance measurements shows a good agreement.

"TOWING TANK EXPERIMENTS OF COLD JET-VORTEX INTERACTION ON A GENERIC WING-FLAP MODEL"

AST4-CT-2005-012238, Delft Univ. of Technology, Delft, The Netherlands, December 2006

The main objective of the present study is to investigate the influence of a jet on the flap end vortex and the wake vortex formation. The investigation focuses on the direct influence of the jet on the flap end vortex and the (merged) vortex characteristics in the near to mid field. The main vortex characteristics addressed in this report are: the vortex trajectory, the maximum tangential velocity, the peak vorticity, and the vortex core radius. With respect to the jet negligible effects were found for the main parameters like circulation and vortex core growth. However, a significant effect emerged for the merging process of the flap end and tip vortex. This leads to noticeable effects on the tangential velocity distribution which in turn determine the induced rolling moment for follower aircraft. Whereas known vortex models in general fail to fit experimental data of double vortex systems, the Double Gaussian model developed and applied in this investigation, leads to accurate fits with the velocity distributions.

Veldhuis, L. L. M., Scarano, F. and Van Wijk, C.

"VORTEX WAKE INVESTIGATION OF AN AIRBUS A340 MODEL USING PIV IN A TOWING TANK"

AIAA Paper No. 2003-3814, Orlando, FL, June 2003

PIV wake-measurements in a towing tank on a 1/48 scaled model of an Airbus A340-300 towed at a speed of 3 and 5 m/s with angles of attack of 2 degrees, 4 degrees, 8 degrees, are discussed. The main objective of the investigation is to demonstrate the applicability of PIV diagnostics in wake vortex research in towing tank facilities. The experiments are performed in a fixed plane perpendicular to the towing direction to measure the streamwise component of the wake vorticity. An underwater moving camera device (traversing-field-of-view or TFOV) is used to keep the moving vortex in the field of view during the vortex whole downward motion. The TFOV method is proposed as a cost-effective solution to the option of camera clusters and minimal efforts are needed for the calibration of the field of view. The measurement yields the wake vortex behavior described during a period that extends from the vortex formation stage up to the mid-field (200 wingspans). The results obtained show that relevant vortex parameters, like vortex trajectory, tangential velocity, peak vorticity, and vortex core radius, can be obtained with the PIV technique both in a global (trajectories) and detailed sense (decay parameters).

"PIV-SURVEY OF THE VORTEX WAKE STRUCTURE BEHIND AN AIRBUS A340 IN A TOWING TANK"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001.

To find detailed information about the vortex structure and its decay, PIV measurements were performed in a 142 m long water tank behind an Airbus A340-300 model. The main objective of the experimental investigations is to demonstrate the applicability of the PIV technique for measuring the mid to far field behind aircraft in towing tank facilities. The collected data are used within the European research program C-WAKE to arrive at a better understanding of the behavior of the vortex system at large distance behind the aircraft. The survey was performed at a 2-, 4- and 8-degree angle of attack and towing speeds of 3 m/s and 5 m/s. Two-dimensional PIV data were taken in a fixed plane perpendicular to the towing direction to measure the stream wise wake vorticity. To be able to track the down going vortices an underwater camera moving vertically with the vortices was used yielding high spatial resolution measurements. Recordings are acquired at an effective rate of 3.3 Hz over a field of view of about 0.5 x 1.2 square meters. The image analysis was performed with an iterative PIV processing technique with multigrid interrogation including a window distortion algorithm. The collected data on the vortex flow demonstrate that the PIV technique is very suitable for this type of experimental research. Moreover, the application of the towing tank facility in conjunction with PIV diagnostics allows to obtain a longer time/space description of the vortex wake (up to 260 wingspans) in comparison with wind tunnel experiments and catapult facilities.

"FORMATION FLIGHT -- FINE-TUNING OF THEORETICAL PERFORMANCE PREDICTION"

AIAA Paper 2013-0961, January 2013, Grapevine, TX.

In this paper we address the theoretical analysis of commercial aircraft formation flight. To investigate the usefulness of wind tunnel tests for detailed analysis of the flow phenomena associated with formation flight of commercial aircraft, the problem is revisited and extended where appropriate. For this purpose, an enhanced mathematical model was developed that allows the investigation of formation flight aspects not yet covered by previous studies. This model is based on a vortex lattice approach which includes a selection of various vortex models as well as the effects of wind tunnel walls and Reynolds number scaling. A formation of two and three aircraft is considered with a separation distance of 10 to 100 spans. It is demonstrated that in some earlier simulations, discussed in open literature, an incorrect lift coefficient is used which leads to erroneous prediction of the induced drag reductions. The application of positive sweep, taper and winglets are all found to have beneficial effects on formation flight induced drag reduction, while aircraft trim causes a slight decrease of induced drag reduction. Furthermore, the wing aspect ratio was not found to have a significant influence. According to the calculation model, a typical medium aircraft exhibits a total drag reduction around 13 percent when flying behind an identical aircraft. Good agreement between scaled and full-scale simulation induced drag reduction is found in terms of both trend and induced drag reduction at the so-called

sweet spot. The addition of wind tunnel walls causes a large increase in maximum induced drag benefits, which signifies the need for accurate wind tunnel wall corrections in case of future wind tunnel tests.

"NON-STEADY VELOCITY MEASUREMENT OF THE WAKE OF A HELICOPTER ROTOR AT LOW ADVANCED RATIOS"

ARO-14142.5-EX, Ohio State Univ., Columbus, OH, September 1981

A system was developed which could measure the instantaneous velocities in the wake of a model helicopter rotor operating at low advance ratios. A three-wire hot film probe was mounted on a traverse and placed at many positions in the wake. The output of the probe was fed into an on-line computer operating in an interactive mode. Computer generated vector plots were made of both time averaged velocities and instantaneous velocities for the case of $\mu = 0.06$.

"DYNAMIC EFFECTS OF TRAILING VORTEX WITH TURBULENCE AND TIME-VARYING INERTIA IN AERIAL REFUELING"

AIAA Paper No. 2004-4945, Providence, RI, August 2004

This paper describes the dynamic modeling of a receiver aircraft undergoing an aerial refueling, including the effect of time-varying mass and inertia properties associated with the fuel transfer, the tanker's vortex induced wind effect and atmospheric turbulence. Three significant refueling effects due to the fuel transfer that have been studied in our model are (i) the continuous mass change (ii) the change in the location of the receiver's center of mass and (iii) the change in the inertia matrix. A new set of nonlinear, 6-DOF, rigid body equations of motion including the wind effect in addition to the above-mentioned effects of fuel transfer, are derived for the receiver aircraft. The assumption of the existence of plane of symmetry is also relaxed for the receiver aircraft, to cater to situations of asymmetric fuel loading. The effect of the aerodynamic disturbances induced on the receiver, due to the tanker's vortices as well as turbulence, are modeled using an averaging technique that computes the effective wind components and gradients from the induced wind velocity distribution. Engine and actuator dynamics are also incorporated into our aircraft dynamic model. The receiver aircraft before fuel transfer is treated as a rigid body made up of 'n' particles. The dynamic effects due to fuel transfer are modeled by considering the mass change to be confined only to a finite number ('k') of lumped masses. These lumped masses would normally represent the fuel tanks on the receiver aircraft. Hence, once the refueling begins, the mass of the individual lumped masses and the location of the CM of the whole receiver aircraft are calculated using the design parameters such as the shape, size, location of the individual fuel tank and the rate of fuel flowing into it.

"MODELING OF AERODYNAMIC COUPLING BETWEEN AIRCRAFT IN CLOSE PROXIMITIES"

AIAA Paper 2004-5172, August 2004, Providence, RI.

A simulation-oriented technique is developed for modeling the aerodynamic coupling between aircraft flying close to each other. The velocities induced by the leading aircraft's vortex on the following aircraft are written as a function of both the relative separation in all the three axial directions and the relative orientation between the two aircraft. These non-uniform vortex-induced wind and wind gradients acting over the trail aircraft are approximated with uniform effective wind and wind gradients that can be directly used in standard equations of motion without having to explicitly compute the induced forces and moments. Thus, the vortex effect modeling on the follower's dynamics is made more naturally adaptable to a wide variety of computer simulations involving multi-aircraft close proximate flight. Several vortex models that were employed to estimate the vortex induced velocities and the various averaging schemes that were applied to compute the effective wind components and gradients are explained. The comparison analysis performed using the wind tunnel measurements for the formation flight of two aircraft shows that the plots of incremental coefficients of the forces and moments induced on the follower aircraft exhibit an improved match over those shown in our earlier work. Finally, the scope for the application of our technique in the contexts of formation flight and aerial refueling, is outlined.

Venkataramanan, S., Dogan, A. and Blake, W.

"VORTEX EFFECT MODELLING IN AIRCRAFT FORMATION FLIGHT"

AIAA Paper No. 2003-5385, Austin, TX, August 2003

This study develops a new technique for the vortex effect modeling and incorporates it in a six-DOF analysis of a close formation flight. The velocities induced by the leader's vortex on the following aircraft are written as a function of the relative separation in all the three axial directions and also the relative orientation between the leader and the follower aircraft (characterized by the rotation matrices) using a modified horseshoe vortex model based on Helmholtz profile. Since the induced wind and wind gradient vary along the span and length of the aircraft, an averaging technique is implemented to compute effective wind and wind gradient on the following aircraft. The effective wind components and gradients are introduced into the nonlinear aircraft equations that include components of wind and temporal variation of wind in the body frame to determine the effect on the follower's dynamics. The effect of vortex decay over time is also included in our model. Special care has been taken to accommodate different geometrical dimensions for the leader and the follower aircraft and to include many useful geometrical parameters of the aircraft like the wing sweep angle, the dihedral angle and the relative distance between the center of mass of the aircraft and the aerodynamic center of the wing, in estimating the vortex effect experienced during formation flight. A comparison study has been presented which shows that the induced forces and moments computed by our method match well with the wind tunnel measurements.

"STUDY OF A POSSIBLE WAKE VORTEX ENCOUNTER OF AN AIRCRAFT OVER THE ARABIAN SEA"

Fifteenth Asian Congress of Fluid Mechanics, published in IOP Journal of Physics Conf. Series, Vol. 822, 2017, pp. 012049-1 - 012049-7.

A Jet airways aircraft encountered severe turbulence over the Arabian sea. We have performed high-resolution numerical simulations of the weather conditions at the time of the incident to ascertain the possible cause of the incident: atmospheric clear-air turbulence or a wake vortex encounter. Our analysis of the turbulence indices and parameters related to vortex propagation/decay at the flight altitude, suggests that wake-vortex encounter was the more likely cause of the incident.

Veovodin, A. V.

"NUMERICAL INVESTIGATION OF THE EFFECT OF WINGLETS ON THE EVOLUTION OF AN AIRCRAFT VORTEX WAKE"

Fluid Dynamics, Vol. 43, No. 5, 2008, pp. 725-730.

The effects of winglets on the aerodynamic characteristics of a heavy aircraft and the parameters of the vortex wake behind it is investigated for the landing regime. The solution of the complete problem is obtained by breaking up the wake into three regions, namely, the near, intermediate, and far flowfields, in which the corresponding subproblems are successively solved. The wake flowfields are obtained at different distances from the aircraft, together with the distributions of the mean azimuthal velocity over the vortex radius, and the lifetime of the vortex system is estimated for several one- and two-element wingtip versions. All the results are compared with those for the baseline layout with no winglets.

Vera, M. and Linan, A.

"ON THE INTERACTION OF VORTICES WITH MIXING LAYERS"

Physics of Fluids, Vol. 16, No. 7, July 2004, pp. 2237-2254

We describe the perturbations introduced by two counter-rotating vortices, in a two-dimensional configuration or by a vortex ring in an axisymmetric configuration, to the mixing layer between two counterflowing gaseous fuel and air streams of the same density. The analysis is confined to the near stagnation point region, where the strain rate of the unperturbed velocity field, is uniform. We restrict our attention to cases where the typical distance between the vortices, or the characteristic vortex ring radius, is large compared to both the thickness of the vorticity core and the thickness of the mixing layer. In addition, we consider that the ratio of the vortex circulation to the kinematic viscosity is large compared to unity. Then, during the interaction time, the viscous and diffusion effects are confined to the thin vorticity core and the thin mixing layer, which, appears as a passive interface between the two counterflowing streams when they have the same density. In this case, the analysis provides a simple procedure to describe the displacement and distortion of the interface, as well as the time evolution of

the strain rate imposed on the mixing layer, which are needed to calculate the inner structure of the reacting mixing layer as well as the conditions for diffusion flame extinction and edge-flame propagation along the mixing layer. Although in the reacting case variable density effects due to heat release play an important role inside the mixing layer, in this paper the analysis of the inner structure is carried out using the constant density model, which provides good qualitative understanding of the mixing layer response.

"PROCEDURES FOR OFF-NOMINAL CASES: VERY CLOSELY SPACED PARALLEL RUNWAY OPERATIONS"

27th Digital Avionics Systems Conf., St. Paul, Minnesota, Oct. 2008

This study investigated procedures to increase capacity in the terminal area using a high-fidelity flight deck simulator. The concept was developed to achieve visual meteorological condition capacities under instrument meteorological conditions when landing aircraft on runways 750 ft apart. The purpose was to investigate procedures related to breakout maneuvers on final approach during off-nominal conditions. Fifty percent of the simulation runs had an off-nominal situation. The off-nominal situation was either the wake of the lead aircraft drifting too close to the trailing aircraft or the lead aircraft deviating from its course and blundering towards the trailing aircraft. The location of the off-nominal situation was also a variable. Results showed that the workload and situational demands experienced by pilots were higher in the off-nominal as compared to the normal scenario. Pilots executed a breakout maneuver earlier for wake intrusion than for aircraft deviation. The location and cause of the off-nominal situation did not have a significant impact on workload or situation awareness. In general, the pilots flew the breakout maneuver accurately and safely. The results provide an assessment of the procedures for breakout maneuvers during off-nominal conditions.

"TURBULENT KINETIC ENERGY DECAY IN SUPERSONIC STREAMWISE INTERACTING VORTICES"

Journal of Fluid Mechanics, Vol. 807, 2016, pp. 353-385.

Only a few fundamental studies on the dynamics and interactions of supersonic streamwise vortices have been conducted so far despite the recognized potential of these structures to enhance supersonic mixing. In an effort to shed light on this largely unexplored field, multiple experimental campaigns were conducted in a Mach 2.5 flow to probe the dynamics of turbulent decay in complex flows originating from selected modes of supersonic streamwise vortex interaction. The first part of the manuscript presents the detailed study of two vortex interaction scenarios: one selected to obtain merging of co-rotating vortices and the other to prevent vorticity amalgamation. In the second part, data from three additional vortex merging cases are used to substantiate the findings of the first part of the study and characterize the decay of turbulence. Stereoscopic particle image velocimetry was employed to probe the resulting flow fields at different downstream stations. It was found that these complex vortex interactions measurably affect both the morphology and the magnitude of the

streamwise vorticity and turbulent kinetic energy as well as the associated decays. Particularly, while the turbulent kinetic energy across each vorticity patch undergoes an initial production before decreasing monotonically in both scenarios, its content in the coalesced structure is roughly double that of the isolated vortices. The manuscript also presents the analysis of the turbulence data from 27 supersonic vortical structures differing in shape, strength and modes of interaction, acquired within a range of vortex Reynolds numbers of almost one order of magnitude. Dimensional analysis was then used to correlate the spatial decay of turbulent kinetic energy with the vortex Reynolds number. For all the cases considered here, where the fluctuating Mach number was found to be subsonic, the form of the resulting law was like that reported in previous scholarly publications, despite the complexity of the vortex dynamics considered in this work.

"INTEGRATED PILOT AND CONTROLLER PROCEDURES: AIRCRAFT PAIRING FOR SIMULTANEOUS APPROACHES TO CLOSELY SPACED PARALLEL RUNWAYS"

Ninth USA/Europe Air Traffic Management Research and Development Seminar (ATM2011), June 2011, Berlin, Germany.

Parallel runway operations have been found to increase capacity within the National Airspace but poor visibility conditions reduce the use of these operations. Previous research examined the concepts and procedures related to parallel runways; however, there has been no investigation of the procedures associated with the strategic and tactical pairing of aircraft for these operations. This study developed and examined the pilot and controller procedures and information requirements for creating aircraft pairs for parallel runway operations. The goal was to achieve aircraft pairing with a temporal separation of 15s (+/- 10s error) at a 'coupling' point that was about 12nmi from the runway threshold. Two variables were explored for the pilot participants: two levels of flight deck automation (current-day flight deck automation and auto speed control future automation) as well as two flight deck displays that assisted in pilot conformance monitoring. The controllers were also provided with automation to help create and maintain aircraft pairs. Results show the operations in this study were acceptable and safe. Subjective workload, when using the pairing procedures and tools, was generally low for both controllers and pilots, and situation awareness was typically moderate to high. Pilot workload was influenced by display type and automation condition.

"WIND TURBINE WAKE AERODYNAMICS"

Progress in Aerospace Sciences, Vol. 39, 2003, pp. 467-510.

The aerodynamics of horizontal axis wind turbine wakes is studied. The contents is directed towards the physics of power extraction by wind turbines and reviews both the near and far wake region. For the near wake, the survey is restricted to uniform, steady and parallel flow conditions, thereby excluding wind shear, wind speed and rotor setting changes and yawed conditions. The emphasis is put on measurements in controlled conditions. For the far wake, the survey focusses on both single turbines and wind farm effects, and the experimental and numerical work are reviewed; the main interest is to study how the far wake decays downstream, in order to estimate the effect produced in downstream turbines. The article is further restricted to horizontal axis wind turbines and excludes all other types of turbines.

"DRAG CHARACTERISTICS FOR OPTIMALLY SPAN-LOADED PLANAR, WINGLETTED, AND C WINGS"

Journal of Aircraft, Vol. 46, No. 3, May-June 2009, pp. 962-971.

This paper focuses on the drag characteristics of optimally span-loaded, wingletted, and C wings. The span load is optimized resulting in minimum induced or total drag. The wing-root bending moment is kept constant for all analyzed wings to ascertain that different wings have comparable weight. The optimum span loadings for the different types of wing are calculated using a fast and simple numerical method. The wings are analyzed in the Trefftz plane, infinitely far behind the wing. Lagrange multipliers are used to calculate the optimum span loading resulting in minimum induced or total drag, with the wing-root bending moment and/or the lift coefficient as constraint. The induced drag can be calculated using the optimum span loading. The profile drag is assumed to be a function of the local lift coefficient. The results indicate that the C wing does not have real aerodynamic performance advantages compared to a wingletted wing. For wings with span and/or aspect ratio constraints, a winglet offers a drag reduction relative to a planar wing.

Verstynen, Jr., H. A.

"NASA FLIGHT RESEARCH ON AIRCRAFT WAKE VORTICES AND MINIMIZATION CONCEPTS"

AIAA Paper No. 1974-0953, Los Angeles, CA, 1974

A summary of NACA and NASA wake vortex flight research is presented with selected data from some tests. A brief review of current NASA wake vortex programs is given and a preview of potential future flight tests in the wake vortex area.

Verstynen, Jr., H. A. and Dunham, Jr., E. R.

"A FLIGHT INVESTIGATION OF THE TRAILING VORTICES GENERATED BY A JUMBO JET TRANSPORT"

NASA TN D-7172, April 1973, NASA Langley Research Center, Hampton, VA.

A flight investigation has been conducted to study the velocity and persistence characteristics of the trailing vortices generated by a jumbo jet transport. The investigation showed that the tangential velocities were initially higher for vortices generated with the flaps up and that they persisted for longer distances behind the aircraft than those generated with the flaps down. The core radii with flaps down appeared to be generally larger than those with flaps up.

Verstynen, Jr., H. A. and Patterson, Jr., J. C.

"PRELIMINARY FLIGHT TEST INVESTIGATION OF AN AIRBORNE WAKE VORTEX DETECTION CONCEPT"

AIAA Paper No. 1990-1282, Ontario, CA, May 1990.

One means to help reduce vortex-limited minimum in-trail separations might be to provide pilots with onboard sensors capable of detecting impending vortex encounters and provide warnings and recommended avoidance maneuvers. Preliminary results of a flight test indicate that measured maximum detection distances using wingtip-mounted flow angularity vanes are slightly lower than predicted.

Verzicco, R., lafrati, A., Riccardi, G. and Fatica, M.

"ANALYSIS OF THE SOUND GENERATED BY THE PAIRING OF TWO AXISYMMETRIC CO-ROTATING VORTEX RINGS"

Journal of Sound and Vibration, Vol. 200, Issue 3, February 1997, pp. 347-358.

The pairing of two axisymmetric co-rotating vortex rings is considered as a model problem for the interaction of the large-scale structures in round jets. By using direct numerical simulations of the incompressible Navier-Stokes equations, the sound radiation of the interaction has been analyzed, with

consideration of the effects of the Reynolds number and initial thickness of the rings. The acoustic signature of the interaction has revealed only minor effects of the Reynolds number. But the signature shows large effects of the vorticity distribution, with the eventual appearance of a secondary frequency.

"VORTEX IDENTIFICATION METHODS BASED ON TEMPORAL SIGNAL-PROCESSING OF TIME-RESOLVED PIV DATA"

Exp. Fluids, Vol. 48, 2010, pp. 441-459.

The lack of a universally accepted mathematical definition of a vortex structure has led to a considerable number of Eulerian criteria to identify coherent structures. Most are derived from the instantaneous local velocity gradient tensor and its derivatives and require appropriate thresholds to extract the boundaries of the structures. Notwithstanding their great potential for studying coherent structures, most criteria are not frame-independent and they lack a clear physical meaning. The Lyapunov exponent, a popular tool in dynamical system theory, appears as a promising alternative. This Lagrangian criterion does not suffer from the drawbacks of the Eulerian criteria and is constructed on a simple physical interpretation that includes information on the history of the flow. However, since the computation of the Lyapunov exponent involves the knowledge of fluid particle trajectories, experimental applications are currently restricted to laminar flows and two-dimensional turbulence, if velocity fields are time-resolved. In this work, we explore temporal post-treatment methods to extract vortical structures developing in a flow through a smooth axisymmetric constriction. Data from planar time-resolved Particle image velocimetry, measuring two or three components of the velocity vectors, are transformed via the Taylor hypothesis to quasi-instantaneous three-dimensional velocity field and are interpreted in terms of the discrete wavelet decomposition, the finite-time Lyapunov exponent, and the linear stochastic estimation. It appears that these methods can concurrently provide very rich and complementary scalar fields representing the effects of the vortical structures and their interactions in the flow.

"FLAP VORTEX MANAGEMENT BY ACTIVE GURNEY FLAPS"

AIAA Paper No. 2008-286, Reno, NV, January 2008

An experimental study was conducted to assess the applicability of limited span Gurney flaps for altering the flap-edge vortex characteristics of a swept constant chord half model with a commercial aircraft airfoil and high lift system (slat and flap). Phase one of the study involved the testing of static Gurney flaps mounted at the trailing-edge and flap-edge where different flap heights and fractions of flap span were evaluated. Data acquisition included PIV measurements downstream of the flap-edge, six-component load measurements and surface pressure measurement on the main-element and in the flap-edge region. The Gurney flaps produced significant variation of the vortex centroids, up to 3.49%

of the semi-span (8.69% of chord) with corresponding small changes to overall lift coefficient and overall drag coefficient. The strategy employed was based on the vortex roll-up relations of Betz, as modified for flapped wings by Donaldson. Phase two of this study, involved the evaluation of dynamically deployed Gurney flaps, where phase-averaged PIV measurements were made of the vortex trailing the flap. This was motivated by the desire to periodically perturb the vortex centroids, with a view to exciting wake instabilities and thus triggering a faster decay. When driving the Gurney flap and hence perturbing the vortices at wavelengths smaller than or greater than the wingspan, the authority over the vortex centroids did not materially diminish.

Vickers, T. K.

"LIVING WITH VORTICES"

The Controller, Vol. 4, January 1965, pp. 6-13

Summary of the most important facts which have been learned about the generation and behavior of trailing vortices. Large aircraft generate turbulent wakes which can be hazardous to small aircraft encountering them. Factors affecting vortex intensity are weight of the aircraft, the load factor, wingspan, air speed, and air density. Vortex rotation, wake movement, helicopter vortices, and vortex dissipation are discussed. Factors involved when an aircraft penetrates a vortex are examined, and various ways of avoiding vortices are presented.

Vickers, T. K.

"ATC IMPLICATIONS OF THE 747 SP"

Journal of the Acoustical Society, Vol. 51, No. 1, January 1972, pp. 206-209.

This year Boeing is shrinking the 747 design to create a more compact, lighter, long-range wide-body transport, the 747 SP. The reduced size combined with the same engines as used in the standard 747 will result in some spectacular increases in performance for the new aircraft. Most of these increases will directly benefit the ATC system. On flights up to 3000 miles in length the SP will lift off in only 25 seconds. Other improvements include a shorter takeoff runway length, a higher climb rate, and a higher cruising altitude. The advantages of these improvements are discussed along with the effects the design changes could have on the alleviation of the trailing vortex problem.

Vicroy, D. D.

"NASA WAKE ENCOUNTER FLIGHT TEST DATABASE"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

In the mid-nineties the National Aeronautics and Space Administration (NASA) began developing the Aircraft Vortex Spacing System (AVOSS) with the goal of improving airport capacity through improved

aircraft arrival spacing. The system involved a set of ground-based sensors used to forecast, detect and monitor vortices on the approach path. An initial requirement of this system was to establish a vortex decay threshold or boundary that defined how weak a vortex on the approach path must be for the in-trail aircraft to safely continue the approach. Developing a decay threshold required extensive use of wake vortex encounter simulations of a variety of aircraft. It was quickly noted that although several wake encounter simulation studies had been conducted since the mid-seventies, the wake encounter models used in the simulations were either not validated or validated purely on subjective pilot evaluation. This was primarily due to the lack of flight test data sufficient to validate the wake encounter simulation models. To fill this void in test data NASA conducted a series of flight tests from 1995 through 1997 using a Lockheed C-130 as the wake generator and a Boeing B737-100 as the wake encounter aircraft. A modified North American Rockwell OV-10 Bronco was used to measure the wake, the atmospheric state and stereo video of the wake encounters. The goal of these tests was to provide a data set for validation of wake encounter simulation models and develop an improved understanding of wake vortex physics and atmospheric interaction. The test data has been compiled into an integrated database available to the wake vortex research community. This paper describes the wake vortex flight tests, the data processing, the database development and access, and results obtained from preliminary wake-characterization analysis using the data sets.

"A NUMERICAL SIMULATION STUDY TO DEVELOP AN ACCEPTABLE WAKE ENCOUNTER BOUNDARY FOR A B737-100 AIRPLANE"

AIAA Paper No. 1996-3372, San Diego, CA, July 1996

NASA is conducting research with the goal of enabling safe improvements in the capacity of the nation's air transportation system. The wake-vortex upset hazard is an important factor in establishing the minimum safe spacing between aircraft during landing and take-off operations, thus impacting airport capacity. A batch simulation study was conducted to assess the sensitivity of various safe landing criteria in the development of an acceptable wake encounter boundary. A baseline six-degree-of-freedom simulation of a B-737-100 airplane was modified to include a wake model and the vortex-induced forces and moments. The guidance and control input for the airplane was provided by an auto-land system. The wake strength and encounter geometry were varied. A sensitivity study was also conducted to assess the effects of encounter modeling methods and accuracy.

"CHARACTERIZING THE HAZARD OF A WAKE VORTEX ENCOUNTER"

AIAA Paper No. 1997-0055, Reno, NV, January 1997

The National Aeronautics and Space Administration (NASA) is conducting research with the goal of enabling safe improvements in the capacity of the nation's air transportation system. The wake vortex upset hazard is an important factor in establishing the minimum safe spacing between aircraft during

landing and take-off operations, thus impacting airport capacity. Static and free-flight wind tunnel tests and flight tests have provided an extensive data set for improved understanding of vortex encounter dynamics and simulation. Piloted and batch simulation studies are also ongoing to establish a first-order hazard metric and determine the limits of an operationally acceptable wake induced upset. This paper outlines NASA's research in these areas.

"WAKE VORTEX ENCOUNTER MODEL VALIDATION EXPERIMENTS"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 371-383

The goal of this current research is to establish a database that validate/calibrate wake encounter analysis methods for fleet-wide application; and measure/document atmospheric effects on wake decay. Two kinds of experiments, wind tunnel experiments and flight experiments, are performed. This paper discusses the different types of tests and compares their wake velocity measurement.

"NASA WAKE VORTEX RESEARCH"

Proceedings of International Council of the Aeronautical Sciences, 19th Congress, Anaheim, CA, September 19-23, 1994, pp. 519-528

The National Aeronautics and Space Administration (NASA) is conducting research that will enable safe improvements in the capacity of the nation's air transportation system. The wake-vortex hazard is a factor in establishing the minimum safe spacing between aircraft during landing and take-off operations, thus impacting airport capacity. The ability to accurately model the wake hazard and determine safe separation distances for a wide range of aircraft, weather, and operational scenarios may provide the basis for significant increases in airport capacity. This paper describes the current and planned NASA research which is focused on increasing airport capacity by safely reducing wake-hazard-imposed aircraft separations through advances in several technologies including vortex motion and decay prediction, vortex encounter modeling, and wake-vortex detection.

"ECOLOGICAL OPTIMIZATION OF JET AIRCRAFT FLIGHTS IN VIEW OF CONTRAILS AND CONTRAIL CIRRUS FORMATION"

ICAS 2014, September 2014, St. Petersburg, Russia.

Presented in the paper are the results of research carried out in the Gromov flight Research Institute in 2004-2013 on elaboration and approbation of calculation-experimental methodic of evaluation and prediction of formation and existence of condensation trails (contrails) and condensation cirrus clouds during flights of civil aviation jet aircraft and of methodology of ecological optimization of aircraft flights on concrete flight routes. As a result of the research conducted there were obtained and approved the quantitative indices determining a necessary and sufficient conditions of contrails and contrail cirrus formation and existence enabling to evaluate and forecast the ecological optimization of aircraft flights planning along flight routes with the aim to reduce the linear contrails and aviation induced cirrus clouds harmful influence on the Earth heat exchange -- 'greenhouse effect.

Vidal, A.

"OPERATIONAL CONCEPT AND SYSTEM REQUIREMENTS FOR AN ATC SYSTEM ALLOWING DYNAMIC WAKE VORTEX SEPARATIONS"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

Several technologies to detect and predict wake-vortex have been developed during the last years. These technologies are now quite mature and weather conditions in which wake vortices decay quickly can be identified and used reliably by 'wake vortex predictors'. There is potential for making the separation distances dependent on these predictors as well as aircraft weight. This could increase the capacity of airports in certain weather conditions. Nevertheless, none of these systems are connected to ATC providers (enroute, approach, tower and arrival/departure managers) and remain at the R&D stage. The ATC-WAKE project intends to develop and build an operational platform. For this purpose, the first step is: To define operational requirements; To define operational concepts and procedures; To update and refine the selected operational concepts and procedures; To define user requirements; To define the system requirements based on operational concepts and user requirements. The following issues have been addressed: Operational issues - need and use of WV information in the context of ATC operations, constraints and required supporting systems; Technical issues - high level interface to existing (legacy) ATC systems of WV targeted system. As a first step towards implementation of ATC-WAKE Facility, the system requirements have drawn the preliminary operational concept and the requirements for using separation minima based on WV detection and prediction information. During the next phase, the operational feasibility of the new integrated ATC system, including an analysis of the interoperability with existing ATC systems and the usability and acceptability by its foreseen end-users (air traffic controllers) will be evaluated. Following the definition of operational concepts and procedures, this will be realized through fast-time simulations with a total airspace and airport model.

Viecelli, J. A.

"STATISTICAL MECHANICS AND CORRELATION PROPERTIES OF A ROTATING TWO-DIMENSIONAL FLOW OF LIKE-SIGN VORTICES"

Physics of Fluids, Vol. A 5, 1993, pp. 2484-2501.

The Hamiltonian flow of a set of point vortices of like sign and strength has a low-temperature phase consisting of a rotating triangular lattice of vortices, and a normal temperature turbulent phase of random clusters of vorticity that orbit about a common center along random tracks. The mean-field flow in the normal temperature phase has similarities with turbulent quasi-two-dimensional rotating laboratory and geophysical flows, whereas the low-temperature phase displays effects associated with quantum fluids. In the normal temperature phase, the vortices follow power law clustering distributions, while in the time domain random interval modulation of the vortex orbit radii fluctuations produces singular fractional exponent power-law low-frequency spectra corresponding to time autocorrelation functions with fractional exponent power-law tails. Enhanced diffusion is present in the turbulent state, whereas in the solid-body rotation state vortices thermally diffuse across the lattice. Over the entire temperature range the interaction energy of a single vortex in the field of the rest of the vortices follows positive temperature Fermi-Dirac statistics, with the zero-temperature limit corresponding to a Maxwellian distribution. Analyses of weather records dependent on the large-scale quasi-two-dimensional atmospheric circulation suggest the presence of singular fractional exponent power-law spectra and fractional exponent power-law autocorrelation tails, consistent with the theory.

"EFFECT OF TIP VORTEX ON WING AERODYNAMICS OF MICRO AIR VEHICLES"

AIAA Paper No. 2004-4971, Providence, RI, August 2004

Tip vortex induces downwash movement that reduces the effective angle of attack. When a wing has a relatively low aspect ratio, such as that employed by the micro air vehicle (MAV), the induced drag by the tip vortex is relatively large and therefore the aerodynamic performance of the vehicle are deteriorated. In this paper we study the effect of two MAV wing shapes, a baseline wing and a modified one, on the overall aerodynamic performances. Also, an endplate is attached to the modified wing to help probe the tip vortex effects. The investigation is facilitated by solving the Navier-Stokes equations around a rigid wing with a root chord Reynolds number of $9 \times 10,000$. It is confirmed that with modest angle of attack, the modified wing with endplate can improve the lift-to-drag ratio by reducing the drag. However, as the angle of attack becomes higher, the wing tip vortex is stronger and the endplate effect decreases.

Viieru, D., Albertani, R., Shyy, W. and Ifju, P. G.

"EFFECT OF TIP VORTEX ON WING AERODYNAMICS OF MICRO AIR VEHICLES"

Journal of Aircraft, Vol. 42, No. 6, Nov.-Dec. 2005, pp. 1530-1536

Tip vortex induces downwash movement, which reduces the effective angle of attack of a wing. For a low-aspect-ratio, low-Reynolds-number wing, such as that employed by the micro air vehicle (MAV), the induced drag by the tip vortex substantially affects its aerodynamic performance. In this paper we use the endplate concept to help probe the tip-vortex effects on the MAV aerodynamic characteristics. The investigation is facilitated by solving the Navier-Stokes equations around a rigid wing with a root-chord Reynolds number of 90,000. It is confirmed that with modest angles of attack the endplate can improve the lift-to-drag ratio by reducing the drag. However, as the angle of attack becomes substantial, the wing tip vortex is stronger and the endplate loses its effectiveness. Detailed fluid flow structures are presented to offer insight into the physics responsible for the observed phenomena.

Vijgen, P. M. H. W., vanDam, C. P. and Holmes, B. J.

"SHEARED WING-TIP AERODYNAMICS: WIND-TUNNEL AND COMPUTATIONAL INVESTIGATION"

Journal of Aircraft, Vol. 26, No. 3, March 1989, pp. 207-213.

Computational and experimental performance benefits are presented for a high-aspect-ratio unswept wing configuration with sheared tips. The sheared tip is a highly swept and highly tapered surface located in the same plane as the inboard wing panel to which it is attached. The computational results were obtained with an inviscid surface panel method that models the nonlinear influence of the trailing wake. Both wind-tunnel and calculated results were obtained for a 12-ft span wing model with various wing-tip configurations. The computational and experimental data are in fair agreement and demonstrate that sheared wing tips can reduce induced drag at cruise and climb lift coefficients. The

drag reduction is the result of wake deformation effects and changes in spanwise load distribution. Wind-tunnel measured longitudinal and lateral directional stability characteristics are also presented for the various wing-tip layouts.

"ADVANCED AUTOMATION IN AIR TRAFFIC SIMULATION FOR ATM DISTURBANCES ASSESSMENT"

Application and Theory of Automation in Command and Control Systems (ATACCS) 2011, May 2011, Barcelona, Spain.

In the context of an ever-increasing complexity in ATM, there is a need for mechanisms to automatically assess new procedures and concepts and their impact into global and specific airspace. To this purpose, this study describes the development of a complex system (system of systems): a simulated Air Traffic environment to analyze the effect of Wake Vortices to trailing aircraft in different flight phases. This project is part of AVANT: a project part-funded by the European Regional Development Fund (ERDF) under the Regional Competitiveness and Employment.

Visser, K. D. and Nelson, R. C.

"MEASUREMENTS OF CIRCULATION AND VORTICITY IN THE LEADING-EDGE VORTEX OF A DELTA WING"

AIAA Journal, Vol. 31, No. 1, January 1993, pp. 104-111.

Cross-wire measurements of the flowfield above a 75-deg flat plate delta wing were performed at a centerline chord Reynolds number of 250000. Surveys normal to the planform yielded velocity field data at incidence angles of 20 and 30 deg for a series of chordwise locations. The distribution of the velocity, axial velocity, and circulation showed a strong conical behavior upstream of the breakdown region and away from the apex and trailing edge regions. Spanwise velocity and vorticity profiles through the core of the vortex upstream of breakdown were scaled with the local geometry. Prior to breakdown, most of the axial vorticity in the primary vortex was observed to be concentrated at the center of the vortex, in a region of about twice that of the subcore diameter. The influences of changes in the angle of attack on axial vorticity with the opposite sense, such as that found in the secondary vortex, was much less than the vorticity in the primary vortex. The growth of the vortex circulation with distance from the apex was approximately linear over the forward end of the planform. The rate of growth was observed to decrease, however, aft of the midchord location. Radial circulation distributions scaled with the local semispan and exhibited a logarithmic behavior with increasing distance from the subcore, implying the possibility of a strong dependence on the local Reynolds stresses. Finally, parameters derived from slender body theory are shown to correlate the circulation for wings of different sweep.

Visser, K. D., Nelson, R. C. and Ng, T. T.

"METHOD OF COLD SMOKE GENERATION FOR VORTEX CORE TAGGING"

J. Aircraft, Vol. 25, No. 11, November 1988, pp. 1069-1071

The use of smoke or dye to enhance a moving fluid visually is an invaluable aid in gaining a better understanding of intricate flow motions. Not only can complex flows, such as those of a three-dimensional nature, be visualized, but the global views provided by the markers can help point out important flow regions where quantitative data should be taken. A particularly interesting flow visualization problem concerns the so-called dark-core region of the vortices formed on the upper side of a delta wing. Smoke visualization techniques employing upstream injection of vaporized kerosene have failed to entrain any smoke particles into the core region. The core is seen as a dark region along the axis of the vortices void of any particles. Other flow visualization experiments using particles introduced into a vortical flowfield confirm the absence of smoke in the core.

Vitalle, R. F.

"AN ANALYSIS OF EN ROUTE WAKE TURBULENCE BEHAVIOR BASED ON IN-FLIGHT MEASUREMENTS"

Air Traffic Control Association (ATCA) Annual Conference, October 2017, Gaylord, MD.

The recent incident involving the encounter of an Airbus A380 wake vortex by a Challenger 604 has drawn attention to the potential hazard of wake vortices en route. To broaden the understanding of the risks associated with en route vortex systems, the FAA in collaboration with the National Research Council of Canada (NRC) has collected high altitude wake turbulence data. An analysis of wake vortex fields based on such in-flight measurements has shown that wake turbulence may exist at distances well beyond minimum separation. The strength of these vortices, as well as transport and decay rates, was found to be highly dependent on atmospheric conditions. A study of historical weather data provided herein suggests that the likelihood for atmospheric conditions that trigger a wake encounter increases as longitudinal separations are reduced. Implementing wake mitigation strategies may allow increasing NAS capacity without compromising safety. Along track separation increases, altitude changes or lateral offsets are discussed as potential mitigations that may be useful in avoiding wake turbulence.

Vitalle, R. F. and Davenport, L. H.

"A METHODOLOGY FOR THE IDENTIFICATION AND MAPPING OF HIGH ALTITUDE AIRCRAFT WAKE VORTICES"

AIAA Paper 2017-4239, June 2017, Denver, CO.

The investigation of the behavior and characteristics of aircraft wake turbulence at high altitude is an important step in defining the risks involved when developing new procedures, separation standards, and mitigation techniques. In this work, high altitude aircraft wake turbulence data has been collected through direct measurement of atmospheric parameters. A retrofitted CT-133 performed wake vortex interceptions in trail of commercial transport category aircraft. A methodology is presented to evaluate the characteristics and behavior of wake vortices through analysis of measured winds in the wake turbulence area associated with the location of the condensate trails. The methodologies described in

this research seek to increase understanding of the behavior of wake turbulence data generated by the current suite of wake behavior models for aircraft operating enroute at high altitudes.

"VORTEX FLOW SIMULATION IN THE FRAMEWORK OF A BOUNDARY-VALUE PROBLEM FOR THE EULER EQUATIONS"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 43-55

For modeling three-dimensional vortex structures forming the vortex wake behind the wing of an aircraft, numerical integration of the full system of the Euler equations is carried out by means of a time iterations method to obtain the steady-state solution using multigrid technology. A numerical algorithm for describing such vortex flows takes into consideration flow compressibility, the free-stream velocity is assumed subsonic, the influence of viscosity is ignored. Discretization of the Euler equations is performed in the context of a finite volume method, structured C-H computational grids are used, for time integration an explicit scheme is employed. Two boundary-value problems are considered: interaction of a wing vortex wake with a solid boundary and diffraction of a vortex (or a vortex pair) by a solid surface (by a wing). The first problem deals with modeling of the effects of ground proximity on the flow around a swept wing and the structure of the near wake behind it. The second problem is concerned with schematizing the interaction of a lifting wing and its vortex system with the vortex wake generated by a heavy aircraft (the case of the longitudinal diffraction of the vortices by the wing). For initializing and describing mathematically the velocity field in the far wake an empirical model is employed.

Vladimirova, N. A., Vyshinsky, V. V., Kravchenko, S. A. and Sakovich, V. S.

"INVESTIGATION INTO VORTEX STRUCTURES IN THE FRAMEWORK OF A BOUNDARY-VALUE PROBLEM FOR THE EULER EQUATIONS"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 66-80

In the framework of the 3-D time-dependent Euler equations, the formation of the vortex system about a wing-body configuration and individual fragments of the vortex structure evolution in the far field in the presence of the vertical plane of symmetry and in-ground effect are considered. Basic outcome of the work is in determining the area of applicability of Jameson's numerical scheme to solve this boundary-value problem when studying the formation and development of a vortex wake. [In Russian.

"NUMERICAL INVESTIGATION OF THE EFFECTS OF WINGLETS ON THE EVOLUTION OF AN AIRCRAFT VORTEX WAKE"

Fluid Dynamics, Vol. 43, No. 5, 2008, pp. 725-730.

The effect of winglets on the aerodynamic characteristics of a heavy aircraft and the parameters of the vortex wake behind it is investigated for the landing regime. The solution of the complete problem is obtained by breaking up the wake into three regions, namely, the near, intermediate, and far flowfields, in which the corresponding subproblems are successively solved. The wake flowfields are obtained at different distances from the aircraft, together with the distributions of the mean azimuthal velocity over the vortex radius, and the lifetime of the vortex system is estimated for several one- and two-element wingtip versions. All the results are compared with those for the baseline layout with no winglets.

Vogel, C. M. and Devenport, W. J.

"THE SOURCE AND EVOLUTION OF TURBULENCE IN TRAILING VORTEX PAIRS"

VPI-AOE-217, April 1995, Virginia Polytechnic Inst. and State Univ., Blacksburg, VA.

The reanalysis of data obtained from the experimental studies of two different trailing vortex pairs has been conducted to obtain a more complete understanding of the turbulence structure of these flows. Statistical and spectral results, as well as filtered results and estimates of the effects of vortex wandering on the characteristics of the flows are presented. The results of the vortex pair are compared with the data from the experimental study of an isolated vortex conducted under similar testing conditions and model configuration to distinguish between the structure and effects of the separate vortices from those of vortex interaction. The analysis of a counter-rotating vortex pair reveals that initially the vortices develop in a manner like an isolated vortex. The cores appear laminar and the turbulence structure outside them is dominated by the spiral wakes. After some distance, flow inside and outside the cores becomes much more turbulent. The cores begin to grow and decay. The results indicate that this change may be a result of wave instabilities developed in the cores. The analysis of the co-rotating vortex pair reveals that turbulence is present in the cores as they spiral about each other and move downstream. After a certain distance, the cores merge into a single core, which contains more turbulence and is over twice the size of the pair that created it. As merger comes to completion, a symmetric core is formed which has much less turbulence. Merger appears to cause an increased rate of vortex decay.

"INVESTIGATIONS OF WING TIP VORTEX IN AIR BY MEANS OF DPIV"

AIAA Paper No. 1996-2254, New Orleans, LA, June 1996

This paper presents results of Particle Image Velocimetry measurements on the tip vortex of a NACA0012 wing. These results were achieved utilizing a digital recording technique based on a

modified CCD video camera and an evaluation process which is based on the cross-correlation technique. Instantaneous velocity fields showing the complete vortex could be gained. Because for each set of experiment parameters many PIV images were recorded, and because the evaluation was fully automatic, time averaging of several hundred images was also possible. Locating the vortex core in each measured velocity field for a fixed free stream velocity allowed to determine the trajectory of the vortex core with respect to the angle of attack. Due to the higher spatial resolution of PIV images taken with a smaller field of view it was also possible to determine the azimuthal velocity components along a line through the vortex core. These velocity profiles indicate a nonlinear increase of the azimuthal velocity with growing distance from the vortex center as it is implied by the solid body rotation model of the vortex core.

"AIRCRAFT EMISSIONS AT CRUISE AND PLUME PROCESSES"

In: Atmospheric Physics, Research Topics in Aerospace, U. Schumann (editor), Springer-Verlag Berlin Heidelberg, 2012, pp. 675-692..

The detection of aircraft emissions at cruise altitudes helps to understand and assess the effects of aviation on atmospheric composition and climate. Since the early 1990s, aircraft emissions of carbon dioxide, water vapor, nitrogen and sulfur oxides, aerosol and soot and their processing in the atmosphere as well as contrail formation have been measured in situ with the instrumented DLR research aircraft Falcon. Scientific results from a series of aircraft missions are summarized and explained, uncertainties are discussed and suggestions are made on how to move forward.

Vollmer, L., Steinfeld, G., Heinemann, D. and Kuhn, M.

"ESTIMATING THE WAKE DEFLECTION DOWNSTREAM OF A WIND TURBINE IN DIFFERENT ATMOSPHERIC STABILITIES: AN LES STUDY"

Wind Energy Science, Vol. 1, September 2016, pp. 129-141.

An intentional yaw misalignment of wind turbines is currently discussed as one possibility to increase the overall energy yield of wind farms. The idea behind this control is to decrease wake losses of downstream turbines by altering the wake trajectory of the controlled upwind turbines. For an application of such an operational control, precise knowledge about the inflow wind conditions, the magnitude of wake deflection by a yawed turbine and the propagation of the wake is crucial. The dependency of the wake deflection on the ambient wind conditions as well as the uncertainty of its trajectory are not sufficiently covered in current wind farm control models. In this study we analyze multiple sources that contribute to the uncertainty of the estimation of the wake deflection downstream of yawed wind turbines in different ambient wind conditions. We find that the wake shapes and the magnitude of deflection differ in the three evaluated atmospheric boundary layers of neutral, stable and unstable thermal stability. Uncertainty in the wake deflection estimation increases for smaller temporal averaging intervals. We also consider the choice of the method to define the

wake center as a source of uncertainty as it modifies the result. The variance of the wake deflection estimation increases with decreasing atmospheric stability. Control of the wake position in a highly convective environment is therefore not recommended.

Vollmers, H.

"DETECTION OF VORTICES AND QUANTITATIVE EVALUATION OF THEIR MAIN PARAMETERS FROM EXPERIMENTAL VELOCITY DATA"

Measurement Science and Technology, Vol. 12, 2001, pp. 1199-1207.

Efficient and well adapted algorithms are necessary to analyze the large number of vector fields generated when observing time dependent flow fields. This paper discusses several possibilities of vortex detection and characterization from two-dimensional instantaneous vector fields like those obtained by means of particle image velocimetry (PIV) technique.

von Karman, T. and Tsien, H-S.

"LIFTING-LINE THEORY FOR A WING IN NON-UNIFORM FLOW"

Quarterly of Applied Mathematics, Vol. 3, No. 1, April 1945, pp. 1-11.

The lifting line theory developed by Prandtl has been extended to handle non-uniform incoming flow. A general and more satisfactory solution for the flow of a wing in a non-uniform stream is examined as a generalized case, introducing the modifications of Prandtl's fundamental concepts. The resulting formulations included generalized expressions of the downwash and induced drag.

Vorropoulos, G.

"AN EXPERIMENTAL STUDY OF COMPRESSIBILITY EFFECTS IN THE LEADING EDGE VORTEX OF A DELTA WING AT INCIDENCE USING LASER DOPPLER VELOCIMETRY"

PhD Thesis, June 1983, Universite Libre de Bruxelles, Rhode-Saint-Genese, Belgium.

The purpose of the work reported in this thesis is the investigation of compressibility effects on a delta wing leading edge vortex by measuring the distributions of the axial and circumferential velocity components across it. These measurements were performed by making use of Laser Doppler Velocimetry (LDV) since this technique does not perturb the vortical flow field. Due to the severe problems arising in LDV applications in compressible vortices, all components at the LDV system used in this study were optimized. Furthermore, the problems of directional bias and seeding particles behavior in high-speed vortices were solved analytically for the first time to improve the accuracy and validity of the results. The LDV system was successfully used up to $M_{\infty} = 0.80$. The LDV measurements were supported by flow visualizations (including the use of a new type of schlieren system specially developed for the purposes of this investigation). The velocity measurements have shown a drastic modification of the vortex structure as a result of compressibility: instead of an axial

velocity excess (as observed at low speed investigations) an axial velocity deficit was observed at $M_{\infty} \geq 0.60$. Furthermore, a pronounced asymmetry became evident from these measurements. The possibility of the existence of a shock wave was examined but neither the LDV measurements, nor the flow visualizations provided concrete evidence of its existence. Since the already existing theory on the compressible vortex structure (based among other assumptions on the vortex axisymmetry) is not adequate to predict the observed compressibility phenomena, detailed theoretical investigation of the compressible vortex is clearly needed in the future.

Voss, G.

"WAKE VORTEX ALLEVIATION BY DIFFERENTIAL AND OSCILLATING FLAP SETTING: AN EXPERIMENTAL STUDY"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

One approach to bring a wake vortex to an early decay is the application of configurative methods to the lift devices. That means for example the trigger of vortex instabilities with movable wing devices like DLC flaps etc. One example of a principal model which was provided at DLR by Vollmers et al. should be shown that it is possible to excite long wavelength instabilities whereas the attention is turned to Crow instabilities. The principal model generates in this connection by means of rectangular wing and a smaller HTP a counter-rotating 4-vortex system. In former studies it was shown that counter-rotating 4-vortex systems are a capable investigation object. On both sides of the model wing respectively three trailing edge flaps are mounted which can be independently moved. Selected oscillating motion causes the periodic generation and collapse of small vortices which are coming to an interaction with the main vortices. In this presentation the results of experimental investigations will be presented.

Voss, G., Carmer, C. V., Konrath, R., Stumpf, E., Kruckeberg, C.-P., Meyer, H. and Mattner, H.

"WAKE VORTEX ALLEVIATION BY DIFFERENTIAL AND OSCILLATING FLAP SETTING: A COMPARATIVE NUMERICAL AND EXPERIMENTAL STUDY"

1st CEAS European Air and Space Conference, Berlin, Germany, CEAS-2007-006, September 2007, pp. 1007-1016

In this article the results of numerical calculations and experimental studies on wake vortex alleviation using Differential Flap Setting (DFS) and Oscillating Flap Setting (OFS) by means of a principal model with rectangular wing as a vortex generator should be presented. The numerical part of the examination was made as a Euler-computation provided with flow solver TAU, the experiment was performed in a water towing tank at DLR Gottingen. The comparison of different configurations according to flap setting, trigger frequency and influence of HTP vortex was conducted in this paper. Both numerical and experimental investigations have shown that it is possible to affect the wake vortex

development using configurative methods on lift devices. Further investigations have to be done to calculate the circulation and the rolling moment influence on following aircraft.

Voss, G., Gerz, T., Baumann, R., Stumpf, E. and Press, M.

"WAKE VORTEX ALLEVIATION BY DIFFERENTIAL FLAP SETTING AND OSCILLATING FLAP SETTING: A FLIGHT TEST"

AIAA Paper No. 2009-3947, June 2009, San Antonio, TX.

This article presents two methods for early vortex decay experimentally investigated by flight testing. The first item is the Differential Flap Setting (DFS). Here, small changes in configuration of lift devices are applied, which leads to a variation of spanwise lift distribution. This generates a selected multiple-vortex-system, whose vortices interact one another and contribute to decay the dangerous main vortices. The second method is the Oscillating Flap Setting (OFS). Aim of this is the trigger of vortex instabilities by periodic moving of aileron and special additional flaps. Every vortex in a vortex system has a characteristic frequency. If this frequency is triggered, resonance occurs which may lead to a vortex decay. Usually, the decay is caused by atmospheric disturbances namely side wind, shear wind or thermal wind. It is possible to accelerate this process by selected triggering of these instabilities. In the flight test described in this article exclusively the behavior of vortices with triggering of long-wavelength instabilities (e.g. Crow-instability) was observed and measured.

Voss, G., Melber-Wilkending, S. and Rudnik, R.

"PREMATURE DECAY OF WAKE VORTICES WITH DIFFERENTIAL- AND OSCILLATING FLAP SETTING"

European Conference on Computational Fluid Dynamics, ECOMAS CFD 2006, 2006, TU Delft, The Netherlands.

This paper gives an overview of the research on wake vortex decay using Differential Flap Setting (DFS) and Oscillating Flap Setting (OFS). The concept of DFS deals with the small deflection of flaps and elevator to produce additional vortices which interact with the vortices from wing, elevator, flaps, and wing-body-junction. Numerical calculations with the A340-300 model at this topic are presented in the first part of the paper. On the other hand, the OFS concept works with the periodic movement of DLC (direct lift control) flaps and/or ailerons to trigger inherent instabilities of the vortices. The basic mechanism of the introduction of the periodic disturbance into the flow field is a periodic alteration of the spanwise lift distribution, i.e. of the circulation and spacing ratios of the distinct vortex pairs in the extended wake vortex flowfield. This can be achieved both by pitch oscillation and oscillating DLC flaps. Pitch oscillation alone are sufficient for accelerating Crow instability as proven already in the 1970s with small aircraft. One can distinguish between long-wavelength and short-wavelength instabilities. The second part of this paper is truncated on short-wavelength instability examinations i.e. the Crow instability.

Voutsinas, S. G.

"VORTEX METHODS IN AERONAUTICS: HOW TO MAKE THINGS WORK"

International Journal of Computational Fluid Dynamics, Vol. 20, No. 1, January 2006, pp. 3-18

Vortex methods constitute a particular class in CFD. They are grid-free, use Lagrangian co-ordinates and most importantly they use vorticity as main flow variable instead of the velocity. In aeronautics they have been in use for over than 30 years with impressive results. However, rather a limited number of researchers would prefer them. This could be due to some particularities vortex methods have in their implementation. In view of trying to clarify things, this paper reviews the current state of the subject and details some of the 'difficult' points of vortex methods. Although the focus is mainly on rotor problems, the presented techniques can be used in other applications as well.

Voyevodin, A. V., Gaifullin, A. M., Zakharov, S. B. and Sudakov, G. G.

"A ZONAL METHOD FOR COMPUTING THE VORTEX WAKE BEHIND AN AIRCRAFT"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 54-65

Based on an analysis of reported experimental data and theoretical models, an empirical model of the aircraft wake has been constructed. The model is considered as an initial approximation while creating a theoretical vortex wake model. Using the asymptotic analysis of the phenomena and numerical solutions to the problems inherent zones and numerically matching the solutions at zone boundaries, a four-zone model was constructed that refines the empirical model and does not lean upon empirical relationships. Such a strategy enables further developing the model with retaining its usefulness as the mathematical tools and numerical methods upgrade. [In Russian.]

"AIRBORNE REMOTE DETECTION OF TURBULENCE WITH FORWARD-POINTING LIDAR"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 22, 2016, Springer International Publishing Switzerland, pp. 443-464.

Presently, the airborne remote detection of atmospheric turbulence is limited to radar-visible regions of the sky, i.e., zones that contain hydrometeors like rain or cloud droplets. The bulk of the actual turbulence, possible in clear air at all flight altitudes, evades such a remote detection, though a remote determination of aircraft-relevant physical parameters relevant to turbulence could significantly increase flight safety. The following chapter reviews possible techniques of remote turbulence detection in clear air and identifies the most promising approaches for future aircraft. These are shown to be optical methods, i.e., LIDAR (Light Detection and Ranging) systems. Principles, as well as pros and cons of some complementary lidar techniques, are discussed.

Vyazmina, E., Nichols, J. W., Chomaz, J.-M. and Schmid, P. J.

"BIFURCATION STRUCTURE OF VISCOUS VORTEX BREAKDOWN"

AIAA Paper 2008-3797, June 2008, Seattle, WA

Incompressible axisymmetric swirling flow with open boundaries is studied by means of direct numerical simulation (DNS). The effects of viscosity and external axial pressure gradient near critical swirl number are investigated. The solution branches obtained from DNS match the bifurcation diagrams from previous theoretical and numerical studies and extend their results.

"FLIGHT SAFETY, AIRCRAFT VORTEX WAKE AND CRISIS OF AIRPORTS"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 5-2.

The paper deals with restrictions on airport capacity associated with the potential hazard for an aircraft in takeoff or landing to encounter the vortex wake generated by another aircraft. The complexity of the problem under study and the lack of a single research tool make one employ a 'mosaic' approach based on combined use of various methods. A specific difficulty therewith appears of the asymptotically non-rigorous division of the problem into subproblems and of thoroughly matching the results obtained. The goal of this work is to validate and assess the potentialities of the methods used and to reveal their weaknesses and strengths as well as to discuss the results obtained. The basic guideline in assessing the methods is the possibilities for obtaining concrete technical decisions aimed at resolving contradictions related to the impossibility of realizing the required air traffic growth in the near future in the framework of available technologies.

"INVESTIGATION OF THE AIRCRAFT VORTEX WAKE EVOLUTION AND FLIGHT SAFETY"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 5-21

Investigated in the present report are the problems of decreasing separation distances between aircraft during their takeoffs and landings. This work reflects in a condensed form the efforts of a large team of specialists and presents a general view on the problem under study, whose complexity lies basically in the fundamental impossibility to create a single method and universal tool of investigation. A fragmentary approach is used with asymptotically non-strict splitting of the problem into subdomains and a multiple mosaic selection of research tools. [In Russian.

Vyshinsky, V. V.

"FLIGHT SAFETY, AIRCRAFT VORTEX WAKE AND AIRPORT OPERATIONAL CAPACITY"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 7-2.

In the framework of the multidisciplinary approach, the vortex wake generated by a heavy passenger aircraft in takeoff and landing regimes is studied and practical ways to enhance the airport capacity are sought. The problem falls into several integral parts: atmospheric turbulence, aircraft generating the multiple vortex structure, coherent vortex pair under atmospheric turbulence environment, aerodynamics, and flight dynamics of a trailing aircraft under wake turbulence conditions. The author gives also a substantiation of the Project's structure and an appraisal of the results obtained and the prospects of separate research directions and considers a matrix of both possible and solved problems.

Vyshinsky, V. V.

"AIRCRAFT VORTEX WAKES AND AIRPORT CAPACITY"

SAE Paper 975519 (also, AIAA Paper 97-5519), Anaheim, CA, October 1997

The paper deals with restrictions on airport capacity associated with the potential hazard for an aircraft in takeoff or landing to encounter the vortex wake generated by another aircraft. The complexity of the problem under study and the lack of a single research tool make one employ a 'mosaic' approach based on combined use of various methods. A specific difficulty therewith appears of asymptotically non-rigorous division of the problem into subproblems and of thoroughly matching the results obtained. The goal of this work is to validate and assess the potentialities of the methods used and to reveal their weaknesses and strengths as well as to discuss the results obtained.

Vyshinsky, V. V.

"FLIGHT SAFETY, AIRCRAFT VORTEX WAKE AND AIRPORT OPERATION CAPACITY"

Air and Space Europe, Vol. 3, No. 3-4, 2001, pp. 206-20.

Atmospheric vortices are very stable formations featuring a slow mass, momentum, and energy exchange with surrounding atmosphere, they are rather difficult for understanding. Concrete measures, concrete technical decisions can be suggested for improving flight safety in the wake turbulence environment and airport operational capacity. Wake vortex investigation is the example of the fruitful international cooperation. A unique experience gained over the last six years of continuous researches requires that it be practically embodied in the technical decisions usable for world community.

Vyshinsky, V. V.

"AIRCRAFT VORTEX WAKE, FLIGHT SAFETY AND CRISIS OF AIRPORTS"

ICAS Paper 98-6.5.1, Sept. 1998, Melbourne, Australia.

In the framework of computational and experimental methods, the problem is solved on improving airport capacity. For this purpose a two-level aerodynamic wake model was developed as well as models intended for studying the problems of flight dynamics, structural strength and aeroelasticity. The element of stochasticity inherent in the phenomenon under study is incorporated into the combined model through the two last models. The mathematical models are combined into a single structure, which enables their using to assess hazardous situations associated with vortex wake encounters of aircraft, to construct criteria to judge as reliably as possible the severity of the vortex hazard in landing, to determine the relationship between the probability of accidents and main parameters of both landing and following aircraft, weather conditions in the airport area and distances between aircraft, to work out recommendations on timely detection of vortex wakes and pilot actions to execute a vortex avoidance maneuver and on establishing safe-separation standards.

Vyshinsky, V. V. and Kuznetsov, O. A.

"WAKE VORTEX PROBLEMS FOR THE AIRPORT WITH CROSSING RUNWAYS"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

Critical from the standpoint of structural strength are wake encounters at angles close to 90 degrees, which is highly probable in airport airspace, especially when airports have crossing runways. In this case a passage through the most dynamic portion of the vortex gust takes about one second, so that one can expect abrupt changes in external forces. They can excite aeroelastic oscillations of the airframe and, consequently, dynamic loads. Since in the course of time the strength of vortices decreases, the response to the wing root bending moment also weakens: the greater is the atmospheric turbulence intensity the greater is the rate of loads' diminishing. The panel method is used to calculate the flow about the aircraft and the vortex wake shape behind it. These data are used as the initial ones for computing the vortex wake evolution in the near field up to the vortex merging (2D RANS with a specially developed algebraic eddy viscosity model). For simulating the vortex wake evolution in the turbulent atmospheric boundary layer, a package of CFD codes GROUNDWAKE was created.

Vyshinsky, V. V. and Soudakov, G. G.

"INVESTIGATION OF THE VORTEX WAKE EVOLUTION AND FLIGHT SAFETY"

ICAS 1996, September 1996, Sorrento, Napoli, Italy.

Investigated in the present report are the problems of decreasing separation distances between aircraft during their takeoffs and landings. This work reflects in a condensed form the efforts of a large collective of scientists and presents a general view on the problem under study, whose complexity lies mainly in the fundamental impossibility to create a single method and universal tool of investigation.

The authors use a fragmentary approach with asymptotically non-strict splitting of the problem into subregions and a multiple mosaic selection of separate subproblems, in the strict sense improperly posed for solving main problem.

Vyshinsky, V. V. and Yaroshevsky, V. A.

"VORTEX WAKE SAFETY: AERODYNAMICS AND FLIGHT DYNAMICS ASPECTS OF THE PROBLEM"

AIAA Paper No. 1998-2522, Albuquerque, NM, June 1998

The main problem of the paper is an approach to establishing criteria for aircraft safe separation distances during takeoff and landing operations on the same runway. The vortex wake longitudinal penetration is a critical situation here. A 'worst case' method is not acceptable in this case; instead of it the probabilistic approaches are used.

Wachspetess, D. A., Quackenbush, T. R. and Boschitsch, A. H.

"FIRST-PRINCIPLES FREE-VORTEX WAKE ANALYSIS FOR HELICOPTERS AND TILTROTORS"

American Helicopter Society 59th Annual Forum, May 2003, Phoenix, AZ.

The development of high-fidelity models of the rotor wake is an issue of continuing, critical importance in the design of new helicopters and tiltrotors, as well as in the understanding of a wide range of problems in rotor aerodynamics, dynamics, and acoustics. This paper outlines a set of interrelated modeling methods developed over the last two decades that have yielded a unified free wake model suitable for the full range of current helicopter and tiltrotor designs. These methods, now embedded in the CHARM comprehensive analysis of rotorcraft aeromechanics, can produce high fidelity predictions of rotor performance, unsteady airloads, and noise as well as accurate predictions of rotor-induced flow fields and airframe loads over a wide range of aircraft configurations. An important feature of the wake modeling described here is that it is a first-principles analysis completely free of user-selected empirical parameters. This allows the model to be used as a design tool for analyzing future rotorcraft concepts as well as in flight simulations where wake characteristics vary with the flight condition. This paper describes the key technical elements of this model and provides numerous examples of its validation against challenging data sets for a wide range of rotorcraft applications. Results include new correlations with Tilt Rotor Aeroacoustics Model airloads measurements establishing that both helicopter and tiltrotor aeromechanics phenomena can be predicted accurately without adjusting the wake model.

Waco, D. E.

"VARIATION OF TURBULENCE WITH ALTITUDE TO 70,000 FT"

Journal of Aircraft, Vol. 13, No. 12, December 1976, pp. 981-986.

The ratio of turbulent to total flight miles has been determined for altitudes up to 65,000 ft by comparing various turbulence data collection programs (e.g., ALLCAT, NASA, NATO, RAE, etc.). An evaluation was made of the criteria used to distinguish turbulence from smooth flight. Results can be used to update currently accepted models of turbulence variation with altitude. The percentage of flight miles with turbulence was found to be near 5% for the entire altitude range between 15,000 and 40,000 ft. Turbulence frequency increased below 15,000 ft, gradually down to 10,000 ft but markedly below 5,000 ft, and decreased above 40,000 ft, dropping to 1% near 65,000 ft. Terrain roughness had a pronounced effect on increasing both amount and intensity of turbulence at all altitudes. At low altitudes (below 1,000 ft) moderate or greater turbulence was up to 13 times more frequent over high mountains than over flat terrain and at least 3 times more frequent above 45,000 ft. The frequency of turbulence was re-evaluated for the HICAT program by careful examination of true gust velocity time histories. The ratio of turbulent to total flight miles was only 70% of the value previously arrived at in the HICAT program (only 33% for moderate and greater turbulence) when 'smooth' and low-intensity portions of the turbulent encounters were properly identified.

Wadcock, A. J., Ewing, L. A., Solis, E., Potsdam, M. and Rajagopalan, G.

"ROTORCRAFT DOWNWASH FLOW FIELD STUDY TO UNDERSTAND THE AERODYNAMICS OF HELICOPTER BROWNOUT"

American Helicopter Society Southwest Region Technical Specialists' Meeting, Technologies for the Next Generation of Vertical Lift Aircraft, October 2008, Dallas-Fort Worth, TX.

Rotorcraft brownout is caused by the entrainment of dust and sand particles in helicopter downwash, resulting in reduced pilot visibility during low, slow flight and landing. Recently, brownout has become a high-priority problem for military operations because of the risk to both pilot and equipment. Mitigation of this problem has focused on flight controls and landing maneuvers, but current knowledge and experimental data describing the aerodynamic contribution to brownout are limited. This paper focuses on downwash characteristics of a UH-60 Blackhawk as they pertain to particle entrainment and brownout. Results of a full-scale tuft test are presented and used to validate a high-fidelity Navier-Stokes computational fluid dynamics (CFD) calculation. CFD analysis for an EH-101 Merlin helicopter is also presented, and its flow field characteristics are compared with those of the UH-60.

Wadcock, A. J., Yamauchi, G. K., Heineck, J. T., Silva, M. J. and Long, K. R.

"PIV MEASUREMENTS OF THE WAKE OF A TANDEM-ROTOR HELICOPTER IN PROXIMITY TO A SHIP"

Proc. American Helicopter Society 4th Decennial Specialists' Conf. on Aeromechanics, Jan. 2004, San Francisco, CA.

The aerodynamic interaction between a tandem-rotor helicopter and an amphibious assault ship is described. The investigation used 1/48th-scale helicopter and ship models. The test was conducted in the Army 7- by 10-ft wind tunnel at NASA Ames Research Center. Particle Image Velocimetry was used

to acquire 3-component velocity field measurements of the ship air-wake and the combined wake of the tandem-rotor helicopter and ship. Ship-alone air-wake measurements are presented for yaw angles of 0, 5, 10 and 15 degrees, for a wind speed of 22.5 ft/sec at one aircraft landing spot of primary interest. The combined wake of the tandem-rotor helicopter and the ship air-wake are described in considerable detail at the same landing spot for both zero- and 15-degrees yaw angle. Variation of the combined wake with position of the upwind aircraft is described in detail. These measurements provide guidance in planning shipboard operations of rotorcraft.

Wadcock, A. J., Yamauchi, G. K., Solis, E. and Pete, A. E.

"PIV MEASUREMENTS IN THE WAKE OF A FULL-SCALE ROTOR IN FORWARD FLIGHT"

AIAA Paper No. 2011-3370, June 2011, Honolulu, Hawaii.

Stereo Particle Image Velocimetry (PIV) measurements were acquired in the wake of a full-scale UH-60A rotor that was tested in the National Full-Scale Aerodynamics Complex 40-ft by 80-ft Wind Tunnel. Flow field velocities were measured in a stationary cross-flow plane located at approximately 90 deg rotor azimuth. The region of interest was 4-ft high by 13-ft wide and covered the outer half of the blade radius. All measurements were acquired in forward flight conditions. The laser and camera systems were synchronized with the rotor 1/rev so that measurements were acquired for different rotor blade azimuths. The main objective of this paper is to describe the design of the PIV system and the installation of the system components in the wind tunnel. Examples of measured velocity fields are presented. These measurements represent the first PIV measurements to be made in the U.S. on a full-scale rotor in forward flight.

Wagener, T. J., Demma, N., Kmetec, J. D. and Kubo, T. S.

"2um LIDAR FOR LASER-BASED REMOTE SENSING: FLIGHT DEMONSTRATION AND APPLICATION SURVEY"

Proceedings of the 13th AIAA/IEEE Digital Avionics Systems Conference, October-November 1994, pp. 574-579

A flight test of a diode-pumped solid-state 2-um Doppler Light Detection and Ranging (LIDAR) system was conducted on-board the NASA Ames DC-8 Airborne Laboratory. This was the first ever airborne demonstration of a 2 um diode-pumped solid-state Doppler LIDAR. The LIDAR performance was verified by comparing the true-airspeed (TAS) estimate with that found using the pneumatic air data system; excellent agreement was found. The capabilities of this pulsed 2um Doppler LIDAR system include high bandwidth air data determination without the need for extensive forebody calibration, remote wind profiling as far as several kilometers away from the aircraft, eye-safe laser transmission at 2um, and diode-pumped solid-state design for compact construction and reliable performance.

Wagner, G., Jacques, D., Blake, B. and Pachter, M.

"AN ANALYTICAL STUDY OF DRAG REDUCTION IN TIGHT FORMATION FLIGHT"

AIAA Paper No. 2001-4075, Montreal, Canada, August 2001

This paper describes research in drag reduction resulting from tight formation flight. The optimal position for the wingman of a tight formation flight of T-38 Talon aircraft is determined in terms of induced drag reduction. This translates directly to fuel savings. Prime consideration is given to the effects of flying a laterally trimmed aircraft in the vortex wake of the lead aircraft. Inclusion into the analysis of the effect of the aileron deflections required for trim yields a significantly different optimal formation position when compared to previous work. Moreover, in this paper the additional benefit derived by the formation when a second wingman is added is investigated. The second wingman is shown to derive an even greater induced drag benefit than the first wingman. The analysis is performed using the vortex code, HASC95. Fuel saving benefits in the range of 11.5% for a tight three-ship formation flight of T-38s operating at Mach .54 at a 10,000-foot altitude are shown.

Wagner, S.

"ON THE NUMERICAL PREDICTION OF ROTOR WAKES USING LINEAR AND NON-LINEAR METHODS"

AIAA Paper No. 2000-0111, Reno, NV, January 2000

Flow fields around helicopter rotors are extremely complex. Thus, the solution of the governing equations can usually only be achieved by numerical methods. Different levels of approximation are used in the industrial design process. The rotor wake system must in any case be represented appropriately. Linear and non-linear methods as well as the coupling of both approaches are discussed. The linear methods are based on the solution of the Laplace equation. The corresponding integral equation is solved via boundary element methods including free wake representation. Sophistication towards non-linearity and compressibility calls for the implementation of field panel methods, where the boundary element approach is extended by using spatial distributions of non-linear source terms, thus solving the Poisson equation. Euler methods can describe transonic effects. The resulting gain in accuracy is, however, achieved at the expense of substantial increase in computational effort. Due to the complex kinematics of the system, computation of a single grid is nearly impossible. The Chimera approach provides a possible workaround procedure. The coupling of Euler and free wake panel methods is used to significantly reduce computational requirements. Special attention is devoted towards wake generation and wake capturing procedures within the aforementioned methods.

Waite, M. L. and Smolarkiewicz, P. K.

"INSTABILITY AND BREAKDOWN OF A VERTICAL VORTEX PAIR IN A STRONGLY STRATIFIED FLUID"

Journal of Fluid Mechanics, Vol. 606, 2008, pp. 239-273.

The dynamics of a counter-rotating pair of columnar vortices aligned parallel to a stable density gradient are investigated. By means of numerical simulation, we extend the linear analysis and

laboratory experiments of Billant and Chomaz (2000) to the fully nonlinear, large-Reynolds-number regime. A range of stratifications and vertical length scales is considered. At early times with a Froude number (F) less than one, linear predictions for the zigzag instability are reproduced. Short-wavelength perturbations with F greater than one are found to be unstable as well, with growth rates only slightly less than those of the zigzag instability but with very different structure. At later times, the large-Reynolds-number evolution diverges profoundly from the moderate-Reynolds-number laboratory experiments as the instabilities transition to turbulence. For the zigzag instability, this transition occurs when density perturbations generated by the vortex bending become gravitationally unstable. The resulting turbulence rapidly destroys the vortex pair.

Walden, A. B. and vanDam, C. P.

"STUDY OF THE MUTUAL INTERACTION BETWEEN A WING WAKE AND AN ENCOUNTERING AIRPLANE"

NASA/CR-1997-206493, March 1996, Univ. of California, Davis, CA

To increase airport productivity, several wind-tunnel and flight-test programs are currently underway to determine safe reductions in separation standards between aircraft. These programs are designed to study numerous concepts from the characteristics and detection of wake vortices to the wake-vortex encounter phenomenon. As part of this latter effort, computational tools are being developed and utilized as a means of modeling and verifying wake-vortex hazard encounters. The objective of this study is to assess the ability of PMARC, a low-order potential-flow panel method, to predict the forces and moments imposed on a following business-jet configuration by a vortex interaction. Other issues addressed include the investigation of several wake models and their ability to predict wake shape and trajectory, the validity of the velocity field imposed on the following configuration, modeling techniques and the effect of the high-lift system and the empennage. Comparisons with wind-tunnel data reveal that PMARC predicts the characteristics for the clean wing-body following configuration fairly well. Non-linear effects produced by the addition of the high-lift system and empennage, however, are not so well predicted.

Walden, A. B., vanDam, C. P. and Brandon, J. M.

"MODELING OF THE INTERACTION BETWEEN A LIFTING WING AND A FOLLOWING AIRCRAFT AND COMPARISON WITH EXPERIMENTAL RESULTS"

AIAA Paper No. 1996-0771, Reno, NV, January 1996

Understanding the wake-vortex/airplane interaction phenomenon is important to help define the parameters which can be used to predict a wake-vortex hazard. To understand the phenomenon, efforts are underway utilizing various computational tools as a means of modeling and verifying wake-vortex hazard encounters. The objective of this study is to assess the capability of PMARC, a low-order potential-flow panel method, to predict the forces and moments imposed on a following business-jet configuration by a wake-vortex interaction. Issues addressed include the investigation of different wake techniques and their ability to predict wake shape and trajectory, the validity of the velocity field

imposed on the following configuration and the effects of the high-lift system and the empennage on the aerodynamic characteristics of the following configuration. Comparisons with wind-tunnel data reveal that PMARC predicts the characteristics for the clean wing-body configuration fairly well. The characteristics for the complete airplane with the high-lift system deployed are not so well predicted.

"MEASUREMENT OF STREAMWISE VORTICES IN LOW-SPEED FLIGHT"

AIAA Paper No. 2012-0916, January 2012, Nashville, Tennessee.

Low Reynolds number aerodynamic experiments with flapping animals (such as bats and small birds) are of particular interest due to their application to Micro Air Vehicles which operate in a similar parameter space. Previous PIV wake measurements described the structures left by bats and birds and provided insight to the time history of their aerodynamic force generation; however, these studies have faced difficulty drawing quantitative conclusions based on said measurements. The highly three-dimensional and unsteady nature of the flows associated with flapping flight are major challenges for accurate measurements. The challenge of animal flight measurements is finding small flow features in a large field of view at high speed with limited laser energy and camera resolution. Cross-stream measurement is further complicated by the predominantly out-of-plane flow that requires thick laser sheets and short inter-frame times, which increase noise and measurement uncertainty. Choosing appropriate experimental parameters requires compromise between the spatial and temporal resolution and the dynamic range of the measurement. To explore these challenges, we do a case study on the wake of a fixed wing. The fixed model simplifies the experiment and allows direct measurements of the aerodynamic forces via load cell. We present a detailed analysis of the wake measurements, discuss the criteria for making accurate measurements, and present a solution for making quantitative aerodynamic load measurements behind free flyers.

"A NUMERICAL MODEL FOR FORESTRY AERIAL SPRAYING"

Agricultural and Forest Meteorology, Vol. 76, Issue 1, August 1995, pp. 19-40

A numerical model for the aerial application of pesticides in forestry aerial spraying is described. The model predicts canopy and ground deposition and drift patterns for evaporating droplets released over a forest canopy by an aircraft flying at right angles to the wind direction. Droplet trajectories are initially calculated from aircraft wake velocities. Wake velocities are generated from a second-order closure model for the turbulent transport and dissipation of aircraft vortices. When the aircraft wake has decayed to background levels of turbulence, droplet trajectory calculations are continued with a Markov type of Lagrangian model for particle dispersion in a turbulent atmosphere.

Wallace, J. M. and Foss, J. F.

"THE MEASUREMENT OF VORTICITY IN TURBULENT FLOWS"

Annual Review of Fluid Mechanics, Vol. 27, 1995, pp. 469-514.

Since Kovasznay (1950) introduced his vorticity 'meter' idea, which has been shown to be incapable of providing quantitatively reliable values of the streamwise vorticity component except in quite special circumstances, several thermal and optical anemometry methods have been developed to measure one or more components of the vorticity vector. Adequately resolving the flow in both time and space is an arduous task for all these methods. Thermal anemometry probes are limited to 'point' measurements, but they can more easily produce long time series of equally spaced data than optical methods. Such data serve, of course, to provide some new insights into the physics of turbulent flows as well as to provide statistical data for comparison to direct numerical simulations. Furthermore, it is possible to carry out experiments with these probes in flows too complex to currently simulate and at Reynolds numbers not yet attainable on the most powerful present-day computers. The optical methods, which are rapidly being refined, can now produce instantaneous planar data and are on the verge of yielding full three-dimensional field data. This review has emphasized the thermal anemometry methods because they are, to date, our principal experimental source of knowledge about statistical properties of turbulent flow vorticity fields.

"MEASUREMENT OF THE VELOCITY GRADIENT TENSOR IN TURBULENT FLOWS"

Annual Review of Fluid Mechanics, Vol. 42, 2010, pp. 157-181.

This article reviews the principal experimental methods currently available to simultaneously measure all the terms of the velocity gradient tensor of turbulent flows. These methods have been available only for a little more than 20 years. They have provided access to the most fundamental and defining properties of turbulence. The methods include small, multisensor, hot-wire probes that provide single-location, time-resolved measurements of the tensor and various optical arrangements, most of which provide the tensor information over a larger spatial extent but, in most cases, without resolution in time. Data-reduction algorithms, spatial-resolution issues, and the use of Taylor's hypothesis are addressed in evaluating the accuracy of the various methods.

Wallin, S. and Girimaji, S. S.

"EVOLUTION OF AN ISOLATED TURBULENT TRAILING VORTEX"

AIAA Journal, Vol. 38, No. 4, April 2000, pp. 657-665

The long-time development of an isolated wing-tip turbulent vortex has been studied by Reynolds-averaged Navier-Stokes computations. The vortex is assumed to extend to infinity and to be axisymmetric and homogeneous in the axial direction, and the axial velocity is assumed to be negligible. The validity of different turbulence models, ranging from Reynolds stress transport models to eddy-viscosity K- ϵ models, has been assessed and qualitative comparisons with field measurements

are made. Reynolds stress transport models correctly predict strong suppression of the turbulence in the rotation-dominated vortex core and a reasonable decay rate of the vortex. Outside of the core, the different Reynolds stress models differ significantly. The standard eddy-viscosity K- ϵ model is insensitive to rotation and, thus, overpredicts the vortex decay rate. Computations using explicit algebraic Reynolds stress models that are strictly based on Reynolds stress transport models show that the algebraic form compares reasonably well with the full transport form. It is, however, important that the curved flow algebraic assumption is invoked when deriving the explicit algebraic model.

Wallin, S. and Girimaji, S. S.

"STUDY OF TRAILING VORTEX DECAY"

AIAA Paper No. 1999-3767, Norfolk, VA, June 1999

The long-time development of an isolated wing tip turbulent vortex has been studied by Reynolds averaged Navier-Stokes computations. The vortex is assumed to extend to infinity and to be axisymmetric and homogeneous in the axial direction, and the axial velocity is assumed to be negligible. The validity of different turbulence models, ranging from Reynolds stress transport models to eddy-viscosity models, has been assessed and qualitative comparisons with field measurements are made. Reynolds stress transport models correctly predict strong suppression of turbulence in the rotation-dominated vortex core but outside of the core the different Reynolds stress models diverge. Computations using explicit algebraic models that are strictly based on Reynolds stress transport models show that the algebraic form reasonably well compares with the full transport form. It is, however, important that the curved flow algebraic assumption is invoked in deriving the explicit algebraic model.

"LEADING-EDGE PRESSURE MEASUREMENTS OF AIRFOIL VORTEX INTERACTION"

NASA CR-112129, January 1970, Massachusetts Inst. of Technology, Cambridge, MA. (Also, ASRL-TR-153-1.)

Experimental pressure-differential measurements made at 10% chord of an airfoil-vortex interaction are presented. A line vortex was oscillated over an airfoil perpendicular to the span and parallel to the chord. The pressure time history was recorded to show the sharp pressure pulses resulting from the bursting of the vortex core as it impinges upon the airfoil. Results for various vortex sizes and free stream velocities were obtained. Measurements were also made when the airfoil was yawed to the line vortex. Maximum pressure differences were observed to occur in phase across the blade even with yaw, and were directly proportional to the square of the free stream velocity. The maximum dynamic pressure coefficients obtained were as high as 1.0 when vortex bursting occurred.

"MEASUREMENT OF THE VELOCITY FIELD IN A SIMULATED TORNADO-LIKE VORTEX USING A THREE-DIMENSIONAL VELOCITY PROBE"

Journal of the Atmospheric Sciences, Vol. 29, 1972, pp. 116-127.

A three-dimensional velocity probe, incorporating hot-film anemometry, is developed to study the mean flow field of a simulated turbulent tornado-like vortex interacting with a smooth, flat boundary. The flow characteristics are essentially controlled by a dimensionless parameter e and a Reynolds number Re . The parameter e is the ratio of sink strength to the product of the free-stream circulation and the vortex core radius. Flow fields for two different e (0.022 and 0.51) are studied, with Re greater than 100,000 in both cases. It is found that: 1) the tangential velocity profiles at more than three core radii from the axis are similar to those of a turbulent flow over a flat plate; 2) the radial velocity close to the boundary is directed inward due to a positive radial pressure gradient, while it changes direction and approaches a constant at a height of two core radii from the boundary; 3) the vertical velocity depends strongly on e and is directed downward near the vortex axis in case 1 and upward in case 2, the magnitude of the vertical velocity becoming quite small far from the axis in both cases; 4) the streamline pattern in the meridian plane has a two-celled structure for case 1 and a one-cell structure for case 2; 5) as a result of radial and axial flow, the circulation distribution is appreciably different from that of a potential vortex due to the stretching of the vortex tube; 6) zones of maximum wind speed form an annular region near the ground boundary; and 7) the maximum pressure drop, occurring at the axis, exceeds twice the core dynamic head for case 1 and 15 times for case 2 due to higher sink strength. Velocity data obtained from a real tornado are compared with the present results. Good agreement was found with case 2.

"AN OVERVIEW OF VARIOUS KINDS OF WIND EFFECTS ON UNMANNED AERIAL VEHICLE"

Measurement and Control, Vol 52, Issue 7-8, May 2019, pp. 731 739.

Attitude, speed, and position of unmanned aerial vehicles are susceptible to wind disturbance. The types, characteristics, and mathematical models of the wind, which have great influence on unmanned aerial vehicle in the low-altitude environment, are summarized, including the constant wind, turbulent flow, many kinds of wind shear, and the propeller vortex. Combined with the mathematical model of the unmanned aerial vehicle, the mechanism of unmanned aerial vehicle movement in the wind field is illustrated from three different kinds of viewpoints including velocity viewpoint, force viewpoint, and energy viewpoint. Some simulation tests have been implemented to show the effects of different kinds of wind on unmanned aerial vehicle's path and flight states. Finally, some proposals are presented to tell reader in which condition, which wind model should be added to simulation, and how to enhance the stability of unmanned aerial vehicle for different kinds of wind fields.

Wang, B., Liu, Z., Peng, X. and Liu, D.

"SIMULATIONS OF TIP VORTEX CAVITATION FLOWS WITH NONLINEAR k-e MODEL"

9th International Symposium on Cavitation, December 2015, Lausanne, Switzerland, Proceedings published in IOP Journal of Physics: Conference Series, Vol. 656, 2015, pp. 012187-1 to 012187-4.

Effects of turbulence models on the simulations of tip vortex wetted flows and cavitating flows are studied. Two types RANS turbulence models, with and beyond the Boussinesq turbulent-viscosity hypothesis, are investigated by examining experimental results regarding strain rate and Reynolds shear stress distributions in the vortex region. The numerical results imply that the spatial phase shift between the mean strain rate and Reynolds stresses can be accurately modeled by the nonlinear k-e turbulence model; the tip vortex cavitation region can only be predicted using the nonlinear turbulence model. The mechanism of the over-dissipation due to the turbulence model is analyzed in terms of the turbulence production, which is one of the dominant source terms in the transport equations of energy. The numerical results imply that the nonlinear k-e model is a promising candidate for predicting tip vortex cavitation flows in practical applications at a reasonable computational cost.

Wang, C. H. J. and Schluter, J.

"NEAR GROUND AIRCRAFT WAKE DISSIPATION WITH OBSTACLES"

AIAA Paper 2015-3298, June 2015, Dallas, TX.

The current study is a collaboration between the German Aerospace Center (DLR), the Nanyang Technological University, and the Civil Aviation Authority of Singapore to explore the effects of different ground-based obstacles on the evolution of near ground wake vortex. Simulations were conducted using OpenFOAM solver, and validated against the DLR water tow-tank data collected using PIV measurements. The simulation domain was scaled to match the tow tank dimensions, and the vortex pair were initialized using Lamb-Oseen vortex equation using initial circulation and core radius values from the PIV data. Simulations were conducted in the tow tank simulation domain for flat ground without obstacles and with obstacles of various configuration and design.

Wang, C. H. J., Paramasivam, S., Zhao, D., Schluter, J., Stephan, A. and Holzaepfel, F.

"OPTIMIZATION OF SINGLE OBSTACLE PAIR FOR AIRCRAFT WAKE DISSIPATION UNDER CROSSWIND CONDITION"

AIAA Paper 2017-4238, June 2017, Denver, CO.

The implementation of ground-based obstacle near the runway threshold has been shown in various simulation, experimental, and flight test studies to be an effective way of reducing the hazard of aircraft wake encounter. These plate-type obstacles functions by accelerating the formation of ground separation based secondary vortex structure (SVS), which wraps around the wake vortex core and induces early dissipation of the wake. Parameter study into the sizing of the obstacle plates has shown that the obstacle can remain effective even with reduced height. However, the effectiveness of these obstacles under crosswind condition is questionable, as previous studies have shown that the

maximum descend height of the vortex increases when subjected to crosswind. Large Eddy Simulation (LES) were carried out with vortical Reynolds number of 52,000 using a single obstacle pair of 0.05(b-zero) in height. Analysis showed that the effect of obstacle plates on wake vortex dissipation was still observed, though not as pronounced as the no-crosswind case.

Wang, C. H. J., Zhao, D., Schluter, J., Holzaepfel, F. and Stephan, A.

"LES STUDY ON THE SHAPE EFFECT OF GROUND OBSTACLES ON WAKE VORTEX DISSIPATION"

Aerospace Science and Technology, Vol. 63, 2017, pp. 245-258.

The lingering wake vortex following a landing aircraft has long been a hazard to aviation safety. Previous studies at the German Aerospace Center (DLR) confirmed the effectiveness of applying ground-based obstacles to improve the dissipation of the wake vortex pair by triggering the onset of the vortex bursting by the artificial introduction of shortwave instability. Following the design of the plate line obstacles as proposed by DLR for vortex dissipation, we further investigate the influence of the shape of the ground obstacles on dissipating wake vortex in the present work. The secondary vortex structure, resulting from the interaction between the vortical flow and the obstacle plate, stems from the location of the obstacle and travels outward along the vortex axis, thus spreading instability to the vortex structure along the way. 3D numerical simulations were conducted using Large Eddy Simulation with OpenFOAM solver. The numerical solutions were first compared to the experimental vortex measurement performed in DLR's Wasser Schleppkanal Gottingen tow-tank. In addition to the baseline setup three different shaped obstacles were numerically tested and compared in the simulation. The numerical results reveal that 50 percent reduction of the wake dissipation, measured with the circulation of the vortex, was achieved within $t^* = 1.5$ compared to $t^* > 4.0$ in the absence of ground obstacle. The present study showed that the shape of the obstacles affects the pattern of the secondary vortex structure created, and the resulting drag force acting on the obstacle has a more direct effect on wake dissipation.

Wang, C. H. J., Zhao, D., Schluter, J., Stephan, A. and Holzaepfel, F.

"EFFECT OF GROUND OBSTACLE OF DIFFERENT ASPECT RATIO ON WAKE VORTEX DISSIPATION"

AIAA Paper 2016-3134, June 2016, Washington, DC.

The employment of obstacles to accelerate dissipation of aircraft wake vortex near ground was proposed by DLR, with several subsequent studies on the effect of the obstacles under different atmospheric conditions. In collaboration with DLR, the NTU research team employed large eddy simulation to study the effect of obstacle shape on the dissipation rate and propagation speed of vortex breakup. Simulation results have shown that while the shape of the obstacle influences the propagation speed of vortex breakup, the flow-facing area of the obstacles is the major contributing factor deciding the magnitude of circulation reduction on top of the obstacle. The current study aims to investigate the effect of the aspect ratio of obstacle on vortex dissipation while holding the biggest contributor to reduction of circulation, form drag from the obstacle projected area, constant. Out

simulation data has shown that, with every other parameter remained constant, the aspect ratio of obstacle makes negligible difference to the dissipation rate of wake vortex. The result suggested that the height of the obstacle could be further reduced into a less intrusive profile and lessen the impact of these obstacles on airport operations.

Wang, C. H. J., Zhao, D., Schluter, J., Stephan, A. and Holzaepfel, F.

"COMPUTATIONAL INVESTIGATION OF VARYING PLATE-LINE GEOMETRY AND PLACEMENT ON WAKE VORTEX DISSIPATION"

Journal of Aircraft, Vol. 55, No. 1, January-February 2018, pp. 133-144.

One of the bottlenecks for the recent increase in air traffic density is near the airport, where wake vortices, bounded by the terrain, could easily rebound into the landing corridor and remain there for a long period of time while maintaining their strength. The threat of near-ground wake vortex could be mitigated by the plate-line technology, which places a series of thin plates across the landing corridor before the runway; the technology was shown to significantly reduce the time it takes for wake vortex dissipation. The current investigation aims to better understand factors such as plate dimension and lateral position influences on the generation of secondary vortex structure and ultimately the dissipation rate of a wake vortex pair. It is found that the wake dissipation could be sped up further by optimizing the lateral position of the plate relative to the obstacle-vortex contact location, while the height of the plate could be significantly reduced without noticeably affecting the performance of the obstacle set.

"A NEW NUMERICAL APPROACH FOR ROTORCRAFT AERODYNAMICS USING VORTICITY CONFINEMENT"

AIAA Paper No. 1997-2328, Atlanta, GA, June 1997

The Vorticity Confinement method is used in conjunction with uniform Cartesian grids for computing flows of blunt bodies. These bodies are defined on the uniform grid by a smooth function where the function is designated zero on the body surfaces. A unique computation procedure is applied to all the grid points with the confinement performed outside the body based on the vorticity whereas inside the body based on the function. For flows around streamline-like bodies, such as a wing, the computation is performed on body-fitted grids where these grids can be encompassed by the uniform grid. Flow information is transferred between the body-fitted grids and the uniform grid, where one or more blunt bodies are embedded, through an overset grid technique. However, there is no hole-cutting needed since the solid bodies are explicitly defined by the smooth function. A NACA0012 wing download under a rotor is computed by the combined approach with a generic nacelle at the wing tip.

Wang, C. M., Steinhoff, J. S. and Wenren, Y.

"NUMERICAL VORTICITY CONFINEMENT FOR VORTEX-SOLID BODY INTERACTION PROBLEMS"

AIAA Journal, Vol. 33, No. 8, August 1955, pp. 1447-1453

A new numerical method based on adding a term to the Euler/Navier-Stokes equations has demonstrated that it can effectively treat vortex-dominated flows using low-order numerical schemes and coarse grids. With the technique, numerical diffusion introduced by convection schemes can be eliminated when solving the modified flow governing equations. The modification of the velocity field, which conserves the total vorticity, essentially convects the vorticity toward its local extreme to offset the numerical diffusion. This method preserves the vortex structure even when vortices travel through a coarse grid region. The method is implemented separately with two distinctive basic solvers: a Navier-Stokes flow solver based on a vorticity-velocity formulation and an Euler solver based on a velocity-pressure formulation. Problems presented in this paper include airfoil dynamic stall, vortex-airfoil interaction, and vortex-fuselage interactions.

Wang, F. Y. and Sforza, P. M.

"AN EXPLORATORY WIND TUNNEL STUDY OF SUPERSONIC TIP VORTICES"

AIAA Paper No. 1993-2923, Orlando, FL, July 1993

Results of recent tests conducted at Polytechnic University on supersonic tip vortices generated by a small aspect ratio, rectangular half-wing in a Mach 3 stream are presented. Surveys were made for two angles of attack at a station approximately two chords downstream of the half-wing. Time-averaged vortex position, Mach number, velocity, pressure, and density were estimated by combining pitot pressure readings and a shadowgraph-based visualization technique. Some very low frequency vortex trajectory oscillations were observed. In many respects, the observed supersonic tip vortex behaved much like its low-speed counterpart with a compressibility correction, that is, a two-dimensional vortex superimposed on a uniform freestream velocity. The downstream convection of the vortex appeared to proceed with negligible diffusion in the near field studied. It was also found that the trailing supersonic tip vortices, although estimated to be weak in terms of swirl, appear to include a substantial stagnation pressure deficit. On the other hand, it appears that the axial component of velocity and the temperature are constant across the profile, within the spatial resolution possible. Suggestions on vortex modeling are provided to aid in formulating initial conditions for numerical studies involving supersonic tip vortices.

Wang, F. Y. and Zaman, K. B. M. Q.

"AERODYNAMICS OF A JET IN THE VORTEX-WAKE OF A WING"

AIAA Paper No. 2001-1119, Reno, NV, January 2001

Results of a low-speed experimental investigation of jet behavior in the trailing vortex-wake of a wing are presented. The effects of varying jet-to-freestream velocity ratio and vortex-wake strength on the downstream evolution of the flow field are quantified via three-dimensional hot-wire anemometry surveys. Under conditions encountered in powered flight, especially during take-off, landing and maneuvering of a vehicle, the jet is found to undergo severe distortion within a very short distance

from the nozzle exit. The interaction of the jet and the wing vortices generates additional vortical structures. Spreading and decay of the jet are shown to be governed predominantly by the interaction of the vortices.

Wang, F. Y. and Zaman, K. B. M. Q.

"AERODYNAMICS OF A JET IN THE VORTEX WAKE OF A WING"

AIAA Journal, Vol. 40, No. 3, March 2002, pp. 401-407.

Results of a low-speed experimental investigation of jet behavior in the trailing vortex wake of a wing are presented. The effects of varying jet-to-freestream velocity ratio and vortex-wake strength on the downstream evolution of the flowfield are quantified via three-dimensional hot-wire anemometry surveys. Under conditions encountered in powered flight, especially flow states characteristics of takeoff, landing, and maneuvering of a vehicle, the jet is found to undergo severe distortion within a very short distance from the nozzle exit. The interaction of the jet and the wing vortices generates additional vortical structures. Spreading and decay of the jet are shown to be governed predominantly by the interaction of the vortices.

Wang, F. Y., Sforza, P. M. and Pascali, R.

"VORTEX-WAKE CHARACTERISTICS OF A HIGH SPEED CIVIL TRANSPORT TYPE WING PLANFORM AT MACH 2.5"

AIAA Paper No. 1995-2284, San Diego, CA, June 1995

An experimental study of the vortex-wake flow of a High-Speed Civil Transport (HSCT) baseline type planform in a Mach 2.5 stream is presented. Surface oil flow visualization was used to indicate certain features of the flow over the wing (Reynolds number based on mean aerodynamic chord was 4.04 million), while spark-shadowgraphs and laser light sheets were used to provide visual information on vortex-wake development up to 11 tip chords downstream of the trailing edge. In addition, pitot pressure surveys were made at 1.3, 7.8 and 16.3 tip chords downstream of the model to map out the trajectory and decay characteristics of the vortex-wake. It was found that three well-defined swirling structures are generated by the representative HSCT planform tested. These results indicate that even for a typical angle of attack of 5 degrees, vortices of substantial strength are generated. The vortex core diameters are observed to persist, essentially unchanged, up to the maximum visual range allowed. The results of the pitot survey demonstrated that the vortices generated are still quite noticeable as far as 16.3 tip chords downstream; in particular, the strength of the tip vortex was virtually unchanged over the entire surveyed range of 16.3 tip chords.

Wang, F. Y., Sforza, P. M. and Pascali, R.

"VORTEX-WAKE CHARACTERISTICS OF A SUPERSONIC TRANSPORT WING PLANFORM AT MACH 2.5"

AIAA Journal, Vol. 34, No. 8, 1995, pp. 1750-1752

An experimental study of the vortex-wake flow of a High-Speed Civil Transport (HSCT) type crank-arrow planform in a Mach 2.5 stream is presented. It is found that three well-defined swirling structures are generated by the representative HSCT planform tested. These are respectively, vortices from wing tip, leading-edge separation from the delta-wing portion and that from the junction of the crank-arrow planform. The Pitot pressure survey suggested that the wing tip vortex would persist farther downstream compared to the other two vortices shed from the planform. The exploratory wake survey also suggested that the application of an incompressible roll-up model could be a viable approach for calculating the vortex-wake evolution from supersonic aircraft, provided that a realistic wing loading on the planform is available to initialize the subsequent vortex-wake computation.

Wang, F. Y., Wassaf, H. S., Gulsrud, A., Delisi, D. P. and Rudis, R. P.

"ACOUSTIC IMAGING OF AIRCRAFT WAKE VORTEX DYNAMICS"

AIAA Paper No. 2005-4849, Toronto, Canada, June 2005

The experience in utilizing a phased microphone array to passively image aircraft wake vortices is highlighted. It is demonstrated that the array can provide visualization of wake dynamics like smoke release or natural condensation of vortices. Examples on how the technique has been integrated with other data to address some of the research issues in wake vortices are documented. These topics include the initial vortex spacing characterization, collaboration with simultaneous pulsed Lidar data to provide a more complete understanding of vortices at a late stage in their evolution, and correlation between atmospheric turbulence with the time-scale involved for vortices developing into a very contorted state. In addition, the paper provides a comparison between the vortex tracks as inferred from their acoustics characteristics vs. those detected from the velocity field (i.e., pulsed Lidar). A preliminary attempt is also made to examine the global link between wake vortex sound and vortex circulation, suggesting that there could be a power law relationship between the two datasets.

Wang, F. Y., Wassaf, H., Dougherty, R. P., Clark, K., Gulsrud, A., Fenichel, N. and Bryant, W. H.

"PASSIVE WAKE ACOUSTICS MEASUREMENTS AT DENVER INTERNATIONAL AIRPORT"

4th NASA Integrated CNS Conference and Workshop, Fairfax, VA, April 2004

From August to September 2003, NASA conducted an extensive measurement campaign to characterize the acoustic signal of wake vortices. A large, both spatially as well as in number of elements, phased microphone array was deployed at Denver International Airport for this effort. This paper briefly describes the program background, the microphone array, as well as the supporting ground-truth and metrological sensor suite. Sample results to date are presented and discussed. It is seen that, in the frequency range processed so far, wake noise is generated predominantly from a very confined area around the cores.

Wang, H.

"SHORT WAVE INSTABILITY ON VORTEX FILAMENTS"

Physical Review Letters, Vol. 80, No. 21, May 1998, pp. 4665-4668

The short-wave instability on corotating vortex filaments is investigated. It is shown that the short-wave instability always occurs on corotating vortex filaments of fixed core structure. Moreover, when the interfilament distance is smaller than or comparable to the core size, vortex filaments produce short wave unstable modes which lead to wild stretching and folding; when vortex filaments are far apart from each other, unstable modes are bounded by a fraction of the core size and the vortex stretching remains bounded. These findings may be used to explain the smooth behavior of superfluid vortices. They also explain the stretching seen in numerical calculations.

Wang, H., Cai, L., Chong, X. and Geng, H.

"EXPERIMENTAL STUDY OF THE JET ENGINE EXHAUST FLOW FIELD OF AIRCRAFT AND BLAST FENCES"

Promet - Traffic & Transportation, Vol. 27, No. 2, 2015, pp. 181-190.

A combined blast fence is introduced in this paper to improve the solid blast fences and louvered ones. Experiments of the jet engine exhaust flow (hereinafter jet flow for short) field and tests of three kinds of blast fences in two positions were carried out. The results show that the pressure and temperature at the center of the jet flow decrease gradually as the flow moves farther away from the nozzle. The pressure falls fast with the maximum rate of 41.7%. The dynamic pressure 150 m from the nozzle could reach 58.8 Pa, with a corresponding wind velocity of 10 m/s. The temperature affected range of 40 deg C is 113.5x20 m. The combined blast fence not only reduces the pressure of the flow in front of it but also solves the problems that the turbulence is too strong behind the solid blast fences and the pressure is too high behind the louvered blast fences. And the pressure behind combined blast fence is less than 10 Pa. The height of the fence is related to the distance from the jet nozzle. The nearer the fence is to the nozzle, the higher it is. When it is farther from the nozzle, its height can be lowered.

Wang, J. J., Li, Y. C. and Choi, K.-S.

"GURNEY FLAP -- LIFT ENHANCEMENT, MECHANISMS AND APPLICATIONS"

Progress in Aerospace Sciences, Vol. 44, 2008, pp. 22-24.

Since its invention by a race car driver Dan Gurney in 1960s, the Gurney flap has been used to enhance the aerodynamics performance of subsonic and supercritical airfoils, high-lift devices, and delta wings. To take stock of recent research and development of Gurney flap, we have carried out a review of the characteristics and mechanisms of lift enhancement by the Gurney flap and its applications. Optimum design of the Gurney flap is also summarized in this paper. For the Gurney flap to be effective, it should be mounted at the trailing edge perpendicular to the chord line of airfoil or wing. The flap height must be of the order of local boundary layer thickness. For subsonic airfoils, an

additional Gurney flap increases the pressure on the upstream surface of the Gurney flap, which increases the total pressure of the lower surface. At the same time, a long wake downstream of the flap containing a pair of counter-rotating vortices can delay or eliminate the flow separation near the trailing edge on the upper surface. Correspondingly, the total suction on the airfoil is increased. For supercritical airfoils, the lift enhancement of the Gurney flap mainly comes from its ability to shift the shock on the upper surface in the downstream. Applications of the Gurney flap to modern aircraft design are also discussed in this review.

"RADIATION DRY BIAS CORRECTION OF VAISALA RS92 HUMIDITY DATA AND ITS IMPACTS ON HISTORICAL RADIOSONDE DATA"

Journal of Atmospheric and Oceanic Technology, Vol. 30, February 2013, pp. 197-214.

The Vaisala RS92 radiosonde is the most widely used type of sonde in the current global radiosonde network. One of the largest biases in the RS92 humidity data is its daytime solar radiation dry bias (SRDB). An algorithm [referred to as NCAR radiation bias correction (NRBC)] was developed to correct the SRDB based on a more complicated algorithm developed by the Global Climate Observing System (GCOS) Reference Upper-Air Network (CRUAN). The NRBC to relative humidity (RH) is a function of the measured RH and temperature, and the temperature solar radiation correction. The latter varies with pressure, season, and time of the day. The RH correction has a mean magnitude of about 2-4 percent and 6-8 percent in the lower-midtroposphere and upper troposphere, respectively. The NRBC is evaluated against the GRUAN-corrected RS92 data and the ground-based GPS-estimated precipitable water (PW). The corrected RH agrees with the GRUAN data within ± 0.5 percent on average, with standard deviations of about 1-2 percent and 2-6 percent in the lower-midtroposphere and upper troposphere, respectively. The NRBC leads to reduced mean biases, and better agreement with the GPS PW and its diurnal cycle. The NRBC has been applied to historical radiosonde data at 65 stations. The radiosonde humidity data, both with and without the NRBC, are homogenized using the method of Dai et al. (2011). The NRBC results in consistently elevated RHs throughout the whole record in the homogenized data. This could have a significant impact on global reanalysis products when they are assimilated into the reanalysis models. However, the NRBC has insignificant effects on the long-term trends as the correction is primarily for mean biases.

"ON THE VORTEX DETECTION METHOD USING CONTINUOUS WAVELET TRANSFORM WITH APPLICATION TO PROPELLER WAKE ANALYSIS"

Mathematical Problems in Engineering, Vol. 2015, Article 242917, pp. 1-9.

The method based on the continuous wavelet transformation to detect and characterize two-dimensional vortex is analyzed for a synthetic flow and applied to vortex detection of propeller wake. The characteristics of a vortex, such as center location, core radius, and circulation, are extracted based

on the Lamb-Oseen and Rankine vortex models, the latter of which is a novel attempt. The effects of various factors such as the difference scheme, the grid and scale discretization, transform variable, and vortex model on vortex detection have been investigated thoroughly. The method is further applied to identify the tip vortex in a propeller wake.

"HIGH-RESOLUTION SIMULATION FOR ROTORCRAFT AERODYNAMICS IN HOVERING AND VERTICAL DESCENDING FLIGHT USING A HYBRID METHOD"

Chinese Journal of Aeronautics, Vol. 31, No. 5, 2018, pp. 1053-1065.

A high-resolution simulation tool for rotorcraft aerodynamics is developed by coupling CFD with a Vorticity Transport Model (VTM). A Eulerian-based CFD module is used to model the blade near body flowfield, and a Lagrangian-based VTM module is employed for vortex tracking in the far wake. The coupling procedure is implemented by transmitting vortex sources to the VTM module and feeding boundary conditions back to the CFD module. The presented CFD/VTM hybrid solver is firstly validated by hover cases of three different rotor configurations. Simulation results, including the blade surface pressure distribution, rotor downwash, and hover figure of merit, exhibit favorable correlations with available experimental data. Then, a rotor operated in vertical descending flight with a fixed collective pitch is investigated. It is shown that the CFD/VTM coupling method is suitable for rotor wake simulation. Wake instabilities (far wake breakdown in hover and toroidal wake pattern in the vortex ring state) are successfully demonstrated with a moderate computational cost.

"AXISYMMETRIC VORTEX BREAKDOWN IN A PIPE"

ESAIM: Proceedings, Vol. 1, 1996, pp. 267-278.

A recent theory of the nearly axisymmetric vortex breakdown in a pipe is presented. We study the motion of an axisymmetric and inviscid swirling flow in a pipe with certain boundary conditions that may reflect the physical situation. The theory is built of global analysis of solutions of the Squire-Long equation and linear stability analysis of these solutions. The theory unifies the major previous theoretical approaches and provides for the first time a consistent explanation of the physical mechanism leading to the vortex breakdown phenomenon as well as the conditions for its occurrence.

Wang, T., Dooland, C. J., Coton, F. N. and Galbraith, A. M.

"EXPERIMENTAL STUDY OF THE THREE DIMENSIONALITY OF ORTHOGONAL BLADE-VORTEX INTERACTION"

AIAA Journal, Vol. 40, No. 10, October 2002, pp. 2037-2046

Wind-tunnel tests were conducted to investigate orthogonal vortex interaction with a stationary blade mimicking the main-rotor/tail-rotor interaction. High-quality experimental results with high-temporal resolution for the interaction have been obtained at different wind speeds and blade incidence angles. A vortex generator was specially designed for the experiment and produced stable trailing vortices. These were identified by hot-wire anemometry, with different vortical parameters for different speeds. When the measurement location is aligned with the vortex axis, pressure data reveal a suction peak on the upper blade surface and a pressure peak on the lower surface during the interaction. Significant dependence of the pressure on spanwise distance from the vortex indicates a strong three-dimensional interaction effect. For example, for spanwise positions above the core axis, a pressure pulse on the upper surface and a suction peak on the lower surface have been observed. It is shown that these differences can be attributed to the influence of the axial and tangential velocity components of the vortex. Pressure data for the blade at high incidence also show that the interaction can exacerbate and alleviate flow separation, depending on the spanwise position.

Wang, T.-I.

"OPTICAL SCINTILLOMETER WAKE VORTEX DETECTION SYSTEM"

U.S. Patent 5838007, November 1998

An optical scintillometer is provided which is operative to measure atmospheric wake vortex turbulence intensity up to a distance of ten kilometers. The optical scintillometer provides real time continuous measurements of aircraft generated wake vortex turbulence intensity in the field of operations employing a transmitter, receiver, and digital processing circuitry. The signal is digitized before comparison with a threshold to eliminate events attributable to objects moving through the path of the optical transmitter and receiver. The system is thereby able to perform calculations to adjust the first order log-amplitude variance function in the saturation regime. An extremely important aspect of the invention is the digitization of the signal and its comparison with the threshold signal. Because a digital signal is compared with a threshold signal level, invalid signal inputs are excluded from the calculation of path-averaged turbulence intensity. The exclusion of such signals assures the data quality in computing the refractive turbulence intensity even when there is an interruption of the infrared beam. This feature is critical for the data processing. Data produced when the optical path is obstructed by moving vehicles, pedestrians, and airplanes is not used for processing to protect the quality of the output measurements.

"TEMPORAL EVOLUTION OF THE RCS OF AIRCRAFT WAKE VORTICES"

Aerospace Science and Technology, Vol. 24, 2013, pp. 204-208.

Knowledge of the radar scattering characteristics is one of the key issues for the development of wake vortex detection technology. This paper studies the temporal evolution of the RCS (radar cross-section) of wake vortices. The RCS-time plot is observed to increase as a whole and step at a certain time. These

properties could provide help to the design of wake vortex detection radar and the optimization of radar station layout. The special spiral structures within the wake, together with the Bragg scattering theory, are used to well explain these phenomena, and some representative radar experiments are also included to verify them.

Wang, Y.

"A METHOD OF ESTIMATING AIRPLANE TURBULENCE USING WIND DATA"

ICAS 2002, Paper 2002-P15, Sept. 2002, Toronto, Canada.

Using the nonlinear Boussinesq equations, the analysis of the relations between the wind and the turbulence kinetic energy (TKE) development is made, and a method of estimating the airplane turbulence using the wind data is obtained. Wind is closely related to the appearance of turbulence and its development. Under a certain condition, wind shear can produce turbulence, and whether the turbulence can be developed is decided by the distribution of wind.

"EXPERIMENTAL INVESTIGATIONS ON THE INTERACTION OF THE SINGLE/CO-ROTATING VORTEX WITH THE GROUND"

AIAA Journal, Vol. 57, No. 2, February 2019, pp. 499-512.

Experiments on the interactions between a single vortex/co-rotating vortex and the ground were conducted in a water channel using particle image velocimetry (PIV) measurements. Both the single vortex (SNV) and co-rotating vortex pair (CVP) were generated by using NACA0012 vortex generators to simulate the main flow features behind one side of the wings at the far field and near field. The ground effect was achieved by allocating a flat plate downstream of the vortex generators. It has been found that the lower initial vortex height led to greater vortex rebound and lateral drift in both the SNV and CVP cases, whereas the development of a secondary vortex was also promoted with lower initial vortex height. In the CVP cases, the mutual rotation of the primary vortices led to variation of the close-to-wall velocity distribution. This effect added the disturbances to the formation and evolution of the secondary vortical structure, which eventually affected the height of the secondary vorticity and the rebound of the primary vortices.

"A LAGRANGIAN STOCHASTIC MODEL FOR AERIAL SPRAY TRANSPORT ABOVE AN OAK FOREST"

Agricultural and Forest Meteorology, Vol. 76, Issues 3-4, October 1995, pp. 277-291.

An aerial spray droplets' transport model has been developed by applying recent advances in Lagrangian stochastic simulation of heavy particles. A two-dimensional Lagrangian stochastic model was adopted to simulate the spray droplet dispersion in atmospheric turbulence by adjusting the

Langrangian integral time scale along the drop trajectory. The other major physical processes affecting the transport of spray droplets above a forest canopy, the aircraft wingtip vortices, and the droplet evaporation, were also included in each time step of the droplets' transport. The model was evaluated using data from an aerial spray field experiment. In generally neutral stability conditions, the accuracy of the model predictions varied from run-to-run as expected. The model prediction was adequate in two-dimensional steady wind conditions, but was less accurate in variable wind condition. The results indicated that the model can simulate successfully the ensemble; average transport of aerial spray droplets under neutral, steady atmospheric wind conditions.

Wang, Y., Qin, S. and Liu, H.

"VORTEX DRAG GENERATED BY AIRCRAFT AFTERBODY VORTICITY-LOOP SYSTEM"

AIAA Paper 2018-0550, January 2018, Kissimmee, FL.

High cruise resistance exerted on the aircraft afterbody is mainly due to a vortex system, which is composed of afterbody vorticity-loop (ABVL) and co-rotating horizontal tail tip vorticity-loop (HTVL). This lift-generated vortex system is associated with the specific viscosity-independent portion of overall drag, which is determined as vortex drag. In this paper, the vortex system of the aircraft afterbody has been investigated using particle image velocimetry (PIV) experiment and improved delayed detached eddy simulation (IDDES). Conventionally, the induced drag is regarded as a steady case of vortex drag without considering vortex interactions. It has been computed with Betz and Maskell wake-integral model to conduct a comparative analysis, which has demonstrated the nonnegligible role played by the non-linear part. To reveal the underlying physical source and meaning of vortex drag, the Vorticity Moment Theorem (VMT) has been developed and applied into the single and multiple vorticity-loop model to quantitatively define and accurately understand vortex drag.

"WIND TURBINE WAKE ENCOUNTER STUDY"

Report, March 2015, University of Liverpool, Liverpool, UK.

The wake vortices generated by a wind turbine or a wind farm could cause interference with passing light aircraft. A wind turbine study using engineering wake modelling, CFD, LIDAR field measurements and piloted flight simulations was carried out at University of Liverpool in collaboration with CAA, UK. A modified Kocurek wind turbine wake model has been developed to simulate wind turbine wakes. It has been validated using the MEXICO wind turbine and the PIV wind tunnel measurements, as well as CFD wake simulation results. This wake vortex model was applied to a WTN250 wind turbine that is installed near the East Midlands Airport, UK, where field measurements of wind turbine wake using LIDAR were carried out. The LIDAR data was compared with the wake velocity fields generated by different wake modelling methods. The WTN250 wind turbine wake velocities generated by the Kocurek wake vortex model were integrated into an aircraft flight dynamic model to simulate a wind turbine wake encounter scenario, designed for a light aircraft approaching an airport, where a wind

turbine was installed. The severity of the wind turbine wake encounter was investigated using piloted flight simulations. The simulation results suggest that the wake generated minor upsets on the aircraft and resulted a severity rating of B if only the disturbances caused by wake velocity deficits were considered. Off-line simulations and analysis of wind turbine wake encounters were also carried out and the results indicated that for the small size WTN250 wind turbine, the approach based on the Beddoes circulation formula appeared to give predictions in line with the LIDAR measurements. The off-line analysis also showed the variability of the predictions based on the employed wake models.

Wang, Y., White, M. and Barakos, G.

"HELICOPTER WAKE ENCOUNTER STUDY"

Report, March 2015, University of Liverpool, Liverpool, UK.

Different methods of modelling helicopter wakes, namely, a hybrid wake model, a free wake model and a CFD actuator disk model are presented and compared with available wind tunnel and flight test data. The free wake model was then used to generate the wake vortices of a helicopter in hover-taxiing over an airport runway. A hybrid wake model, with a wake decay law, was also used to generate the far wake of a helicopter in level flight. The wake induced velocity fields were integrated into an aircraft flight dynamics model and piloted flight simulations were carried out to study a light aircraft encountering a helicopter wake during landing and level flight. It was found that for the current landing wake encounter scenario, the existing wake encounter criteria and severity metrics for the determination of the hazardous distance might not be appropriate if the wake encounter occurs close to the ground. The landing simulation results suggest that for a helicopter in low-speed hover-taxiing (less than 40 kt airspeed), the wake encounter detectable horizontal distance is about three times the diameter of the rotor, which coincides with the current safety guidelines of the Civil Aviation Authority of the UK. The level flight simulations revealed the effects of the vertical separation distance and of the wake decay on the encounter severity.

Wang, Y., White, M. and Barakos, G. N.

"WIND-TURBINE WAKE ENCOUNTER BY LIGHT AIRCRAFT"

Journal of Aircraft, Vol. 54, No. 1, January-February 2017, pp. 366-369.

Wake-field measurements using LIDAR were carried out on a WTN250 wind turbine located at the East Midlands Airport in the United Kingdom. The measurements captured the wake flow patterns in terms of wake induced mean velocity deficit and indicated that, for this wind turbine, the mean wake velocities recovered to the freestream wind speed at a position about five rotor diameters downstream. The LIDAR measurements were compared with the results of a full CFD simulation, which was conducted on the MEXICO wind turbine with a similar tip speed ratio, and were also compared with the wind-turbine velocity deficit wake models. In general, reasonable agreement was shown. The piloted flight simulation results suggest that the WTN250 wind-turbine wake mainly generated yaw disturbances on the encountering aircraft of less than 10 deg. The wake-encounter severity was

regarded as minor. The wake model and the LIDAR measurements can only generate the wake velocity deficit flowfields. The mean velocity deficits in wind-turbine wakes normally decay faster than that of the wake turbulence. The wake turbulence persists farther downstream. If the length scales of the wake turbulence are comparable with the size of aircraft lifting surfaces, it could cause unsteady upsets on the encountering aircraft. Methods of modeling and measuring wind-turbine wake turbulence will be sought and implemented in future wake-encounter flight simulations.

"NUMERICAL MODELING OF CHEMISTRY, TURBULENT MIXING AND AEROSOL DYNAMICS IN NEAR-FIELD AIRCRAFT PLUMES"

Ph.D. Thesis, University of California at Berkeley, Berkeley, CA, 1998.

A detailed mechanism including gas phase HO_x, NO_x, SO_x, and CO_x chemistry between the aircraft exhaust and the ambient air in near-field aircraft plumes is compiled. A reduced mechanism capturing the major chemical pathways is developed. Predictions by the reduced mechanism is found to be in good agreement with those by the detailed mechanism. With the reduced chemistry, the computer CPU time is saved by a factor of more than 3.5 for the near-field plume modeling. Distributions of major chemical species are obtained and analyzed. Sensitivities of major species with respect to reaction step are deduced for identification of the dominant gas phase kinetic reaction pathways in the jet plume.

Wang, Z., Tian, W. and Hu, H.

"AN EXPERIMENTAL STUDY ON THE WAKE CHARACTERISTICS OF DUAL-ROTOR WIND TURBINES BY USING A STEREOSCOPIC PIV TECHNIQUE"

AIAA Paper 2016-3128, June 2016, Washington, DC.

An experimental study was performed to investigate the wake characteristics behind an innovative dual-rotor wind turbine (DRWT) with co- and counter-rotating configurations, in comparison with those of a traditional single-rotor wind turbine (SRWT). The comparative study was performed in a large-scale Atmospheric Boundary Layer (ABL) wind tunnel with the scaled DRWT and SRWT models under neutral stability conditions. In addition to measuring the power outputs of the DRWT and SRWT systems, static and dynamic wind loads acting on the test models were also investigated to assess the effects of the secondary, smaller, co-axial rotor in either counter-rotating (rotors rotate at opposite directions) or co-rotating (rotors rotate at same direction) configuration on the power production performance and the resultant dynamic wind loads (both aerodynamic forces and bending moments) acting on the DRWT models. Furthermore, a high-resolution stereoscopic Particle Image Velocimetry (Stereo-PIV) system was also used to make both 'free-run' and 'phase-locked' measurements to quantify the transient behavior (i.e., formation, shedding and breakdown) of unsteady wake vortices and the flow characteristics behind the DRWT and SRWT models. The detailed flow field measurements were correlated with the power output data and dynamic wind loading measurements to elucidate underlying physics for higher total power yield and better durability of wind turbines operating in turbulent non-homogeneous atmospheric boundary layer winds.

Wang, Z., Wang, J. and Shortle, J.

"SENSITIVITY ANALYSIS OF POTENTIAL WAKE ENCOUNTERS TO STOCHASTIC FLIGHT-TRACK PARAMETERS"

5th International Conf. on Research in Air Transportation, May 2012, Berkley, CA.

Many NextGen technologies and concepts, when implemented, will change the underlying stochastic nature of flight tracks. This paper investigates how changes in the stochastic variability of flight tracks have the potential to impact the probability of potential wake encounters. We investigate these relationships for a single runway and for parallel runways. The results show that the mean and standard deviation of separation, and the vertical standard deviation are the key parameters affecting potential wake encounters. In the parallel-runway scenario, effects of crosswind and runway spacing are studied. A full factorial design is conducted to estimate the impact of parameters and their interactions, with dominating factors identified. In some cases, results can be different even for the same parameter when different circulation thresholds are used for defining wakes. Outputs from different wake models (TDAWP vs. D2P) are compared. The overall objective is to assess the sensitivity of these results to parameters of the stochastic input distribution.

Ward, D. T. and Myatt, J. H.

"PRELIMINARY DESIGN OF AN INTERMITTENT SMOKE FLOW VISUALIZATION SYSTEM"

NASA-CR-186027, January 1993, NASA Dryden Flight Research Center, Edwards, CA.

A prototype intermittent flow visualization system has been designed to study vortex flow field dynamics and has been constructed and tested through its ground test phase. It produces discrete pulses of dense white smoke consisting of particles of terephthalic acid by the pulsing action of a fast-acting three-way valve. The trajectories of the smoke pulses can be tracked by a video imaging system without intruding in the flow around in flight. Two methods of pulsing the smoke were examined. The simplest and safest approach is to simply divert the smoke between the two outlet ports on the valve; this approach should be particularly effective if it were desired to inject smoke at two locations during the same test event. The second approach involves closing off one of the outlet ports to momentarily block the flow. The second approach requires careful control of valve dwell times to avoid excessive pressure buildup within the cartridge container and does also increase the velocity of the smoke injected into the flow. The flow of the smoke has been blocked for periods ranging from 30 to 80 milliseconds, depending on the system volume and the length of time the valve is allowed to remain open between valve closings.

"DEVELOPMENT AND TESTING OF A TRIPLE-BEAM DOPPLER LIDAR SYSTEM FOR 3D WIND MEASUREMENT"

19th Coherent Laser Radar Conference (CLRC), Paper Tu6, June 2018, Okinawa, Japan.

We present results from our recent development of a triple-beam Doppler lidar system for accurate 3-dimensional wind measurements. The eye-safe all-fiber system consists of a central unit and three spatially separated remote units. The central unit contains a single seed laser that is shared between the remote unit. Each remote unit has its own optical amplifier, Risley prism beam steerer, and heterodyne detector. The photodiode signals are digitized and analyzed in the central unit. The three lidar emitters were verified against each other and a calibrated meteorological mast at Myres Hill near Glasgow. To test the converging beam methodology, the three remote units were arranged in an equilateral triangle with an 8 m distance from each to the central unit and the three beams were brought to intersect at a height of 60 m. Steps towards wind turbine blade integration will be outlined.

"A MULTICHANNEL RADIOMETRIC PROFILER OF TEMPERATURE, HUMIDITY, AND CLOUD LIQUID"

Radio Science, Vol. 38, No. 4, July 2003, pp. 44-1 - 44-12.

A microwave radiometer is described that provides continuous thermodynamic (temperature, water vapor, and moisture) soundings during clear and cloudy conditions. The radiometric profiler observes radiation intensity at 12 microwave frequencies, along with zenith infrared and surface meteorological measurements. Historical radiosonde and neural network or regression methods are used for profile retrieval. We compare radiometric, radiosonde, and forecast soundings and evaluate the accuracy of radiometric temperature and water vapor soundings based on statistical comparison with radiosonde soundings. We find that radiometric soundings are equivalent in accuracy to radiosonde soundings when used in numerical weather forecasting. A case study is described that demonstrates improved fog forecasting based on variational assimilation of radiometric soundings. The accuracy of radiometric cloud liquid soundings is evaluated by comparison with cloud liquid sensors carried by radiosondes. Accurate high-resolution three-dimensional water vapor and wind analysis is described based on assimilation of simulated thermodynamic and wind soundings along with GPS slant delays. Examples of mobile thermodynamics and wind profilers are shown. Thermodynamic profiling, particularly when combined with wind profiling and slant GPS, provides continuous atmospheric soundings for improved weather and dispersion forecasting.

"PERFORMANCE VERIFICATION OF VAISALA ANEMOMETERS"

Instrument Test Report 676, September 2003, Commonwealth Bureau of Meteorology, Melbourne, Australia.

As part of a larger study of anemometers, a Vaisala WAA151 [S/N S45504] and a Vaisala WAA251 (S/N 803408) anemometer were tested to determine whether they met the Bureau of Meteorology Specification for accuracy and functionality. The WAA251 anemometer was installed over the winter of 1998 at Mt Hotham while the WAA151 anemometer was a new unit.

Wasileski, B. J.

"A STATE-SPACE FREE-VORTEX HYBRID WAKE MODEL FOR HELICOPTER ROTORS"

D.Sc. Thesis, June 2006, Washington University, St. Louis, MO.

This paper presents the development of a new hybrid wake model merging two distinctly different modeling approaches into a single, more comprehensive solution. The objective of the work was to leverage the strengths of each individual wake model creating a more flexible and extensible solution that could be used across the entire flight envelope of a helicopter. The results of the work indicate that the two wake models can be successfully merged. The results also show that hybrid wake provides a mechanism by which finite-state wake imparts a level of stability on the free wake solution allowing the free wake to provide consistent, repeatable results from hover through high-speed forward flight. While the new hybrid wake includes the geometric distortion needed for predicting the off-axis control response, the new model, as configured in this work, shows no sign of improvement in this area.

Wassaf, H. S.

"WAKE LOCALIZATION ENHANCEMENT VIA GEOMETRIC MEAN RECOMBINATION OF MULTI-SUBBAND ACOUSTIC IMAGES"

PhD Thesis, 2009, University of Massachusetts, Lowell, MA.

Airplane-generated wing tip wake vortices have been the subject of investigation and research by the FAA and NASA since the early 1970s. Their impact on airport safety and capacity has prompted more than thirty years of research and tens of millions of dollars. An integral part to the advancement of wake vortex research is the development of sensors capable of detecting and tracking wake vortices. In particular, passive acoustic based wake sensors such as microphone arrays have recently attracted attention. Advantages of such a sensor include remote sensing capability (unlike other surface wind measuring equipment such as sonic and propeller anemometers), capability to produce a 2-D smoke-like visualization of wakes, as well as potential capability to operate under fog and light rain when the performance of laser-based remote sensors are hampered. Wake hazard depends on many factors including wake strength, wake shape, as well as size and encountering geometry of the following aircraft relative to the wake of another aircraft. Therefore, improvements in acoustic imaging that lead to improvements in wake detection, localization, and the ability to resolve the shape of the core filament can help in quantifying the wake hazard. In this thesis, we devise a novel technique based on geometric mean of narrowband beamformed images to enhance wake detection, localization, and 2-D resolution of each wake filament. We introduce a localization and smoothing algorithm that transforms the enhanced images into two-dimensional wake positions. A wavelet packet extension of the

proposed geometric mean technique that gives greater control over the size and number of subbands is also presented. Finally, the effects of augmenting the proposed approach with an image deconvolution technique are evaluated. The advantages of the geometric mean approach are evaluated through a combination of analytical statistical analysis, simulations, and processing of real data. Throughout this evaluation, new metrics are defined and used to quantify the advantages of the new technique over the conventional time domain beamforming technique. It is also worthy to note that this newly devised approach can have applications beyond wake for imaging of broadband sources and is particularly effective when there is strong narrow band interfering sources.

Wassaf, H. S. and Wang, F. Y.

"DUALITY OF CIRCULATION DECAY STATISTICS AND SURVIVAL PROBABILITY"

AIAA Paper No. 2010-7990, August 2010, Toronto, Canada.

Survival probability and circulation decay history have both been used for setting wake turbulence separation standards. Conceptually a strong correlation should exist between these two characterizations of the vortex behavior, however, the literature lacks a rigorous development in establishing this correlation. The objective of this current paper is to establish the clear linkage between survival probability and circulation decay, and illustrate how they can be mapped to one another depending on need. The impact of the study is twofold. Firstly, it provides a means to infer circulation decay probabilistic bounds from survival probability curves, which is particularly useful in providing insight on circulation statistics at old wake ages where direct circulation measurements are often challenging. This is referred to as the reverse process. Second, in analyses that require survival probability such as encounter probability analysis, this survival probability can be inferred from known statistical decay curves. This will be referred to as the forward process.

"WAKE VORTEX TANGENTIAL VELOCITY ADAPTIVE SPECTRAL (TVAS) ALGORITHM FOR PULSED LIDAR SYSTEMS"

16th Coherent Laser Radar Conference, Long Beach, CA, June 2011.

Doppler Lidars have proven to be a major enabling technology for measuring aircraft wake vortices and effecting safety and capacity changes over the past decades. To date, the Lockheed Martin Coherent Technologies matched-filter software is the only commercially available pulsed Lidar wake vortex processing package and has provided the bulk of the wake data used by the FAA and EUROCONTROL to change wake separation rules. In 2008 the FAA tasked the Volpe Center with the development of a government owned processing package capable of performing wake detection, characterization and tracking. The current paper presents the background, progress, and capabilities to date on the Volpe Center developed Tangential Velocity Adaptive Spectral (TVAS) wake processing

package. The TVAS wake processing package is comprised of four major components: detection, localization, circulation estimation and Kalman filter based automated tracking.

Wassaf, H. S., Burnham, D. C. and Wang, F. Y.

"DIRECT MEASUREMENT OF INITIAL WAKE SEPARATION AND INITIAL CIRCULATION USING PULSED LIDARS"

17th Coherent Lidar Conference, June 2013, Barcelona, Spain.

A new direct approach to measuring the separation between two airplane wake vortices using the mean wind measurements from a short pulse lidar in an upward looking RHI configuration was presented. The simulation analysis showed that initial circulation can also be accurately measured after applying a correction factor. The correction factor was calculated as a function of look angle to the vortex pair center and varies from 1.33 to 1.36 for the angles of interest. The simulation shows that there are no significant biases in the b-zero measurement. The uncertainty analysis performed shows that 92 measurements per airplane type and configuration are approximately needed to meet the required uncertainty bounds of 2 percent for both circulation and b-zero measurement uncertainties. The future work will focus on the analysis of real measurement data and use it to build airplane specific circulation decay curves.

"WAKE VORTEX TANGENTIAL VELOCITY ADAPTIVE SPECTRAL (TVAS) ALGORITHM FOR PULSED LIDAR SYSTEMS"

16th Coherent Laser Conference, June 2011, Long Beach, CA.

The TVAS processing package for the tracking and characterization of wake vortices using pulsed Doppler lidar systems was presented. The published DLR algorithms for localization and circulation estimation formed the starting point for this development. The enhancements provided by TVAS in the areas of spectral modeling, localization and circulation estimations were described. Finally, simulation and field data validation of TVAS were presented. The simulation results showed that the hybrid algorithm is significantly less biased than the DLR FT algorithm at low circulations and produces a better match relative to the known input circulation values. In the case of field data, the differences between the TVAS and LMCT results were on the order of the self-consistency within each algorithm and are therefore not very significant. Although the discrepancy is not believed to be important in certain applications of the data, the sources of differences will be the subject of future studies. A KF tracker based on wake vortex dynamics is undergoing tuning and validation for the purpose of full automation of the processing, and will be presented in future publications.

"ACOUSTICAL SPECTRAL ANALYSIS OF A WAKE VORTEX CROSS-SECTION USING MICROPHONE-ARRAYS"

149th Acoustical Soc. of America Meeting, Vancouver, Canada, May 2005

The ability to unambiguously identify the acoustic energy generated by airplane wake vortices using phased microphone-array intensity distribution maps is hampered by the lack of knowledge of the associated non-stationary spectrum throughout the wake's duration. This ambiguity is especially pronounced when the low broadband signal to noise ratio renders the wake signal difficult to isolate from contaminating background noise. In this paper, a technique to isolate the acoustic spectral content of a cross-sectional wake track (CSWT) is presented. First, image processing is used to generate a CSWT from vertical intensity distribution maps. In a second beamforming stage, the array's main-lobe traces the track to amplify the acoustic signal along the CSWT and estimate its time-varying Power Spectral Density (PSD) using Short Time Fourier Transform. Simultaneously, the time-varying upper confidence limit curve on the PSD of the background noise is also estimated at each time increment by steering the array away from the wake source. The time-varying upper confidence limit is then used as an adaptive threshold function on the estimate of the PSD in order to dynamically identify the wake frequency bands from those of the contaminating noise sources.

"ATMOSPHERIC TURBULENCE EFFECTS ON NEAR-GROUND WAKE VORTEX DEMISE"

88th AMS Annual Meeting, New Orleans, LA, January 2008

Departure wake vortex and atmospheric turbulence data collected from George Bush Intercontinental Houston Airport have been used to examine the relationship between eddy dissipation rate and wake demise near the ground. The analysis is made from the perspectives of the downwind vortex circulation decay as well as breakup dependence on wind and EDR. It is shown that a decrease of wake age with increasing wind magnitude and EDR is most likely due to an earlier onset of Crow instability as opposed to vortex decaying into background turbulence levels. However, it is worthy to note that most of the non-dimensional EDR values available in this study are considered low to moderate. So it is possible that more significant acceleration of the decay might be observed under higher EDRs. This will be further examined as more data from various airport sites become available.

"WAKE ACOUSTIC ANALYSIS AND IMAGE DECOMPOSITION VIA BEAMFORMING OF MICROPHONE SIGNAL PROJECTIONS ON WAVELET SUBSPACES"

AIAA Paper No. 2006-2536, Cambridge, MA, May 2006

This paper describes the integration of wavelet analysis and time-domain beamforming of microphone array output signals for analyzing the acoustic emissions from airplane generated wake vortices. This integrated process provides visual and quantitative simultaneous information about the wake signal composition and array resolution for a particular wavelet subspace during a time interval.

In the results section, an example is given on how image processing algorithms might be used to automate the extraction of this information and select the wavelet subspaces from which to perform image reconstruction. This process begins with the projection of all the microphone signals on wavelet multi-resolution subspaces. The projections of these signals on the same wavelet subspace or scale are then beamformed to produce an image of the wake corresponding to that scale. Therefore, for each time interval, the process produces several images equal to that of the wavelet scales. This is equivalent to a more conventional Fourier-based idea of filtering the microphone signals with band-pass filters having non-uniform bandwidths then beamform in different sub-bands, but offers greater flexibility and enhanced computational speed. Results from both approaches will be shown, which ultimately illustrate the advantages of wavelet analysis over that of the Fourier-based analysis. Amongst the advantages are the speed of the decomposition and ease of the image reconstruction from selected subspaces aided by the perfect reconstruction and orthogonality properties of wavelet analysis.

"ATMOSPHERIC EFFECTS ON MICROPHONE ARRAY ANALYSIS OF AIRCRAFT VORTEX SOUND"

AIAA Paper No. 2006-2539, Cambridge, MA, May 2006.

This paper provides the basis of a comprehensive analysis of vortex sound propagation through the atmosphere to assess real atmospheric effects on acoustic array processing. Such effects may impact vortex localization accuracy and detection probability over longer distances. The paper shows that propagation through the atmosphere can significantly alter the propagation time of the rays from the source to the receiver from that which would be experienced in an ambient atmosphere. More importantly, it can also change the delay time between microphones on which the array processing is based. Implications of these results on the design and resolution of microphone arrays are discussed.

Watanabe, S. and Kato, H.

"STEREO PIV APPLICATIONS TO LARGE-SCALE LOW-SPEED WIND TUNNELS"

AIAA Paper No. 2003-0919, Reno, NV, January 2003

A stereo digital PIV technique is applied to some practical flowfields in large-scale low-speed wind tunnels in National Aerospace Laboratory of Japan. Instantaneous three-component velocity vectors are measured by using a stereo PIV system consisting of a high-intensity Nd:YAG laser, two high-resolution CCD cameras, a commercial PIV software on a PC, a calibration target traverse system, etc. Also, average velocity and turbulent quantities are obtained based on ensembles of the instantaneous velocity data. The wind tunnel applications include a tip vortex generated from a rectangular wing, jet-engine exhaust/external flow interactions for transport-type airplane, helicopter blade-vortex interactions (BVI), and leeward flow of a cranked-arrow-type wing. The results indicate that the stereo PIV is suitable and effective to investigate practical, complex velocity fields, at least qualitatively, in the large-scale low-speed wind tunnels. Some comparisons of the PIV results with seven-hole probe results

show relatively good agreements, proving quantitative validity of the PIV measurements to some degree, while detailed evaluations of the measurement uncertainty still remain to be conducted.

Watnick, M.

"AIRCRAFT WAKE VORTEX HAZARD WARNING APPARATUS"

US Patent 5,724,040, March 1998

An apparatus for monitoring the position of objects in a space including a target supervisor, a location supervisor, and a hazard monitoring supervisor. The apparatus can detect and respond to a potential wake-vortex hazard condition. The tracking supervisor receives target data from a sensor, characterizes and tracks selected objects, and provides target outputs having features respective of the selected objects. The location supervisor characterizes and displays features in the space, and provides a location output having the aforementioned features. The hazard monitoring supervisor detects and responds to potential hazard conditions, and provides a notice of such conditions, responsive to the target outputs and the location output. A data logger selectively retains the target outputs, the location output, or both. The position monitoring apparatus has six modes: full operation, non-airport-surveillance-radar, isolation, set-up, adaptation, and simulation. The target supervisor receives data from an airborne surveillance radar, a secondary surveillance radar, a global-positioning-system-based sensor, a ground-based sensor, or an auxiliary sensor.

Watson III, R. M.

"APPLICATION OF THE DISCONTINUOUS GALERKIN METHOD TO WAKE VORTEX FLOWS"

MS Thesis, May 2015, Auburn University, Auburn, Alabama.

A code was developed that utilizes the discontinuous Galerkin method to solve the Euler equations while utilizing a modal artificial viscosity sensor developed by Klockner. The sensor was augmented for the purpose of this research so that it could be run more quickly as well as having a more robust adaptation to different problems and specifically for this research the vortex burst problem. The sensor had several flops reduced from its calculation using a different approach for creation of the modes. This new approach was based on multiplying through by the Vandermonde matrix built from a one dimensional system instead of a three dimensional system. This was done by taking the cube of nodes for a cell and multiplying it by slices of data. The sensor was then made more robust by changing the value by which baseline decay model was added to the modes. The baseline decay model is needed to remove white noise from being sensed upon. Both these changes were reflected in examinations of routine test problems involving the Sod shock tube and the Kelvin-Helmholtz phenomena. With test cases validating the improvements to the sensor, the approach was then used against an element of wake vortex flow to show the sensor's robustness. Through plotting the pressure, vorticity, and total kinetic energy the test case was validated against previous research.

"NUMERICAL EVALUATION OF A VORTEX-BREAKDOWN CRITERION"

Phys. Fluids, Vol. 8, No. 11, November 1996, pp. 3063-3071

Numerical experimentation is used to examine the onset of axisymmetric vortex breakdown in a completely closed, cylindrical environment. Modification of the boundary motion allows one to compute a state of incipient vortex breakdown. The numerically determined states are used to test a recently posed hypothesis for the occurrence of vortex breakdown.

Wauben, W. M. F.

"EXPERIENCES WITH SONIC WIND SENSORS IN OPERATIONAL CONDITIONS"

WMO Technical Conference of Meteorological and Environmental Instruments and Methods, October 2012, Brussels, Belgium.

Previous investigations indicate that sonic wind sensors can be considered for operational use. In 2008 KNMI selected a 2D sonic wind sensor and introduced sonics in the measurement network to get operational experience. The reason for the replacement of conventional cup anemometers and wind vanes by sonic wind sensors is economical. The sonics have been installed at ten locations throughout the Netherlands, which have been selected to give a wide variety of conditions. At all locations the sonic has been installed in parallel to the existing operational cup anemometer wind vane combination. The measurements of the sonics and the cup anemometers and wind vanes have been made available in the measurement network to facilitate the user evaluation. A total of fifteen sonics were in the field for periods of about 1/2 to 2 1/2 years. Wind tunnel tests have been performed to verify the absolute calibration of the sonics and to check any possible degradation of the sonics during the field deployment. Based on the experiences of the field evaluation, specifically the interference and the damage inflicted by birds and ageing of the sonics, KNMI decided not to replace the cup anemometer and wind vane of the measurement network with sonics at this moment.

Wauben, W. M. F.

"WIND TUNNEL AND FIELD TEST OF THREE 2D SONIC ANEMOMETERS"

Technical Report No. 296, September 2007, Royal Netherlands Meteorological Institute, De Bilt, The Netherlands.

Three 2D sonic anemometers (so-called sonics) have been selected by KNMI and have been subjected to tests to establish whether they are suitable for operational use. The three sonics are the Thies 2D, the Gill Windobserver 2 and the Vaisala WAS425. The sonics have been compared to the KNMI cup anemometer and wind vane that are used operationally. After some initial tests, during which all three sensors showed some problems, all sensors were upgraded and the tests commenced. Wind tunnel tests were performed for wind speeds up to 75 m/s. Overall, the agreement of all sensors is within the WMO requirements, although in detail all three sensors have strong and weak points. The field test

showed that all 3 sonics worked properly although the Thies showed some signs of wear and the Vaisala occasionally missed a measurement. Overall, the sonics agree very well with each other. The differences between the sonics and the conventional cup and vane are larger. The differences for the 10-minute averaged wind speed show a strong directional dependence that is probably related to surface roughness. The results also show a dependency on precipitation intensity. Overall, the sonics seem suitable for operational use, but the use of sonics instead of the conventional wind sensors requires the construction of transfer functions for the homogenization of the climatological measurements.

"LASER DOPPLER TECHNOLOGY APPLIED TO ATMOSPHERIC ENVIRONMENTAL OPERATING PROBLEMS"

Proceedings Aircraft Safety and Operating Problems, NASA, Washington, DC, 1976, pp. 287-302.

Carbon dioxide laser Doppler ground wind data were very favorably compared with data from standard anemometers. As a result of these measurements, two breadboard systems were developed for taking research data: a continuous wave velocimeter and a pulsed Doppler system. The scanning continuous wave laser Doppler velocimeter developed for detecting, tracking and measuring aircraft wake vortices was successfully tested at an airport where it located vortices to an accuracy of 3 meters at a range of 150 meters. The airborne pulsed laser Doppler system was developed to detect and measure clear air turbulence (CAT). This system was tested aboard an aircraft, but jet stream CAT was not encountered. However, low altitude turbulence in cumulus clouds near a mountain range was detected by the system and encountered by the aircraft at the predicted time.

Webber, C. P.

"TESTING WAKE VORTICES FOR FORMATION PERSONNEL AIRDROP"

AIAA Paper No. 2003-2164, Monterey, CA, May 2003.

Development of new or significantly modified airlifters since 1990 with the potential to conduct formation personnel airdrops has presented the flight test community with a new challenge. Determination of acceptable formation geometry while minimizing the risk of paratrooper-vortex interactions during low-altitude tactical deployments has required new test and analysis techniques. This need became apparent in the mid-1990's during developmental flight test of the C-17A Globemaster III cargo plane. The original goal was to use standard C-141 formation geometry during personnel airdrop. However, the stronger wake vortices of the C-17A increased the probability of paratroopers having interactions with wake vortices from C-17A aircraft farther forward in the formation. A technique for studying wake vortices of aircraft in formation was required. Previous wake vortex studies had focused on the airfield environment with respect to takeoff and landing intervals for various sizes of aircraft. The phenomenon had not been studied from the perspective of formation personnel airdrop. It became necessary to measure the strength and location of the wake vortices of several different types of airlifters and compare the results of the C-17A wake measurements against

them. Since no vortex strength or position versus in-trail distance data were available for the C-130 or the C-141B, these aircraft were tested to provide a baseline to establish C-17A airdrop formation geometry. A ground-based Light Detection and Ranging (LIDAR) apparatus was employed to measure the strength and track the position of the vortices. The C-17A flew an oval 'racetrack' pattern phased with a C-130 or C-141B aircraft for comparison. From the vortex data, relative comparisons of the various aircraft could be made regarding vortex characteristics. This resulted in the spacing for C-17As to conduct formation personnel airdrop with minimum risk of paratrooper/vortex encounters. When the C-130J was undergoing Qualification Test and Evaluation (QT&E), the same type of equipment and methodology was used to verify whether it could fly in the same formation geometry as earlier models of C-130 without increasing the risk of paratrooper/vortex encounters. This was a desire of the using command. The external differences of the C-130J compared to a C-130H are new propellers and engines and the lack of wing-mounted external fuel tanks. The two aircraft made numerous alternating passes by the Lidar equipment. The processed data were compared to determine whether the vortex characteristics of the two aircraft were measurably different, and if so, by what margin. Subsequently, the vortices of a C-130J-30 (fuselage extended 15 feet from a standard C-130J) were compared to those of a C-130H by the same method. This paper details the background, test and analysis methods, and conclusions of wake vortex studies at the Air Force Flight Test Center.

Webel, O. M. and Bearman, P. W.

"A TOWING TANK STUDY OF THE DYNAMICS OF TRAILING VORTICES IN VARIOUS CONFIGURATIONS"

AIAA Paper No. 2006-3750, San Francisco, CA, June 2006

A towing tank study is presented investigating the dynamics of two and three vortices in various configurations (orientation, vortex strength and separation). These vortices are generated by an array of rectangular planform wings at chord-based Reynolds number in the range 1,000 to 10,000. A Dye Flow Visualisation technique is applied to determine the qualitative behavior of the flow and to measure the wavelengths of occurring instabilities. Two-dimensional Particle Image Velocimetry measurements and subsequent postprocessing will provide a number of quantitative flow characteristics such as vortex circulation, vorticity fields and flow energy.

Weber, F.

"WAKE VORTEX TURBULENCE AND ITS EFFECT ON THE FLIGHT OPERATIONS -POSSIBILITIES FOR ITS EXPLORATION AND PREDICTION"

Ortung und Navigation, No. 3, 1977, pp. 77-85

It has been found that turbulence effects produced in the wake of a large aircraft can constitute a danger for other aircraft which are passing through the turbulent region. The danger is particularly great during takeoff and landing operations. A description is presented of the results of investigations which have been conducted in the U.S. and England to obtain information regarding the origin and the characteristics of wake turbulence. It was found that wake vortices are generated at the wing tip in the

form of a pair of vortices which consist of masses of air rotating in the opposite direction. The behavior of the wake vortices after their generation is discussed. Predicted and photographically observed vortex paths are shown in a graph. The nature of the hazards represented by the trailing vortices is examined and a description is provided of vortex tracking systems. Attention is also given to the time periods during which trailing vortices remain in a certain 'security zone' of the London-Heathrow Airport.

Weber, O. and Ulken, R.

"A THEORETICAL STUDY OF THE IMPACT OF AIRCRAFT WAKE VORTICES ON ROOFS IN THE FINAL APPROACH AREA OF DUSSELDORF AIRPORT"

DFVLR-MITT-82-01, December 1981, DFVLR, Braunschweig, Germany.

Damage to buildings caused by the impact of trailing wake vortices shed from wide-bodied aircraft in the final approach area of Dusseldorf Airport was studied. Forty-two occurrences of roof damage were analyzed, using a simplified model for the strength, transport, and decay of wake vortices. The model is interpreted with reference to the results of a vortex alleviation program carried out in the U.S. Wake vortex characteristics, maximum tangential velocity and vortex decay are discussed. Measurement of vortex far field reduction is considered. Other investigations of roof damage in the approach areas of Hamburg, Berlin (Tempelhof), and London (Heathrow) airports are summarized. The value of potential aircraft modifications and precautions on the ground are assessed, suggesting supplementary measurements on board aircraft and in buildings. [In German.]

Webster, C. A. G.

"AN EXPERIMENTAL STUDY OF TURBULENCE IN A DENSITY-STRATIFIED SHEAR FLOW"

Journal of Fluid Mechanics, Vol. 19, Issue 2, June 1964, pp. 221-245.

This paper concerns an investigation of turbulence in the density stratified shear flow of a specially designed wind tunnel in which the density gradient is created by differential heating of the air. The first three sections of the paper consist of a description of the apparatus and of the mean temperature and velocity gradients in the tunnel, together with a discussion of a method of measuring low wind speeds based on the periodic shedding of vortices by a circular cylinder. In the remaining sections details of the experimentally determined structure of the turbulence of the flow and of its eddy conductivity and viscosity are presented and their dependence on the over-all gradient form of Richardson number considered.

Wedemeyer, E.

"VORTEX BREAKDOWN"

AGARD-VKI Lecture Series 121 on High Angle of Attack Aerodynamics, Rhode Saint Genese, Belgium, March 1982

The different forms of vortex breakdown are considered. Experimental results, theoretical explanations, and predictions are discussed with emphasis on vortex breakdown over wings with highly swept leading edges.

Wedemeyer, E. H.

"STABLE AND UNSTABLE VORTEX SEPARATION"

Fluid Dynamics Panel Symposium, AGARD-CP-247, October 1978, pp. 13-1--13-10.

A theoretical study of the stability of leading-edge separation on delta wings is presented. The theory explains the change from steady vortex type separation which is observed for highly swept wings to flow with unsteady 'separation bubble' which is typical for wings of small sweepback. Calculations show, that solutions of the vortex-sheet model of leading-edge separation can become unstable if the angle of attack is sufficiently high. The critical angle of attack beyond which no stable solutions exist, decreases with decreasing sweepback angle. The calculated stability boundary is in good agreement with the boundary for observed leading edge vortices. These findings suggest, that the change from 'vortex type' to 'bubble type' separation is due to the change from stable to unstable leading-edge vortices. Finally, the theory explains the effect of a strake on a wing of moderate sweep and aspect ratio: The strong leading-edge vortices generated by the strake induce an outboard flow on the main wing and thereby increase the effective sweep of the leading edge. The higher effective sweep stabilizes the leading-edge separation on the main wing.

Weger, J. and Chokani, N.

"EXPERIMENTAL DESIGN OF A SUPERSONIC SHOCK WAVE/VORTEX INTERACTION AT MACH 3"

ASME Forum on Turbulent Flows, Vol. 112, June 1991, pp. 17-22.

Research was conducted to develop an experimental design for the qualitative and quantitative investigation of a supersonic shock wave/vortex interaction. This interaction is of importance in the design and performance analysis of supersonic combustors. The research involved flow field verification of the North Carolina State University Supersonic Wind Tunnel Facility, test model design, schlieren door design, and experimental verification of the model design. The test design, mounting of shock wave and vortex generators upon a flat plate, provides the capability to investigate the oblique shock wave/vortex interaction. Considerations were given to both optical (non-intrusive) and pitot probe (intrusive) data acquisition. Design features include the minimization of interaction interference from shock and expansion waves emanating off the test section models, prevention of tunnel blockage, and the minimization of any three-dimensional effects. Test results indicate a successful design, as the interaction was achieved. Recommendations for continued research in this area and planned modifications to the test design are included.

Wei, Z., Li, Z., Liu, F. and Liu, W.

"METHODS OF AIRCRAFT RE-CATEGORIZATIONS FOR REDUCING WAKE VORTEX SEPARATIONS"

12th USA/Europe Air Traffic Management Research and Development Seminar (ATM2017), June 2017, Seattle, WA.

The current criteria of wake vortex separation may limit the capacity of the busy airports despite ensuring flight safety. Based on plenty of measured data together with the knowledge of wake vortex behavior, the concept of Re-categorization (RECAT) has been proposed by the international air traffic researchers. This concept has attracted more and more interests, as it can apply to reduce separations with more precision by increasing the number of aircraft categories. The methods for classifying aircraft categories were studied systematically, and the parameters termed as Required Decay Distance (RDD) and Wake Vortex Impedance (WVI) were proposed by authors to consider the influence of leading aircraft's wake vortex circulation, and the resistant ability of following aircraft when encountering wake vortex. By comparing RECAT-I with RECAT-EU, the standard we proposed called RECAT-NEW can obtain more balanced and reasonable results in safety domain. Furthermore, based on the data in airport peak operation conditions, the RECAT-NEW is expected to increase 2.2 percent of airport capacity.

Weigand, A. and Gharib, M.

"ON THE EVOLUTION OF LAMINAR VORTEX RINGS"

Experiments in Fluids, Vol. 22, 1997, pp. 447-457

Using Laser Doppler Anemometry (LDA) and Digital Particle Image Velocimetry (DPIV), the physical properties of laminar vortex rings are investigated in the Reynolds-number range of 830-1650. The measured initial circulations of the vortex rings are found to agree well with corrected versions of the vorticity-flux (slug-flow) model proposed by Didden and Pullin. The DPIV and LDA data show excellent agreement regarding local velocities and vortex-ring circulations. The DPIV data depict the distribution of the vorticity and circulation in the core regions, where the resulting vorticity distributions are found to be self-similar Gaussian profiles. The propagation velocity of the vortex rings is well approximated by an analytical model of Saffman for large core sizes. In the asymptotic limit, the trajectories are in excellent agreement with the exact Stokes-dipole solution of Cantwell and Rott.

Wells, J.

"EFFECTS OF TURBULENCE MODELING ON RANS SIMULATIONS OF TIP VORTICES"

MS Thesis, August 2009, Virginia Polytechnic Institute and State University, Blacksburg, VA.

The primary purpose of this thesis is to quantify the effects of RANS turbulence modeling on the resolution of free shear flows. The simulation of aerodynamic wing-tip vortices is used as a test bed.

The primary configuration is flow over an isolated finite wing with aspect ratio 8.66 and Reynolds number 530000. Tip-vortex velocity profiles, vortex core and wake turbulence levels, and Reynolds stresses are compared with wind tunnel measurements. Three turbulence models for RANS closure are tested: the Lumley, Reece, and Rodi full Reynolds stress transport model and the Spalart-Allmaras model with and without a proposed modification. The main finding is that simulations with the full Reynolds stress transport model show remarkable mean flow agreement in the vortex and wake due to the proper prediction of a laminar vortex core. Simulations with the Spalart-Allmaras model did not indicate a laminar core and predicted over-diffusion of the tip-vortex.

Wen, C. Y., Wu, W. J. and Chen, H.

"SHOCK-VORTEX INTERACTIONS IN A SOAP FILM"

Shock Waves, Vol. 18, 2008, pp. 185-191

This work experimentally visualizes the interaction of a quasi-one-dimensional moving shock wave with a two-dimensional vortex in a soap film for the first time. A vertical soap film shock tube was used to generate a quasi-one-dimensional moving shock wave and a NACA-0012 airfoil intruded into the soap film was towed to shed the starting vortex. The interesting interaction phenomena were then visualized using a traditional high-speed flash photography. The concentration of sodium dodecyl sulfate (SDS) used was 0.5 CMC (critical micelle concentration) to keep the surfactant molecules behave as two-dimensional gases. A sequence of pictures shows that the shock is distorted non-symmetrically as it passes through the spiral vortex flow field and the vortex structure is compressed in the direction normal to the shock. These flow features observed in soap films are qualitatively similar to their counterparts in gases. In addition, the visualization of the interactions of a quasi-one-dimensional moving shock wave with a Karman vortex street are presented.

Wendt, B. J.

"PARAMETRIC STUDY OF VORTICES SHED FROM AIRFOIL VORTEX GENERATORS"

AIAA Journal, Vol. 42, No. 11, November 2004, pp. 2185-2195.

Extensive parametric study of vortices shed from the tips of airfoil vortex generators has been conducted to determine the dependence of initial vortex circulation and peak vorticity on elements of airfoil geometry and impinging-flow conditions. The vortex generators were symmetric airfoils examined in subsonic airflow on the surface of a straight pipe. The circulation and peak-vorticity data were derived from cross-plane velocity measurements acquired with a seven-hole probe one chord length downstream of the airfoil-trailing-edge-tip location. Circulation and peak vorticity are observed to be proportional to the freestream Mach number, the angle of attack, and the span-to-boundary-layer-thickness ratio. Unlike circulation, which decreases in monotonic fashion with increasing airfoil aspect ratio, peak vorticity is observed to increase with increasing aspect ratio, reaching a maximum before falling off at higher values. The circulation may be accurately modeled with an expression based on Prandtl's relationship between finite airfoil circulation and airfoil geometry. A correlation for the

peak vorticity has been derived from a conservation relationship equating the moment at the airfoil tip to the rate of angular-momentum production of the shed vortex, modeled as a Lamb (ideal viscous) vortex, and is shown to provide excellent qualitative agreement with the observed behavior of peak vorticity.

Wendt, B. J.

"INITIAL PEAK VORTICITY BEHAVIOR FOR VORTICES SHED FROM AIRFOIL VORTEX GENERATORS"

AIAA Paper No. 1998-0693, Reno, NV, January 1998

Simple 2D models of a vortex are constructed to mimic a vortex newly shed from an airfoil vortex generator. The model vortices have Oseen-like properties, and are constructed in terms of circulation and peak vorticity. The models are integrated for cross plane angular momentum, and an expression based on Prandtl's relationship between finite airfoil circulation and airfoil geometry is substituted for vortex circulation. Using a conservation relationship, peak velocity of the shed vortex is then isolated in terms of vortex generator geometry. Results indicate a good comparison to data taken on low aspect ratio airfoil vortex generators. The influence of the wall is studied using a patchwork model vortex patterned after the Rankine vortex. The wall is modeled by superimposing an image vortex. Both the analysis and the data indicate that the presence of the wall depresses the magnitude of peak vorticity for the lowest values of aspect ratio and span-to-boundary layer thickness ratio.

Wendt, B. J. and Reichert, B. A.

"SPANWISE SPACING EFFECTS ON THE INITIAL STRUCTURE AND DECAY OF AXIAL VORTICES"

AIAA Paper No. 1996-2518, New Orleans, LA, June 1996

The initial structure and axial decay of an array of streamwise vortices embedded in a turbulent pipe boundary layer is experimentally investigated. The vortices are shed in counter-rotating fashion from an array of equally-spaced symmetric airfoil vortex generators. Vortex structure is quantified in terms of cross plane circulation and peak streamwise vorticity. Flow conditions are subsonic and incompressible. The focus of this study is on the effect of the initial spacing between the parent vortex generators. Arrays with vortex generators spaced at 15 and 30 degrees apart are considered. When the spacing between vortex generators is decreased the circulation and peak vorticity of the shed vortices increases. Analysis indicates these strengthening results are from regions of fluid acceleration in the vicinity of the vortex generator array. Decreased spacing between the constituent vortices also produces increased rates of circulation and peak vorticity decay.

Wenren, Y. and Steinhoff, J.

"APPLICATION OF VORTICITY CONFINEMENT TO THE PREDICITON OF THE WAKE OF HELICOPTOR ROTORS AND COMPLEX BODIES"

AIAA Paper No. 1999-3200, Norfolk, VA, June-July 1999.

A new method is described for computing high Reynolds number incompressible vortex dominated flows which is fundamentally different from conventional viscous CFD schemes. The method is completely Eulerian and can be used with regular Cartesian grids, yet it allows the computation of thin convecting vortices over arbitrarily long distances with no numerical spreading, which is inherent in Lagrangian methods but not possible in conventional Eulerian ones. Further, it automatically allows the general separation, linking and other types of interactions of vortical regions inherent in Eulerian methods but difficult with Lagrangian ones. The technique is also applied to thin boundary layers on solid surfaces with (non-conforming) Cartesian grids. The method is based on a technique - 'Vorticity Confinement' that effectively represents a new type of model for turbulent vortical regions. This model does not involve formulating model partial differential equations for these regions, which then must be discretized. Instead, difference equations are solved (in the vortical regions) which directly result in the desired vortical structure. After a basic description, an application is given for the computation of wake flow for a rotor in hover. This is followed by computations of separating flow over rotorcraft fuselages and, finally, an entire helicopter in forward flight, including rotor, wake, and fuselage.

Wentz, Jr., W. H., Ostowari, C. and Seetharam, H. C.

"EFFECTS OF DESIGN VARIABLES ON SPOILER CONTROL EFFECTIVENESS, HINGE MOMENTS, AND WAKE TURBULENCE"

AIAA Paper No. 1981-0072, St. Louis, MO, January 198.

Wind tunnel tests have been conducted to determine effects of certain design variables on spoiler performance and spoiler flow field characteristics. Measurements include forces and surface pressures, oil flow surveys on a vertical splitter plate, wake pressures, and wake velocity and turbulence measurements using a dual split-film anemometer system. Results include the effects of spoiler design variables, such as: spoiler slope for constant projection height, hingeline gap, lower surface venting and deflector, spoiler trailing edge notching and spoiler porosity. Hingeline gap, porosity, lower surface venting and lower surface deflector can be designed to reduce control dead-band tendency. Wake turbulence studies show that certain modifications can be utilized to diminish peak frequencies in the wake.

Werle, H.

"ON VORTEX BURSTING"

NASA TM-77587, June 1984, Washington, DC.

The phenomena of vortex bursting has been pointed out for the first time in 1960, in 'La Recherche Aeronautique'; since then, it has been the subject of many theoretical and experimental papers. Now it is studied mostly by means of visualization. In this manner, the physical behavior of the phenomenon is emphasized, and its similarity with boundary layer separation or wake bursting becomes apparent. The essential influence of an increasing pressure gradient on the initiation, the position and the type of

bursting is clearly confirmed. Lastly, the evolution of the phenomena as a function of several parameters is analyzed in the case of delta wings, alone or installed on aircraft models; and compared with the results of similar wind tunnel or flight tests.

Werle, H.

"VORTEX INTERACTIONS OF FIXED AND OSCILLATING DELTA WINGS (WATER TUNNEL VISUALIZATIONS)"

La Recherche Aerospatiale, No. 1989-2, January 1989, pp. 43-68.

Vortex interactions around a wide variety of models with delta wings have been visualized in a series of water tunnel tests at ONERA. The effects can be either beneficial (delaying a stall or vortex breakdown) or harmful (critical configurations that are difficult to control). The present article reviews a few typical examples that were observed, first in steady regime around stationary models (wings with or without canard, full aircraft with or without canard, missiles) and then in unsteady mode around models driven in harmonic oscillatory pitching motion. In many cases, visualization of the near wakes of the tested models are also provided.

Werle, H. and Fiant, C.

"WATER-TUNNEL VISUALIZATION OF THE FLOW AROUND THE MODEL OF A 'CONCORDE' TYPE AIRPLANE"

La Recherche Aerospatiale, No. 102, September-October 1964, pp. 3-19.

Tests at the water-tunnel opened the way to the qualitative study of the flow around a model of a simplified 'Concorde' type airplane in the landing configuration. They have shown the structure, the location and the bursting of the upper surface vortices, the evolution of these elements versus the flow parameters, the shape and the configuration, the turbojet exhaust induction on the flow and the ground effect (with a fixed plate and with an endless belt simulating the ground). Many pictures are included. [In French.]

Werner, C.

"FAST SECTOR SCAN AND PATTERN RECOGNITION FOR A CW LASER DOPPLER ANEMOMETER"

Applied Optics, Vol. 24, November 1985, pp. 3557-3564.

A fast data system was developed for a CW laser Doppler anemometer. Using a digital differentiation technique, it allows multiple peak values in a Doppler spectrum to be recorded at 50-msec intervals. Computer programs for sine wave fitting of the data for a velocity-azimuth-display (VAD) scan pattern or a reduced sector VAD scan are used to reduce the errors in the wind field determination in unfavorable weather conditions. The sector scan is necessary if the field of view is limited by buildings etc., and the time consumption for a sector scan is much less than the full VAD scan. For atmospheric inhomogeneities such as wake vortex signatures, a special pattern recognition procedure was

developed. This procedure identifies inhomogeneities in the stored velocity information, and the result can be used to draw the wake vortex distribution in time or range.

"WIND INFRARED DOPPLER LIDAR INSTRUMENT"

Optical Engineering, Vol. 40, No. 1, January 2001, pp. 115-125.

The purpose of the project WIND (wind infrared Doppler lidar) is the development of an airborne conical scanning CO₂ Doppler lidar in French-German cooperation by CNRS/CNES and DLR. The instrument and its peculiarities are described. Measurements of the Doppler shift from a moving platform with an accuracy of 1 m/s require instantaneous access to the position data of the platform. Therefore, this part of the instrument is described in detail. Ground-based tests, airborne tests and a validation flight were performed. The instrument can be used for mesoscale meteorology to test models and contribute to a spaceborne Doppler lidar in the future.

Werner, C., Kopp, F., Schwiesow, R. and Bachstein, F.

"METHOD FOR DETERMINING THE DIRECTION AND SPEED OF WIND IN THE ATMOSPHERE"

US Patent 4,735,503, April 1988.

A method and device is provided for determining the direction and speed of wind in the atmosphere by means of a laser-Doppler anemometer, wherein only values measured in a sector of about 100 degrees and less of an azimuth scan are supplied or fed to a multiple-peak finder of a measuring device. To eliminate the influences from clouds, haze, fog and the like in the measuring device, several frequency maximums are always traced in the multiple-peak finder, whereby in each case a preceding maximum is related to a trailing maximum until the trailing maximum is smaller than the preceding maximum. Because of the attainable high-speed sector scanning, the measuring device can be used for the determination of multiple wind peaks caused by clouds and/or fog echoes, or at an installation site where the measuring range is highly restricted, or also for detecting aircraft wake vortices.

Wernert, P., Koerber, G. and Wietrich, F.

"NEW EXPERIMENTAL APPARATUS FOR THE STUDY OF THE UNSTEADY FLOWFIELD OVER AN AIRFOIL IN PITCHING AND HEAVING MOTIONS USING LASER DOPPLER ANEMOMETRY"

ETN-94-95126, October 1992, Institut Franco-Allemand de Recherches, Saint-Louis, France.

An experimental setup used for the study of the flowfield over an airfoil undergoing arbitrary pitching or heaving motions is described. This setup is basically composed of two parts: a novel driving mechanism, based on an automatic apparatus, two speed drives, two brushless motors and a support

system, which allows the airfoil to be put into a wide range of periodic or transient motions and a classical two-dimensional laser Doppler anemometry system which provides streamwise and transversal components of the velocity. Data acquisition, data reduction and synchronization problems are discussed. Results concerning dynamic stall features observed in the near wake of a pitching airfoil at a Reynolds number of 287,000 are given.

"HAZARD DETECTION ANALYSIS FOR A FORWARD-LOOKING INTERFEROMETER"

NASA TP 2010-216845, August 2010, Langley Research Center, Hampton, VA.

The Forward-Looking Interferometer (FLI) is a new instrument concept for obtaining the measurements required to alert flight crews to potential weather hazards to safe flight. To meet the needs of the commercial fleet, such a sensor should address multiple hazards to warrant the costs of development, certification, installation, training, and maintenance. The FLI concept is based on high-resolution Infrared Fourier Transform Spectrometry (FTS) technologies that have been developed for satellite remote sensing. These technologies have also been applied to the detection of aerosols and gases for other purposes. The FLI concept is being evaluated for its potential to address multiple hazards including clear air turbulence (CAT), volcanic ash, wake vortices, low slant range visibility, dry wind shear, and icing during all phases of flight (takeoff, cruise, and landing). The research accomplished in this second phase of the FLI project was in three major areas: further sensitivity studies to better understand the potential capabilities and requirements for an airborne FLI instrument, field measurements that were conducted to provide empirical demonstrations of radiometric hazard detection, and theoretical work to support the development of algorithms to determine the severity of detected hazards. With respect to wake vortices, the report documented a series of simulation and analyses of flight test experiences. It appears that there is no convincing evidence wake signatures had been found in these trials.

"AIRBORNE FORWARD-LOOKING INTERFEROMETER FOR THE DETECTION OF TERMINAL-AREA HAZARDS"

NASA CR 2014-218167, February 2014, NASA Langley Research Center, Hampton, VA.

The Forward-Looking Interferometer (FLI) program was a multi-year cooperative research effort to investigate the use of imaging radiometers with high spectral resolution, using both modeling/simulation and field experiments, along with sophisticated data analysis techniques that were originally developed for analysis of data from space-based radiometers and hyperspectral imagers. This investigation has advanced the state of knowledge in this technical area, and the FLI program developed a greatly improved understanding of the radiometric signal strength of aviation hazards in a wide range of scenarios, in addition to a much better understanding of the real-world

functionality requirements for hazard detection instruments. The project conducted field experiments on three hazards (turbulence, runway conditions, and wake vortices) and analytical studies on several others including volcanic ash, reduced visibility conditions, in flight icing conditions, and volcanic ash.

West, L., Gimmestad, G., Smith, W., Kireev, S., Cornman, L. B., Schaffner, P. R. and Tsoucalas, G.

"APPLICATIONS OF A FORWARD-LOOKING INTERFEROMETER FOR THE ON-BOARD DETECTION OF AVIATION WEATHER HAZARDS"

NASA/TP-2008-215536, October 2008, Langley Research Center, Hampton, VA

The Forward-Looking Interferometer (FLI) is a new instrument concept for obtaining measurements of potential weather hazards to alert flight crews. The FLI concept is based on high-resolution Infrared (IR) Fourier Transform Spectrometry (FTS) technologies that have been developed for satellite remote sensing, and which have also been applied to the detection of aerosols and gasses for other purposes. It is being evaluated for multiple hazards including clear air turbulence, volcanic ash, wake vortices, low slant range visibility, dry wind shear, and icing, during all phases of flight.

"NUMERICAL STUDIES OF THE MERGING OF VORTICES"

AIAA Paper No. 1986-0557, Reno, NV, January 1986

A newly improved method has been employed to study the roll-up and decay of trailing vortex sheets. This method is obtained by using a scheme formulated recently Liu et al., September 1985 to improve the accuracy of the boundary data. The scheme is much more efficient than the previous one used by Weston and Liu (1982). Comparisons of the present numerical results with other numerical solutions of the Navier-Stokes equations are presented.

Westwater, F. L.

"ROLLING UP OF THE SURFACE OF DISCONTINUITY BEHIND AN AEROFOIL OF FINITE SPAN"

R&M 1692, August 1935, Aeronautical Research Council, Great Britain

The existence of a surface of discontinuity or vortex sheet behind an airfoil of finite span is well known. In aero-dynamic problems it is necessary to calculate the interference flow due to the vortices of this sheet. The vortex sheet is unstable and rolls up, the rolling up beginning at the edges. The paper discusses the rolling up process in detail.

Wetmore, J. W.

"AIRCRAFT TRAILING VORTICES - A HAZARD TO OPERATIONS"

Aeronautics and Astronautics, Vol. 2, No. 12, December 1964, pp. 44-51.

It is shown how a thorough understanding of the phenomenon of aircraft trailing vortices, coupled with air-traffic procedures emphasizing appropriate sequencing and flight-path control, can help prevent an increase in incidents as the volume of air traffic grows. The characteristics of vortices are reviewed and expected load factors which could develop on aircraft which inadvertently penetrate a vortex are shown.

Wetmore, J. W. and Reeder, J. P.

"AIRCRAFT VORTEX WAKES IN RELATION TO TERMINAL OPERATIONS"

NASA TN D-1777, April 1963, NASA Langley Research Center, Hampton, VA.

An analysis has been made, based on present understanding of trailing vortex characteristics, to provide an indication of the possible effects on aircraft encountering these vortices, the circumstances under which encounters might occur in terminal-area operations, and some means of dealing with the vortex problem in operations planning and traffic control.

Wetmore, J. W. and Reeder, J. P.

"AIRCRAFT VORTEX WAKES IN RELATION TO TERMINAL OPERATIONS"

NASA TM-X-51683, November 1962, NASA Langley Research Center, Langley Station, VA

The purpose of this paper is to examine the problems associated with trailing vortices, particularly in the airport terminal area where separation of aircraft must be kept to a safe minimum for efficient traffic handling and where the low flight speeds result in more intense vortices. A brief discussion is given of the formation of trailing vortices from lifting surfaces and of the effects of such major factors as aircraft weight, wingspan, and speed on intensity and extent of the resulting airflow disturbance. The decay of vortex intensity with time is considered in the light of available experimental results and theory. Effects on aircraft encountering trailing vortices including structural loads, upset, and settling are considered together with the influencing factors. Finally, the theoretically determined timewise settling and spreading of the trailing vortices from an airplane in typical takeoff and landing are described and discussed in relation to safe procedures for following airplanes. Airplanes considered as examples in the discussion include a heavy jet transport of 300,000 lb gross weight, a 35,000 lb light turboprop transport and a 2,000 lb light personal airplane.

Wetzel, B. E. and Pfyl, F. A.

"MEASUREMENTS OF DOWNWASH AND SIDEWASH BEHIND CRUCIFORM TRIANGULAR WINGS AT MACH NUMBER 1.4"

NACA-RM-A51B20, April 1951, Ames Aeronautical Lab., Moffett Field, CA.

The results of an experimental investigation of the downwash and sidewash flow angles in a transverse plane behind a cruciform-wing and body combination are presented. The wing-body combination was composed of a cruciform arrangement of two identical triangular wings of aspect ratio 2.31 corresponding to a leading-edge sweep angle of 60 degrees, placed on a body of fineness ratio of 16. The investigation was conducted at a Mach number of 1.40 and at a Reynolds number of 1.25 million based on the mean aerodynamic chord of the wings. Downwash and sidewash measurements were made for angles of bank of 0, 11.25, 22.5, and 45 degrees and through an angle-of-attack range of + and -8 degrees.

Whitcomb, R. T.

"A DESIGN APPROACH AND SELECTED WIND TUNNEL RESULTS AT HIGH SUBSONIC SPEEDS FOR WING-TIP MOUNTED WINGLETS"

NASA TN D-8260, July 1976, NASA Langley Research Center, Hampton, VA.

Winglets, which are small, nearly vertical, winglike surfaces, substantially reduce drag coefficients at lifting conditions. The primary winglet surfaces are rearward above the wing tips; secondary surfaces are forward below the wing tips. This report presents a discussion of the considerations involved in the design of the winglets; measured effects of these surfaces on the aerodynamic forces, moments, and loads for a representative first-generation, narrow-body jet transport wing; and a comparison of these effects with those for a wing-tip extension which results in approximately the same increase in bending moment at the wing-fuselage juncture as did the addition of the winglets.

White, Jr., R. P.

"VORTEX DISSIPATOR"

US Patent 3,845,918, November 1974

A vortex dissipator for the tip of an airfoil or hydrofoil lifting surface is formed as a fixed plate secured to the tip and aligned with the free stream direction. The plate extends forward from the trailing edge of the tip and outward from the suction side of the lifting surface and is configured so that the resultant of the velocity of the free stream flow and the rotational velocity of the vortex produces a stall angle of attack relative to the plate and dissipates much of the strength of the vortex.

White, Jr., R. P. and Balcerak, J. C.

"THE NEMESIS OF THE TRAILED TIP VORTEX - IS IT NOW CONQUERED?"

28th Annual National V/STOL Forum, American Helicopter Society, Washington, DC, May 1972

A recent experimental research program was conducted by the authors in which the outer section of an UH-1D helicopter blade was modified to incorporate a system for injecting the tip vortex produced by the blade with a mass of linearly-directed air. The effects of nozzle geometry, the velocity of

injection, the turbulence wavelength, and the angle of injection on the resulting strength of the trailed tip vortex are presented in terms of quantitative measurements of the circulation strength as a function of the injected mass of air. Data obtained from flow-visualization studies in which illuminated helium bubbles, smoke, and tuft grids were used are also presented. Comparisons are made with results of associated research investigations previously conducted by the authors, and with results of similar research efforts conducted by other investigators.

White, Jr., R. P., Gangwani, S. T. and Janakiram, D. S.

"A THEORETICAL AND EXPERIMENTAL INVESTIGATION OF VORTEX FLOW CONTROL FOR HIGH LIFT GENERATION"

RASA/SRL-14-78-1, March 1978, Systems Research Labs., Newport News, VA.

An experimental and theoretical program of research was conducted to determine the effect of the main wing wake on the effectiveness of the horizontal tail surface and to further refine and expand the predictive theory initiated during the previous years' effort. Experimentally, it was determined that while the vortex flows developed large pitching moments on the wing, the horizontal tail surface, regardless of its geometrical location with respect to the wing MAC, was able to counter the pitching moment and trim the configuration. The experimental data also indicated that, while large changes in the pitch angle of the horizontal tail were required to obtain configuration trim when the concentrated wing vortex wake was in the vicinity of the horizontal tail surface, the aerodynamic angle of attack remained relatively small and the tail effectiveness did not change by more than 25%. The refined and expanded theoretical prediction method provided greater insight in the aerodynamic characteristics on the upper and lower surface and, in general, predicted the vortex flow effects more accurately. The results suggest that with the proper program streamlining and documentation the predictive program can be used successfully as a design tool.

White, R. J.

"EFFECT OF WIND SHEAR ON AIRSPEED DURING AIRPLANE LANDING APPROACH"

J. Aircraft, Vol. 29, No. 2, March-April 1992, pp. 237-242

Equations are presented for calculating the gust velocity along the landing flight path of an airplane due to the presence of wind shear. Based on this gust input data, airplane equations of motion are solved to determine the minimum airspeed developed during trimmed flight along the landing flight path. Using the developed gust equations, it is shown that the use of a tilted vortex pair provides an improved agreement with measured wind shear velocities. Here, a longitudinal velocity ratio is defined along with a selected vortex core radius. The nonlinear gust velocities are then approximated by a broken line linear ramp gust to use as input gust data for the airplane equations of motion. From this, the minimum airspeed is found along with the flight-path position.

Whitehead, E. J.

"THE STABILITY OF MULTIPLE WING-TIP VORTICES"

PhD Thesis, July 2009, University of Adelaide, Adelaide, South Australia.

Over the last forty or so years interest in the study of wing-tip vortices has increased, primarily due to the introduction of larger passenger aircraft and their subsequent interaction with smaller aircraft. The vortices generated by these larger aircraft present a problem in two main areas: the wake hazard problem, where other aircraft can be subjected to the large tangential velocities of the vortex, and the interaction with ground-based features of vortices created during landing and take-off. The first of these is particularly dangerous close to the ground when aircraft are in a high lift configuration at take-off and landing. As the vortices effectively scale with aircraft wing span, significant encounters between large vortices and smaller aircraft have been documented over the years. An example of one such documented wake vortex interaction incident can be found in Ogawa. In this study, the system of vortices are described as classical Batchelor vortices (or linear superpositions thereof) which are then subjected to small perturbations. By discretizing the domain and solving for the eigenvalues of the system it is possible to ascertain the stability characteristics of the flow as a function of the system parameters which include the axial wave-number, the spacing of the vortices, their cross-flow decay rate and their axial strength. We first consider the inviscid instability of multiple tip vortices, an approximation which is valid in the limit of large Reynolds numbers. In this limit the stability of the flow is dominated by the axial component of the basic vortex flow. The governing equations of continuity and momentum are reduced to a second order partial differential equation (PDE). This equation is solved numerically to determine which vortex configurations produce the greatest instability growth rate. These results are extended to consider the effect of compressibility on the inviscid instability. Finally, we consider the effects of viscosity on the stability of the full Batchelor similarity solution which results in a second order PDE in four dependent variables. The stability equations are solved both globally (for the entire eigenspectra) and locally (for a single eigenvalue in a pre-determined region) using codes that run in both serial and parallel form. The numerical methods are based on pseudo-spectral discretization (Chebyshev polynomials for Cartesian and radial directions and Fourier for azimuthal) in the global scheme, the eigenvalues being recovered either with a QZ algorithm or a shift-and-invert Arnoldi algorithm. For the local scheme, fourth order centered finite-differences are used in conjunction with an iterative eigenvalue recovery method.

Whitehouse, G. R. and Brown, R. E.

"HELICOPTER ROTOR RESPONSE TO WAKE ENCOUNTERS IN GROUND EFFECT"

59th Forum, American Helicopter Society, Phoenix, AZ, May 2003

Interactions between helicopters and aircraft wakes are most likely to occur near airports, especially during takeoff and landing. Under these conditions, helicopter flight is characterized by low forward speeds and the presence of ground effect. Recent studies conducted out of ground effect have suggested that, particularly at low speeds, the mutually-induced deformation of both the rotor wake and the wake of the aircraft with which it is interacting may be an important factor in limiting the thrust

and flapping response of the helicopter during a wake encounter. Numerical prediction of helicopter performance in ground effect remains a challenge, however. In particular, certain experimentally observed features of the rotor flow, such as the formation of the characteristic 'ground vortex' and the dynamics of its interaction with the remainder of the rotor flow field, require extremely long-term calculations to capture. In this paper, the development of the rotor flow field in ground effect is studied using a CFD-based approach which, through its vorticity conserving properties, is ideally suited to capturing vortical features in the flow that take many rotor revolutions to develop. Preliminary calculations of the rotor's response to interactions with an aircraft's wake in ground effect are then presented. The rotor's response to a wake interaction in ground effect appears to be more severe than its response in free air, principally because the presence of the ground plane restricts the mutually-induced deformation of the wakes of the helicopter and the interacting aircraft.

Whitehouse, G. R. and Brown, R. E.

"MODELLING A HELICOPTER ROTOR'S RESPONSE TO WAKE ENCOUNTERS"

Aeronautical Journal, January 2004, pp. 15-26.

In recent years, various strategies for the concurrent operation of fixed- and rotary-wing aircraft have been proposed as a means of increasing airport capacity. Some of these strategies will increase the likelihood of encounters with the wakes of aircraft operating nearby. Several studies now exist where numerical simulations have been used to assess the impact of encounters with the wakes of large transport aircraft on the safety of helicopter operations under such conditions. This paper contrasts the predictions of several commonly-used numerical simulation techniques when each is used to model the dynamics of a helicopter rotor during the same idealized wake encounter. In most previous studies the mutually-induced distortion of the wakes of the rotor and the interacting aircraft has been neglected, yielding the so-called 'frozen vortex' assumption. This assumption is shown to be valid only when the helicopter encounters the aircraft wake at high forward speed. At the low forward speeds most relevant to near-airfield operations, however, injudicious use of the frozen vortex assumption may lead to significant errors in predicting the severity of a helicopter's response to a wake encounter.

Whitehouse, G. R. and Brown, R. E.

"MODELING THE MUTUAL DISTORTIONS OF INTERACTING HELICOPTER AND AIRCRAFT WAKES"

Journal of Aircraft, Vol. 40, No. 3, May-June 2003, pp. 440-449

Flight procedures that will decrease the following distance between successive aircraft have been considered as a means of alleviating pressures on airport capacity while still conforming to conventional air traffic management rules. A major limitation to the implementation of such procedures is perceived to be an associated increase in the possible severity of encounters with the wakes of nearby aircraft. Modeling efforts have focused on quantifying such interactions in terms of structural loading or degradation in handling and have established that helicopters respond in a fundamentally different way than fixed-wing aircraft to encounters with wake vortices. This paper

suggests that, particularly at the low forward speeds typical of terminal phase operations, the mutually induced distortion of the helicopter's own wake and the wake of the interacting aircraft strongly influences the aerodynamics of the helicopter rotor. Results from numerical simulations suggest that neglecting this aspect of the interaction, as has commonly been done in the past, can indeed be valid at high helicopter forward speeds, but can lead to significant misrepresentation of the severity of wake encounters under terminal flight conditions.

Whitehouse, G. R., Wachspress, D. A. and Quackenbush, T. R.

"AERODYNAMIC DESIGN OF HELICOPTER ROTORS FOR REDUCED BROWNOUT"

International Powered Lift Conference, American Helicopter Society, October 2010, Philadelphia, PA.

Rotorcraft brownout is caused by the entrainment of dust and ground debris by the rotor wash during takeoff and landing, and is a critical operational problem. Brownout affects safe operations due to the reduction of visibility, in addition to damaging engine components and rotor blades. Recent experience gained from operations in brownout with a variety of rotorcraft configurations, dynamically scaled test facilities as well as ongoing work with validated analyses at Continuum Dynamics, Inc., indicates that aerodynamic modifications to the aircraft may offer a complementary approach to sensor-based brownout solutions. This paper reviews the underlying brownout flow-physics, with particular emphasis on the critical connection between wake dynamics and tip vortex properties, and the development of a strategy to best exploit fluid-dynamic mechanisms to reduce brownout without adversely affecting the aerodynamic performance of the rotor system. Emphasis will be placed on explaining why basic rotor scaling parameters have little influence on brownout and why AW101/EH101/US101, and the Sea King with advanced blades, might offer improved brownout performance. Practical methods are presented for implementing modifications in a retrofittable manner that do not degrade the aerodynamic performance of the helicopter and are commensurate with current procurement systems.

Whitelaw, J. H.

"CONFERENCE ON CAPACITY AND WAKE VORTICES HELD IN IMPERIAL COLLEGE OF SCIENCE, LONDON ON 11-14 SEPTEMBER 2001"

USGRDR0209, September 2001, Imperial College of Science and Technology, London, England

Reports the effects of swirling turbulence caused by jets taking off and landing on planes in Singapore. Creation of disruptive swirling vortex; Formation of wake vortices; Importance of rollers in the stopping of swirling vortex.

Whitford, R.

"DESIGN OF AN ULTRA-HIGH CAPACITY AIRCRAFT"

AIAA and SAE, World Aviation Conference, September 1998

Recent forecasts have been that airline passenger traffic will almost triple by the year 2015 even if growth is less than the air transport industry's average of 5.5 percent over the last 20 years. This will lead to further increases in ATC system and airport congestion, forcing airlines to use larger aircraft than hitherto. Design teams on both sides of the Atlantic are working on concepts for ultrahigh capacity airliners (UHCAs) to satisfy the anticipated need. However, larger aircraft present major problems: taxiway and runway width limits, gate limits, passenger handling, emergency evacuation, community noise, and aircraft separation due to wake vortices. Several different feasibility studies (occupying approximately 1,500 manhours each) have been carried out at the Royal Military College of Science into the design of UHCAs of broadly classical design. Each of the designs has been aimed at providing 600-700 triclass seat/1000 economy seat transport aircraft. The topics of configuration, passenger cabin layout, and size constraints are addressed.

Wickens, R. H.

"WAKE VORTEX TRAJECTORIES OF LOW FLYING SPRAY AIRCRAFT"

Canadian Aeronautics and Space Journal, Vol. 26, No. 1, First Quarter 1980, pp. 41-45

Under stable atmospheric conditions with no wind, the spray cloud descends to the forest canopy under the combined effects of gravity, and the aircraft vortex wake which, during the initial stage of formation, has a great influence on the configuration and dimensions of the emission. In fact, the motion of droplets smaller than 100 microns in diameter conforms almost completely to the classical patterns of vortex flow, rotating around the trailing vortices. In such conditions, the vortex cores and their entrained droplets are visible and still coherent at tree level, and the spray deposition will have a lateral dimension not too different from the aircraft span.

Wickens, R. H.

"THE AERODYNAMIC CHARACTERISTICS AND TRAILING VORTEX WAKE OF PROPELLER V/STOL CONFIGURATIONS"

Canadian Aeronautics and Space Journal, Vol. 21, No. 3, March 1975, pp. 81-98

This paper describes the aerodynamic characteristics of lifting propellers and wing-propeller configurations, with particular reference to the concept of a powered-lift system, and its complex flows downstream in the wake. The propeller, when inclined to large angles, and at high advance ratios, is a singular example of a powered-lift system in which lift is derived partly by deflecting and energizing a stream tube of air, and, in part, by a wing-like vortex flow in which the propeller disc can be thought of as a low aspect ratio wing of circular plan form. The trailing wake is characterized by mixed regions of propulsive and vortex flow in which concentrations of vorticity may induce downwash and sidewash velocities of considerable magnitude in the surrounding fluid. The propulsive stream tube, or slipstream, is an integral part of this wake, and deforms with it, ultimately rolling up with the trailing vortices.

Wickens, R. M.

"THE VORTEX WAKE AND AERODYNAMIC LOAD DISTRIBUTION OF SLENDER RECTANGULAR WINGS"

Canadian Aeronautics and Space Journal, Vol. 13, June 1967, pp. 247-260

An experimental investigation has been made of the aerodynamic characteristics of two slender rectangular plates or wings having an aspect ratio of 1/4. One of the plates was flat, the other had a midchord deflection of 20 deg. The flow on the upper surface of both plates was characterized by a pair of rolled up vortex sheets, which spring from the streamwise edge and are similar to those shed from slender, sharp-edged delta wings. The secondary vortices, which are frequently seen on deltas, however, were not observed (for zero yaw) at any incidence.

Wickens, R. M.

"THE TRAILING VORTEX WAKE DOWNWIND OF AN EXTERNAL FLOW JET FLAP"

Canadian Aero. and Space Journal, Vol. 18, No. 3, March 1972, pp. 67-68

A five-hole probe was used to map out the flow behind a wing containing both propulsive and vortical components. The rolled-up vortices which characterize the trailing jet sheet were observed by smoke flow visualization, but strong vorticity was evident in the relative orientation of the side-wash and downwash contours.

Wickens, R. M.

"A TECHNIQUE FOR SIMULATING THE MOTION AND GROUND EFFECT OF AIRCRAFT WAKE VORTICES"

Canadian Aero. and Space J., Vol. 26, 1980, pp. 129-133

An experimental technique is described which is intended to simulate the motion and induced flows of a vortex pair in ground effect without the use of a wind tunnel or lifting surface. The basic principle of the simulation is that the trailing vortex flows which occur in planes downwind of the aircraft, relative to an observer fixed on the ground, are similar in most respects to the vortex pair in two-dimensional flows. The production of lift and the shedding of trailing vortices result from a large number of short impulsive flows which disturb the ambient fluid and merge into a continuous streamwise effect. The sudden appearance of the vortices and their subsequent downward motion is meant to represent the passage of an aircraft above an observer on the ground.

Widnall, S. E.

"A CORRELATION OF VORTEX NOISE DATA FROM HELICOPTER MAIN ROTORS"

Journal of Aircraft, Vol. 6, No. 3, May-June 1969, pp. 179-281.

The present and future use of helicopters as flexible air transportation in and out of highly restricted heavily populated areas is threatened by the community noise problems associated with these vehicles. In the next generation of vehicles, noise requirements may play a major role in the design process. It is important to have in the early stages of the design process an estimate for the effect of a given design change upon both the noise and DOC of the vehicle. This Note presents a correlation of existing data on main rotor noise which is, at the present state-of-the-art, an irreducible effect of operating the main rotor. Although basic research into the effect of airfoil cross-section and tip planform shape on the noise from main rotors may eventually lead to noise reductions below this curve, an examination of the present data can also serve as a base to compare later improvements.

Widnall, S. E.

"THE STABILITY OF A HELICAL VORTEX FILAMENT"

J. Fluid Mech., Vol. 54, Part 4, March 1972, pp. 641-663

The stability of a helical vortex filament of finite core and infinite extent to small sinusoidal displacements of its center-line is considered. The influence of the entire perturbed filament on the self-induced motion of each element is taken into account. The effect of the details of the vorticity distribution within the finite vortex core on the self-induced motion due to the bending of its axis is calculated using the results obtained previously by Widnall, Bliss & Zelay. In this previous work, an application of the method of matched asymptotic expansions resulted in a general solution for the self-induced motion resulting from the bending of a slender vortex filament with an arbitrary distribution of vorticity and axial velocity within the core. The results of the stability calculations presented in this paper show that the helical vortex filament has three modes of instability; a very short-wave instability which probably exists on all curved filaments, a long-wave mode which is also found to be unstable by the local-induction model and a mutual-inductance mode which appears as the pitch of the helix decreases and the neighboring turns of the filament begin to interact strongly. Increasing the vortex core size is found to reduce the amplification rate of the long-wave instability, to increase the amplification rate of the mutual-inductance instability and to decrease the wavenumber of the short-wave instability.

Widnall, S. E.

"THE STRUCTURE AND DYNAMICS OF VORTEX FILAMENTS"

Annual Review of Fluid Mechanics, Vol. 7, Annual Reviews Inc., Palo Alto, CA, 1975, pp. 141-165

A review is given of the fluid mechanics of trailing vortices and vortex rings as well as in the more general problem of the structure, motion, and stability of free vortices: compact regions of concentrated vorticity in free motion in a surrounding fluid that is either homogeneous and at rest or with weak background vorticity or stratification.

Widnall, S. E. and Bliss, D. B.

"SELF-INDUCED MOTION AND STABILITY OF CONCENTRATED VORTEX FILAMENTS"

Archives of Mechanics (Archiwum Mechaniki Stosowanej), Vol. 26, No. 3, 1974, pp. 459-478.

The self-induced motion and stability of vortex filaments has been investigated both theoretically and experimentally. Through an application of the method of matched asymptotic expansions, a general solution is obtained for the self-induced motion of a vortex filament containing an arbitrary distribution of swirl and possibly axial velocities. This solution has been applied to several vortex-flow stability problems: the stability of a vortex line containing an axial jet, the mutual inductance instability of a vortex pair and the instability of helical vortex filaments and vortex rings. Only the results for the vortex ring will be discussed in detail. Experimental studies of a vortex ring using a Laser Doppler Velocimeter were performed to determine the circulation and vorticity distribution within the vortex rings. Comparison of the observed vortex-ring motion and instability with theoretical predictions will be presented.

Widnall, S. E. and Bliss, D. B.

"SLENDER-BODY ANALYSIS OF THE MOTION AND STABILITY OF A VORTEX CONTAINING AN AXIAL FLOW"

J. Fluid Mech., Vol. 50, Part 2, November 1971, pp. 335-353

Previous results concerning the effects of axial velocity on the motion of vortex filaments are reviewed. These results suggest that slender-body force balance between the Kutta-Joukowski lift on the vortex cross-section and the momentum flux within the curved filament will give some insight into the behavior of the filament. These simple ideas are exploited for both a single vortex filament and a vortex pair, both containing axial flow. The stability of a straight vortex filament containing an axial flow to long wave sinusoidal displacements of its center-line is investigated and the stability boundary obtained. The effect of axial flow on the stability of a vortex pair is explored. It is shown that to lowest order (in the ratio of vortex core radius to distance between the vortices) the effect of axial flow is to reduce the self-induced rotation of a single filament and that this effect can be considered as a change in effective core radius. To the next order, travelling waves appear in the instability, the instability mode for the vortex pair becomes non-planar but the amplification rate of the instability is not affected.

Widnall, S. E., Bliss, D. B. and Tsai, C. Y.

"THE INSTABILITY OF SHORT WAVES ON A VORTEX RING"

J. Fluid Mech., Vol. 66, Part 1, 1974, pp. 35-47.

A simple model for the experimentally observed instability of the vortex ring to azimuthal bending waves of wavelength comparable with the core size is presented. Short-wave instabilities are discussed for both the vortex ring and the vortex pair. Instability for both the ring and the pair is predicted to occur whenever the self-induced rotation of waves on the filament passes through zero. Although this

does not occur for the first radial bending mode of a vortex filament, it is shown to be possible for bending modes with a more complex radial structure with at least one node at some radius within the core.

Widnall, S. E., Bliss, D. B. and Zalay, A. D.

"THEORETICAL AND EXPERIMENTAL STUDY OF THE STABILITY OF A VORTEX PAIR"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, pp. 305-338

The linear stability of the trailing vortex pair from an aircraft is discussed. The method of matched asymptotic expansions is used to obtain a general solution for the flow field within and near a curved vortex filament with an arbitrary distribution of swirl and axial velocities. The velocity field induced near the vortex core by distant portions of the vortex line is calculated for a sinusoidally perturbed vortex filament and for a vortex ring. General expressions for the self-induced motion are given for these two cases. It is shown that the details of the vorticity and axial velocity distributions affect the self-induced motion only through the kinetic energy of the swirl and the axial momentum flux. The presence of axial velocity in the core reduces both the angular velocity of the sinusoidal vortex filament and the speed of the ring. Experimental results for the distortion and breakup of a perturbed vortex pair are presented.

"NUMERICAL SIMULATION OF ROTOR USING COUPLED COMPUTATIONAL FLUID DYNAMICS AND FREE WAKE"

Journal of Aircraft, Vol. 47, No. 4, July-August 2010, pp. 1167-1177.

Rotor aerodynamics is governed by wake behavior. Particularly, aerodynamic performance in the hovering flight condition is determined by the structure and the strength of the wake. In this paper, rotating blades were simulated using a tightly coupled computational fluid dynamics and time-marching free-wake method in hovering and forward flight. The rotating blades and a flowfield near the rotor are calculated by computational fluid dynamics, and the strength and motions of the wake are simulated with the time-marching free-wake method. A moving overset grid technique is applied to consider rotor motions during hovering and forward flight. Inflow and outflow conditions in the computational fluid dynamics domain are provided from an induced flow rate by the time-marching free-wake method at each time step. The strength of the trailed vortices is determined from a sectional lift calculated in the rotating blade, which is computed using the computational fluid dynamics. The present coupled method was compared with other inflow and outflow conditions, such as source-sink and Riemann-invariant conditions. To investigate the robustness of the present method, grid-size effects were also tested in large and small background grid systems.

Wie, S. Y., Lee, S. and Lee, D. J.

"POTENTIAL PANEL AND TIME-MARCHING FREE-WAKE COUPLING ANALYSIS FOR HELICOPTER ROTOR"

Journal of Aircraft, Vol. 46, No. 3, May-June 2009, pp. 1030-1041.

A potential-based panel method coupled with advanced time-marching free-wake techniques is developed to achieve fast and accurate prediction for unsteady aerodynamics and wake dynamics of helicopter rotating blades. This coupling analysis is enabled by using the equivalence of the doublet-wake panels and the vortex filaments. The coupled panel method allows the inclusion of the self-induced velocity of curved vortex filaments and high-order time integration for the computation of wake convection. A parallel computation is applied to the wake convection for fast numerical calculation. The computation of the induced velocity from each vortex filament is parallelized and computed separately. The velocity-field integration technique is used to avoid numerical singularity during the interaction between the wake and blades. It is found that blade-pressure predictions and the wake roll-up agree well with the measured data for helicopter rotors, both in hover and forward flight. Tip-vortex pairing phenomena are also predicted and compared with the measured data.

Wiegele, A., Rahm, S. and Smalikho, I.

"GROUND-BASED AND AIR-BORNE LIDAR FOR WAKE VORTEX DETECTION AND CHARACTERISATION"

1st CEAS European Air and Space Conference, Berlin, Germany, September 2007, pp. 1055-1059

In the last two years several ground-based and airborne wake vortex campaigns have been performed with the DLR coherent Doppler Lidar. The objectives of those campaigns were (i) measurements for comparison with the wake vortex prediction and monitoring system WSVBS, (ii) the measurement and description of wakes generated by the new Airbus A380 aircraft and a reference aircraft for the ICAO landing separation, and (iii) the observation of the influence of different configurations on the vortex life time in the project AWIATOR.

"ENHANCING SHORT TERM WIND ENERGY FORECASTING WITH REMOTE SENSING: THE WIND FORECAST IMPROVEMENT PROJECT (WFIP)"

9th International Symposium on Tropospheric Profiling (ISTP), September 2012, University of L'Aquila, L'Aquila, Italy.

It is widely recognized within the wind energy and electric utility operations communities that current skill levels of wind energy forecasting are adding increased costs to the integration of wind energy onto the U.S. electrical grid. To address this, the U.S. Department of Energy has implemented a joint research program with NOAA and private industry to improve wind energy forecasts. The key elements of this program are 1) a one-year deployment of extensive meteorological observing systems in two regions with significant wind energy production; 2) assimilation of these observations into research models; and 3) evaluation of the benefits of these improved wind forecasts on electrical utility operations, especially for ramp-events in the 0-6 h forecast time-frame.

Wild, J.

"WAKE PREDICTION AND MODELING IMPROVEMENT OF AN EXISTING MODEL"

MS Thesis, April 2014, double degree with ISAE Supaero, Toulouse, France, and KTH Royal Institute of Technology, Stockholm, Sweden.

This thesis is dedicated to the study of atmospheric turbulence and its effects on wake-vortex decay. Wake-vortices are a by-product of the lift that makes every aircraft fly. Under certain special conditions, the decay-time of a wake-vortex can be high and thereby impose constraints on separation between aircraft. A precise knowledge of background turbulence will hence improve the ability of predicting the decay of a wake-vortex. To compute the turbulence, LIDAR measurements have been used to calculate an EDR value (Eddy Dissipation Rate) of the air mass of interest. This parameter indeed quantifies the background turbulence and is of importance in the decay model. The results of this calculation will then be used to improve an overall wake-vortex simulation tool developed by AVTECH. The work performed during this master thesis has established several improvements in the wake-vortex decay model developed by AVTECH thanks to the input of the LIDAR data.

Wilk, L. S.

"BACKSCATTER DATA ANALYSIS"

MIT-MSL-RE-88, August 1973, MIT Measurement Systems Lab., Cambridge, MA

This report presents the results of data analysis performed on data acquired from a previous test operation. That operation undertaken in September, October, and November 1972 at the Vortex Test Facility at the National Aviation Experimental Center, Pleasantville, N.J., involved the design, operation and data acquisition of a monostatic acoustic backscatter vortex detection sensor. This report briefly reviews the previous effort, describes the technique used to reduce the data, and draws conclusions from the analysis. The end results of the data processing - various types of acoustograms - are contained under separate cover and have not been reproduced. Those acoustograms from an integral part of this report. The conclusion drawn from this study is that it is possible to build a monostatic, acoustic backscatter vortex sensor, and that the next phase of development can be undertaken with a considerable degree of confidence that the technical feasibility of a backscatter sensor can be demonstrated.

Willert, C.

"STEREOSCOPIC DIGITAL PARTICLE IMAGE VELOCIMETRY FOR APPLICATION IN WIND TUNNEL FLOWS"

Measurement Science and Technology, Vol. 8, 1997, pp. 1465-1479.

A particle image velocimetry system capable of accurately recovering the out-of-plane velocity component has been realized based on a stereoscopic viewing arrangement. To allow a large viewing

angle with long focal length objective lenses, the angular displacement or Scheimpflug imaging configuration is employed in which the image, object and lens planes intersect in a common line. The varying magnification factor associated with this imaging configuration is accounted for using an accurate and simple-to-use calibration procedure based on solving the projection equations for each of the two cameras. A pair of high-resolution cameras, both capable of recording image pairs in the microsecond range, are synchronized to a pulsed Nd-YAG laser. By placing the cameras on either side of the light sheet the favorable light scattering characteristics of micron-sized seeding particles in forward scatter provide images at significantly higher illumination than at normal or backscatter viewing angles. Ultimately designed for use in industrial wind tunnels, the camera system can work with non-symmetric arrangements. It has been successfully tested in a laboratory environment by imaging the unsteady flow field of a vortex ring passing through a laser light sheet. Adaptive processing software capable of dynamically adjusting the sample location of the interrogation windows to the local displacement vector significantly improves data yield. The algorithm requires only the selection of the final window/overlap size. The hierarchical interrogation approach permits the processing of images whose displacement dynamic range exceeds the interrogation window size.

"APPLICATION OF DOPPLER GLOBAL VELOCIMETRY IN CRYOGENIC WIND TUNNELS"

12th International Symposium on Applications of Laser Techniques in Fluid Mechanics Paper 25-3, Lisbon, Portugal, July 2004

A specially designed Doppler global velocimetry system (DGV, planar Doppler velocimetry) was developed and installed in a high-speed cryogenic wind tunnel facility for use at free stream Mach numbers between 0.2 and 0.88 and pressures between 1.2 and 3.3 bar. The necessary particle seeding was achieved by injecting a mixture of gaseous nitrogen and water vapor into the dry and cold tunnel flow which then immediately formed a large amount of small ice crystals. As operational and access conditions are very restrictive with respect to other facilities, DGV is currently considered the best choice for the non-intrusive measurement of flow fields. Three component velocity maps were achieved by simultaneously imaging a common area in the flow field from three different directions through the wind tunnel side walls by means of a multiple branch fiber imaging bundle attached to a common DGV image receiving system. The complete imaging system and fiber-fed light sheet generators were installed inside the generally inaccessible pressure plenum surrounding the wind tunnel's test section. The control PC and frequency-stabilized laser system, requiring occasional re-adjustment, were placed outside of the pressure shell. The DGV system acquired flow maps with an area of 300 x 300 mm (squared) in the wake of simple vortex generators as well as from a half-span aircraft model with different wing tip devices. While the remotely controlled hardware operated reliably over the course of three months, a variety of problems mainly relating to light reflections and icing on the observation windows significantly impaired the measurements. These problems could partially be resolved by covering the view background with dull black paint.

"APPLICATION OF DOPPLER GLOBAL VELOCIMETRY IN CRYOGENIC WIND TUNNELS"

Experiments in Fluids, Vol. 39, 2005, pp. 420-430.

A specially designed Doppler global velocimetry system (DGV, planar Doppler velocimetry) was developed and installed in a high-speed cryogenic wind tunnel facility for use at free stream Mach numbers between 0.2 and 0.88, and pressures between 1.2 bar and 3.3 bar. Particle seeding was achieved by injecting a mixture of gaseous nitrogen and water vapor into the dry and cold tunnel flow, which then immediately formed a large amount of small ice crystals. Given the limited physical and optical access for this facility, DGV is considered the best choice for non-intrusive flow field measurements. A multiple branch fiber imaging bundle attached to a common DGV image receiving system simultaneously viewed a common area in the flow field from three different directions through the wind tunnel side walls. The complete imaging system and fiber-fed light sheet generators were installed inside the normally inaccessible pressure plenum surrounding the wind tunnel's test section. The system control and frequency-stabilized laser system were placed outside of the pressure shell. With a field of view of 300x300 square mm, the DGV system acquired flow maps at a spatial resolution of 3x3 square mm in the wake of simple vortex generators as well as in the wake of different wing-tip devices on a half-span aircraft model, although problems mainly relating to light reflections and icing on the observation windows significantly impaired part of the measurements, the remotely controlled hardware operated reliably over the course of three months.

Williams, D.

"MORE AIR TRAFFIC"

Aerospace International, Vol. 25, No. 5, May 1998, pp. 24-25

This article discusses how the UK's Defence Evaluation and Research Agency (DERA) is harnessing its expertise to the task of wake vortex measurements to improve safety at busy airports. The use of lidar for measurements of wake vortices and for more general atmospheric monitoring, for instance to measure the wind field surrounding an airport, is discussed.

Williams, D. and Lohr, G.

"WAKE TURBULENCE MITIGATION FOR ARRIVALS (WTMA)"

ICAS 2008, Anchorage, AK, Sept. 2008

The preliminary Wake Turbulence Mitigation for Arrivals (WTMA) concept of operations is described in this paper. The WTMA concept provides further detail to work initiated by the Wake Vortex Avoidance System Concept Evaluation Team and is an evolution of the Wake Turbulence Mitigation for Departure concept. Anticipated benefits about reducing wake turbulence separation standards in crosswind conditions, and candidate WTMA system considerations are discussed.

Williams, G. M.

"A TWO-DIMENSIONAL WAKE MODEL FOR THE VISCOUS TRAILING VORTEX PAIR FORMED
DOWNSTREAM OF A LIFTING WING"

LR-25070, February 1972, Lockheed-California Company, Burbank, CA

The trailing vortex wake system downstream of a lifting, finite wing is modeled with a pair of two-dimensional, laminar, viscous vortex models of the multi-vortex type. The initial, or 'embryonic' form of this viscous wake model is matched to the inviscid Betz model of the trailing vortex pair formed by the roll-up of the trailing-edge vortex sheet. Downstream profiles derived from the viscous wake model appear to agree well with limited results from published experimental data. The proposed wake model predicts that the wing span load distribution will have a strong influence on the character and aging processes of the downstream flow; some of these predictions have been qualitatively observed in published reports of flight test investigations.

Williams, G. M.

"VISCOUS MODELLING OF WING-GENERATED TRAILING VORTICES"

Aero. Quarterly, Vol. 25, May 1974, pp. 143-154

The trailing vortex wake system generated by a lifting wing of finite span is modeled with a pair of laminar, viscous vortex models of a new type. This embryonic form of the viscous wake model is matched, at several interior collocation points, to the viscous Betz model of the wake convolution process that transforms the wing trailing-edge vortex sheet into a pair of axisymmetric trailing vortices. The present laminar theory appears to offer a useful basis for developing an engineering prediction method of airplane wake characteristics.

Williams, G. M.

"TRAILING VORTEX WAKE SYSTEMS"

LR-24275, January 1971, Lockheed-California Company, Burbank, CA

The report is a general review of the aircraft wake turbulence problem. More emphasis is given to the aerodynamic aspects of the problem than is devoted to related areas such as operational avoidance procedures. The fundamental properties of vortices are discussed, and mathematical models of vortex formation and decay are developed.

Williams, J. E. F. and O'Shea, S.

"SOUND GENERATION BY HYDRODYNAMIC SOURCES NEAR A CAVITATED LINE VORTEX"

Journal of Fluid Mechanics, Vol. 43, part 4, 1970, pp. 675-688.

The paper examines the scattering properties of a cavitated line vortex when excited by line and point sources of sound. It is found that the vortex resonances discovered by Kelvin for incompressible flow are essentially unmodified by fluid compressibility, and that many of the resonant modes radiate energy to infinity. Those resonant modes dominate the vortex response, their amplitude growing algebraically with time in a driven instability of the model flow. The off-resonance response is dependent on the value of a normalized frequency parameter (w/Q) squared times.

"REMOTE TURBULENCE DETECTION USING GROUND-BASED DOPPLER WEATHER RADAR"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 7, 2016, Springer International Publishing Switzerland, pp. 149-178.

Turbulence in and around clouds can pose a significant hazard to aviation, with convective turbulence identified as being responsible for a majority of all turbulence-related aircraft accidents. Regions of convective turbulence may be small (about 1 km) and highly transient (about a few minutes). Graphical Turbulence Guidance, an operational NWP-based turbulence forecast, produces hourly forecasts at a relatively coarse spatial resolution and does not explicitly forecast convective turbulence. High-resolution storm data from radar reflectivity or satellites may provide some indication of the likelihood of convective turbulence development, but cannot pinpoint its location or severity. The NCAR/NEXRAD Turbulence Detection Algorithm (NTDA) uses ground-based Doppler weather radar data to measure in-cloud turbulence, with a focus on identifying convective turbulence hazards. NTDA utilizes Level II data from the U.S. network of WSR-88Ds (NEXRADs) to produce real-time, rapid-update, three-dimensional mosaics of in-cloud turbulence. An NTDA product is also produced operationally in the Taiwan Advanced Operational Aviation Weather System using NEXRAD and Gematronik radar data. NTDA turbulence maps are suitable for tactical use by pilots and airline dispatchers and for providing input to comprehensive turbulence nowcasts. They also provide information about storm evolution useful for studying the relationship of turbulence production to thunderstorm dynamics and kinematics. This chapter motivates and describes the NTDA and discusses its performance.

"CLEAR-AIR TURBULENCE IN A CHANGING CLIMATE"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 23, 2016, Springer International Publishing Switzerland, pp. 465-480.

How might the processes generating clear-air turbulence change in a warmer world? We know that observations support an association between clear-air turbulence and shear instability. We also know that the upper atmospheric wind shears are changing in response to greenhouse gas forcing. In particular, theoretical reasoning and climate model simulations both suggest that the vertical shear in horizontal wind is increasing in magnitude at typical aircraft cruising altitudes in the middle latitudes,

especially in the winter months in each hemisphere. This increased shearing implies that clear-air turbulence may itself be changing because of climate change. This chapter reviews the various lines of observational and model-based evidence for trends in clear-air turbulence, by analyzing data from turbulence encounters with aircraft, turbulence diagnosed from reanalysis datasets, passenger injuries caused by turbulence, and turbulence diagnosed from climate models. The possibility of anthropogenic trends in clear-air turbulence opens a whole new field of academic study, which exists at the interface between the two scientific disciplines of aviation turbulence and climate change. We call for future work to improve our understanding of this poorly understood but potentially important impact of climate change.

Williamson, C. H. K.

"DYNAMICS AND INSTABILITIES OF VORTEX PAIRS IN OPEN FLOW OR CLOSE TO THE GROUND"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

We present results on the spatial development of delta wing trailing vortices, and we briefly mention the temporal development of vortex pairs, and finally present studies of vortex pair dynamics approaching the ground. We have studied the case of the temporal growth of vortex pairs. Comparisons between experiment and theory, for the growth rates of the long-wave instability, appears to be very good. The vortex pair pinches off to form vortex rings. Interestingly, the long-time development involves oscillations of the elliptically-shaped rings, and can lead to a new phenomenon, whereby the vortex rings can re-reconnect back into the original vortex pair configuration. We also study the spatial development of vortex pairs (generated from a delta wing), where we find three distinct instability length scales. By imposing disturbances on the delta wing incident velocity, we find that the largest-scale (Crow) instability is receptive to a range of wavelengths. Our DPIV measurements of instability growth rate, considering the circumferential velocity profile as well as the axial velocity, are compared with the theory of Widnall et al, without ad-hoc assumptions. There is good agreement, even though the vortices are fat, and there is substantial axial flow. Finally, we shall show new results concerning the dynamics and instabilities of vortex pairs as they approach the ground. In essence, in the presence of the ground the long wavelength instability can be inhibited. As one might expect, there exists a critical initial formation height, above which the vortices reconnect and form vortex rings. Below this height, the incipient Crow instability develops, but due to the ground effect, can apparently even reverse the initial phase of the wavy instability.

Williamson, C. H. K., Leweke, T. and Miller, G. D.

"FUNDAMENTAL INSTABILITIES IN SPATIALLY-DEVELOPING WING WAKES AND TEMPORALLY-DEVELOPING VORTEX PAIRS"

1998 ASME Fluids Engineering Division Summer Meeting, June 1998, Washington, DC

In this presentation we include selected results which have originated from vortex dynamics studies conducted at Cornell, in collaboration with IRPHE, Marseille. These studies concern, in particular, the spatial development of delta wing trailing vortices (Miller & Williamson, 1998), and the temporal development of counter-rotating vortex pairs (Leweke & Williamson, 1998a, 1998b). There are clear similarities in the instabilities of both these flows, as shown in our laboratory-scale studies. At full-scale, the trailing vortices behind wings can reach considerable strengths, and represent a danger to following aircraft, especially smaller ones, due to the rolling moment they induce.

Williamson, C. H. K., Leweke, T. and Miller, G. D.

"WING WAKE VORTICES AND TEMPORAL VORTEX PAIR INSTABILITIES"

Lecture Notes in Physics, Vol. 566, 2001, pp. 379-400

In the case of the temporal growth of vortex pairs, formed by the closing of a pair of long flaps underwater, we find two principal instabilities; namely, a long wavelength Crow instability, and a short-wavelength 'elliptic' instability. Comparisons between experiment and theory for the growth rates of the long-wave instability, over a range of perturbed wavelengths, appears to be very good. The vortex pair 'pinches off', or reconnects, to form vortex rings in the manner assumed to occur in contrails behind jet aircraft. We discover a symmetry-breaking phase relationship for the short-wave disturbances growing in the two vortices, which we show to be consistent with a kinematic matching condition between the two disturbances. Further results demonstrate that this instability is a manifestation of an elliptic instability, which is here identified for the first time in a real open flow. We therefore refer to this flow as a 'cooperative elliptic' instability. The long-term evolution of the flow involves the inception of secondary miniscule vortex pairs, which are perpendicular to the primary vortex pair.

"ON THE OPERATION OF AIRCRAFT IN THE WAKES OF OTHER AIRCRAFT"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 136-149

The study explores the possible benefits of the operation of one aircraft in the wake of another through utilization of the energy contained in the wake vortices.

Willis, D. J., Peraire, J. and White, J. K.

"A COMBINED pFFT-MULTIPOLE TREE CODE, UNSTEADY PANEL METHOD WITH VORTEX PARTICLE WAKES"

AIAA Paper No. 2005-0854, Reno, NV, January 200.

The two main difficulties in using potential flow solvers in aircraft design are the limitations on the number of discretization elements and the user expertise and effort required to specify the wake location. In the paper, we present an automatic wake generation strategy for a potential flow solver, and accelerate the method using a pFFT-Fast Multipole Tree algorithm. The combined method can be used to simulate both steady and unsteady flows. The steady state solution is achieved by running an unsteady flow simulation until it reaches a steady state.

Willis, D. J., Peraire, J. and White, J. K.

"A COMBINED pFFT-MULTIPOLE TREE CODE, UNSTEADY PANEL METHOD WITH VORTEX PARTICLE WAKES"

International Journal for Numerical Methods in Fluids, Vol. 53, 2007, pp. 1399-1422.

Potential flow solvers for 3-D aerodynamic flows are commonly used in industrial applications. Two main difficulties preventing the even more widespread use of these codes are the limitations on the number of discretization elements and the user expertise and effort required to specify the wake location. In the paper we present an automatic wake generation strategy for a potential flow solver, and accelerate the method using a pFFT-Fast Multipole Tree algorithm. The combined method can be used to simulate both steady and unsteady flows. The steady state solution is achieved by running an unsteady flow simulation until it reaches a steady state. Computation results are given to demonstrate that the method is fast enough to automatically simulate entire heaving and flapping wing crafts in under an hour on a desktop computer.

"VORTEX PAIR GENERATION AND INTERACTION WITH A FREE SURFACE"

Physics of Fluids, Vol. A1, No. 2, February 1989, pp. 170-173.

Two vertical, rotating flaps are used to generate a vortex pair beneath a free surface. Vortex pair formation, propagation, and interaction with a free surface are described. Numerical simulations for inviscid flow about a constant upwash sheet of vorticity beneath a free surface agree with experiment up to the time that turbulent mixing occurs during interaction with the free surface. The spacing between the vortex pairs then becomes larger than the calculated spacing. The experiments and lines of marked particles included in the simulations show fluid ingestion and transport toward the free surface.

Wilmott, P.

"ON THE DISTRIBUTION OF IMPULSES IN INVISCID, INCOMPRESSIBLE FLOW -- THE INDUCED DOWNWASH ON A ROTATING WING"

Acta Mechanica, Vol. 61, 1986, pp. 129-137.

We consider the prescribing of singularities in inviscid fluid flows by including Dirac delta functions in the Euler momentum equation. Examples are given of the modeling of the flows due to the lifting bodies, in particular that due to a wing simultaneously translating and rotating and find that the induced downwash due to the trailing vortex wake.

"WAKE VORTEX AVOIDANCE SYSTEM"

FAA-RD-72-108, December 1972, Lockheed Missiles & Space Company, Huntsville, AL

This report provides a conceptual design for a predictive-detective system to: (a) predict the movement and decay of aircraft-generated vortices in air corridors near the air terminal using forecast meteorological conditions; (b) periodically update the prediction by monitoring vortex movements; (c) provide a forecast of separation requirements for optimum aircraft spacing according to prevailing vortex conditions, and (d) provide a wave off (or hold) capability for rare cases when vortices stray unpredictably into a 'hazard' zone. In addition, the report discusses the predictive system computer model including the meteorological input data and the fluid mechanics used to develop the vortex prediction. Fluid mechanic discussions include wind, wind shear and buoyancy effects upon vortex transport and decay. Computer runs are presented to demonstrate vortex transport under numerous meteorological conditions at example airports. Finally, a test for proof of the predictive system concept is discussed.

Wilson, D. J., Brashears, M. R., Carter, E. A., Shrider, K. R., Hallock, J. N. and Szymkowicz, J. S.

"WAKE VORTEX AVOIDANCE SYSTEM"

Proceedings of the Accident Prevention Forum on Aircraft Approaches and Landings, NTSB, October 1972, pp. 1-15.

Four options exist for wake vortex avoidance systems: a predictive concept in which the aircraft spacings are set based upon predicted meteorological conditions; a surface sensor concept in which surface winds are used to determine whether crosswinds are above a predetermined threshold which in turn indicates that minimum spacings may be used; a scanning sensor concept in which active sensors are employed to track the vortices and a wave off is called for if the vortices are still within an approach corridor when a following aircraft arrives; and a predictive-detective concept in which vortex movement is monitored and used to update predictions of what separations may be safely employed.

"DEVELOPMENT AND TESTING OF LASER DOPPLER SYSTEM COMPONENTS FOR WAKE VORTEX MONITORING. VOL. 1: SCANNER DEVELOPMENT, LABORATORY AND FIELD TESTING AND SYSTEM MODELING"

NASA CR-120466, August 1974, Lockheed Missiles & Space Company, Huntsville, A.

Three elevation and range scanners were developed for the NASA LDV systems. The elevation scanners provide a capability to manually point the LDV telescope at operator selected angles from 3.2 to 89.6 degrees within 0.2 degrees or to automatically scan the units between operator chosen limits at operator chosen rates of 0.1 to 0.5 Hz. Likewise, the range scanners provide a capability to manually adjust the focal point of the system from a range of 32 meters to 896 m; range and elevation scanner controls are designed to allow simultaneous range and elevation scanning so as to provide finger scan patterns, arc scan patterns and vertical line scan patterns.

"CONDUCT OVERALL TEST OPERATIONS AND EVALUATE TWO DOPPLER SYSTEMS TO DETECT, TRACK AND MEASURE VELOCITIES IN AIRCRAFT WAKE VORTICES"

NASA CR-120600, December 1974, Lockheed Missiles & Space Company, Huntsville, A.

The report discusses a program plan, a critical path review of events necessary to check out the laser Doppler systems, and the results of the tests. The tests included noise and wind tests, large blower flowfield tests, single unit (1-D) flyby tests. The scanning laser Doppler systems were found to be capable of accurately tracking aircraft wake vortices from small aircraft or large aircraft and in almost any type of weather.

"FEASIBILITY OF WAKE VORTEX MONITORING SYSTEMS FOR AIR TERMINALS"

HREC 6668-1, August 1972, Lockheed Missiles & Space Company, Huntsville, AL

Wake vortex monitoring systems, especially those using laser Doppler sensors, were investigated under this contract. The initial phases of the effort involved talking with potential users (air traffic controllers, pilots, etc.) of a wake vortex monitoring system to determine system requirements from the user's viewpoint. These discussions involved the volumes of airspace to be monitored for vortices, and potential methods of using the monitored vortex data once the data are available. A subsequent task led to determining a suitable mathematical model of the vortex phenomena and developing a mathematical model of the laser Doppler sensor for monitoring the vortex flow field. The mathematical models were used in combination to help evaluate the capability of laser Doppler instrumentation in monitoring vortex flow fields both in the near vicinity of the sensor (within 1 km) and at long ranges (10 km).

"WAKE FLOW MEASUREMENTS WITH A MOBILE LASER DOPPLER VELOCIMETER SYSTEM"

AIAA Paper 78-0823, April 1978, San Diego, CA.

Wake flow measurements were conducted with a mobile laser Doppler velocimeter (LDV). The measurements included surveys of aircraft wake vortices behind a B-747 aircraft, aircraft carrier wake measurements from aboard the U.S.S. Nimitz, and tower wake measurements for a 100-kW wind turbine. Results of these tests demonstrated that a mobile ground-based LDV is a versatile and useful tool for the measurement of full-scale three-dimensional wake flows. The potential is demonstrated for utilization of this system to study complex wakes for a variety of applications.

"REAL TIME DEVELOPMENT OF THE WAKE OF A FINITE WING"

M.S. Thesis, February 1974, West Virginia Univ., Morgantown, WV

A real time, three-dimensional method is presented to monitor the development of the wake generated by a finite wing, which suddenly begins to produce lift in an irrotational, incompressible fluid. The wake is represented by equal strength vortex filaments which are bounded by a lifting line at the wing position and a starting vortex which washes downstream with the free stream velocity. The geometric angle of attack of the wing was changed with time so that only one starting vortex was shed and the circulation of the bound vortex remains constant. The computational time was significantly reduced by neglecting the component of induced velocity in the free-stream direction. The Biot-Savart law was needed to calculate the wake deformation of an Army O-1 aircraft, for which experimental results have been reported by B. W. McCormick. Experimental and theoretical values for circulation at contours in the wake showed agreement although the experimental results, which consisted of contours of constant vorticity, were limited to a region near the wing tips and within a chord length of the wing trailing edge.

Wilson, J. M.

"WAKE VORTEX ENCOUNTER RESEARCH"

Langley Aerospace Research Summer Scholars, Part 2, January 1995, pp. 817-823

The National Aeronautics and Space Administration (NASA) is conducting research to improve airport capacity by reducing the separation distance between aircraft. The limiting factor in reducing separation distances and improving airport capacity is the wake vortex hazard. The ability to accurately model wake vortices and predict the outcome of a vortex encounter is critical in developing a system to safely improve airport capacity. This is the focus of the wake vortex research being done at NASA Langley Research Center. This paper will concentrate on two topics. The first topic is the control system developed for the Boeing 737 free flight model in support of vortex encounter tests to be conducted in the 30- by 60-foot tunnel at NASA Langley Research Center later this year. The second topic discussed is the limited degree of freedom trajectory generation study that is being conducted to determine the relative severity of a multitude of paths through a wake vortex.

"VORTEX PAIRING: THE MECHANISM OF TURBULENT MIXING-LAYER GROWTH AT MODERATE REYNOLDS NUMBERS"

J. Fluid Mech., Vol. 63, Part 2, April 1974, pp. 237-255

A mixing layer is formed by bringing two streams of water, moving at different velocities, together in a Lucite-walled channel. The Reynolds number, based on the velocity difference and the thickness of the shear layer, varies from about 45, where the shear layer originates, to about 850 at a distance of 50cm. Dye is injected between the two streams just before they are brought together, marking the vorticity-carrying fluid. Unstable waves grow, and fluid is observed to roll up into discrete two-dimensional vortical structures. These turbulent vortices interact by rolling around each other, and a single vortical structure, with approximately twice the spacing of the former vortices, is formed. This pairing process is observed to occur repeatedly, controlling the growth of the mixing layer. A simple model of the mixing layer contains, as the important elements controlling growth, the degree of non-uniformity in the vortex train and the 'lumpiness' of the vorticity field.

Winckelmans, G. S.

"TOPICS IN VORTEX METHODS FOR THE COMPUTATION OF THREE- AND TWO-DIMENSIONAL INCOMPRESSIBLE FLOWS"

PhD Thesis, Feb. 1989, California Institute of Technology, Pasadena, CA.

Contributions to vortex methods for the computation of incompressible unsteady flows are presented. Three methods are investigated, both theoretically and numerically. The first method is the inviscid method of vortex filaments in three dimensions, and the following topics are presented: (a) review of the method of regularized vortex filaments and of convergence results for multiple-filament computations, (b) modeling of a vortex tube by a single filament convected with the regularized Biot-Savart velocity applied on the centerline: velocity of the thin filament vortex ring and dispersion relation of the rectilinear filament, and (c) development of a new regularization of the Biot-Savart law

that reproduces the lowest mode dispersion relation of the rectilinear vortex tube in the range of large to medium wavelengths. Next the method of vortex particles in three dimensions is investigated, and the following contributions are discussed: (a) review of the method of singular vortex particles: investigation of different evolution equations for the particle strength vector and weak solutions of the vorticity equation, (b) review of the method of regularized vortex particles and of convergence results, and introduction of a new algebraic smoothing with convergence properties as good as those of Gaussian smoothing, (c) development of a new viscous method in which viscous diffusion is taken into account by a scheme that redistributes the particle strength vectors, and application of the method to the computation of the fusion of two vortex rings at $Re=400$, and (d) investigation of the particle method with respect to the conservation laws and derivation of new expressions for the evaluation of the quadratic diagnostics: energy, helicity and enstrophy. The third method considered is the method of contour dynamics in two dimensions. The particular efforts presented are (a) review of the classical inviscid method and development of a new regularized version of the method, (b) development of a new vector particle version of the method, both singular and regularized: the method of particles of vorticity gradient, (c) development of a viscous version of the method of regularized particles and application of the method to computation of the reconnection of two vortex patches of same sign vorticity, and (d) investigation of the particle method with respect to the conservation laws and derivation of new expressions for the evaluation of linear and quadratic diagnostics.

"THE VORTEX FORECAST SYSTEM (VFS): PREDICTION OF TRAJECTORIES AND DECAY FOR AIRCRAFT WAKE VORTICES IN AN OPERATIONAL ENVIRONMENT"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

The VFS is an operational wake vortex predictor system based on the Method of Discrete Vortices (MDV). It was developed under contract with Transport Canada and its Transportation Development Center, during 6 Phases (from 1993 to 2000) and by an international team. The VFS is now a sophisticated, validated, and mature technology: one that can be used in real-time operational systems. It could nevertheless be further validated and improved. It handles: Creation of the initial near wake using either SABIGO's detailed Near Wake DataBase (NWDB) or the simplified Universal Near Wake (UNW) which then assumes the 'universal' circulation profile for aircraft wakes shortly after rollup; Modelling of wake transport, using the vortex-induced velocities and the cross-wind velocity profile; Modelling of the slow wake decay, using the atmospheric turbulence profile (either EDR decay model or TKE decay model) and of the fast decay time (time to demise as function of EDR); Modelling of inviscid near ground effects (by image discrete vortices) and of viscous in ground effects (by injection of secondary discrete vortices from the ground); Modelling of non-uniform wind shear effects (by additional vertical velocities acting on the discrete vortices); Modelling of stratification effects, using the atmospheric stratification profile (model implementation is ongoing). For simulations of landing, the VFS is run in multiple cross-plane 'gates' (typically 5 gates, ranging from the intercept plane to the touchdown plane), so that a more realistic space-time vortex evolution is obtained. It can also be used for closely-spaced parallel runway applications.

Winckelmans, G. S. and Leonard, A.

"CONTRIBUTIONS TO VORTEX PARTICLE METHODS FOR THE COMPUTATION OF THREE-DIMENSIONAL INCOMPRESSIBLE UNSTEADY FLOWS"

Journal of Computational Physics, Vol. 109, 1993, pp. 247-273

Recent contributions to vortex particle methods for the computation of three-dimensional incompressible unsteady flows are presented. Both singular and regularized vortex particle methods are reviewed, along with an investigation of different evolution equations for the particle strength vector. For the regularized method, a new algebraic smoothing is presented with convergence properties equal to those of Gaussian smoothing. A version of the regularized method which can account for viscous diffusion is developed using a scheme that redistributes the particle strength vectors. Finally, particle methods are investigated with respect to conservation laws, and new expressions for the quadratic diagnostics, energy, helicity, and enstrophy are derived.

Winckelmans, G. S. and Ploumhans, P.

"ON THE EFFICIENT SIMULATION OF VORTEX WAKES IN GROUND EFFECT, INCLUDING THE VISCOUS INTERACTION WITH THE GROUND: SAMPLE COMPUTATIONS USING THE VORTEX PARTICLE METHOD COMBINED WITH THE BOUNDARY ELEMENT METHOD"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 77-8.

During vortex wake generation and evolution near the ground, the presence of the ground is strongly affecting the evolution of the wake - vorticity is continuously being produced at the ground because the ground acts as a solid boundary to the wake flow. This ground-generated vorticity is also continuously being diffused from the ground into the wake flow. The simplest picture which consists in assuming that the ground only cancels the normal velocity is not physical because it allows for a tangential velocity at the ground. A fully Lagrangian fast code based on the combination of the vortex particle method with the boundary element has been developed. The boundary elements are M discrete vortex sheet 'panels' whose strength is computed at every time step to ensure the condition of zero tangential velocity at the ground plane. The M vortex sheets are also diffused into the flow, at every time step, in a manner which is consistent with the diffusion equation for vorticity (assuming an effective 'turbulence' viscosity) and accurate. Sample computations have been carried out and will be presented. One main conclusion is that the viscous ground indeed has a strong effect on the global lateral and vertical displacement of the wake vortices. The value of the effective turbulence viscosity has a strong incidence on the diffusion of ground-generated vorticity and hence on the global decay of the wake vortices. In the presence of crosswind, a strong asymmetry appears between port and starboard vortices: asymmetry in vertical position and in decay rate.

Winckelmans, G. S. and Ploumhans, P.

"PREDICTION OF AIRCRAFT WAKE VORTICES DURING TAKEOFF AND LANDING, PHASE 4"

USGRDR0024, 1999, Transportation Development Center, Civil Aviation Directorate, Montreal (Quebec), Canada.

This report outlines the background of two versions of the method of discrete vortices and their advantages and limitations in the modelling and simulation of aircraft wake vortices. The treatment of the viscous interaction with the ground is also described for each method. Results using version B in ground effect studies, with and without cross-wind, are presented, including the simulation of a real case and comparison with version A. Activities for the next phase of a wake vortex prediction project are also proposed.

Winckelmans, G. S. and Ploumhans, P.

"PREDICTION OF AIRCRAFT WAKE VORTICES DURING TAKEOFF AND LANDING - PHASE 4"

TP-13374E, March 1999, Universite Catholique de Louvain, Louvain-la-Neuve, Belgium

This report outlines the background of two versions of the Method of Discrete Vortices (MDV-A and MDV-B) and their advantages and limitations in the modeling and simulation of aircraft wake vortices. The treatment of the viscous interaction with the ground is also described for each method. For a large number, N , of discrete vortices, a fast order $O(N \log N)$ tree-code is used to increase the computational efficiency. MDV-A is used for small N simulations as needed for a real-time Vortex Forecast System (VFS). MDV-B is fine-grain (large N) and efficient (because of the fast tree code) but is not real-time; it is used for detailed wake studies and for MDV-A validation. Results from MDV-B in-ground effect studies, with and without cross-wind, are presented, including the simulation of a real case and the comparison with MDV-A. Activities for the next phase of the Wake Vortex Prediction Project are proposed.

"VORTEX METHODS AND THEIR APPLICATION TO TRAILING WAKE VORTEX SIMULATIONS"

C. R. Physique, Vol. 6, 2005, pp. 467-486

Vortex methods are competitive for simulating incompressible unsteady flows, because they have negligible dispersion error and good energy conservation. The various methods are presented, including the recent developments: particle redistribution, diffusion, relaxation (by projection), efficient solvers (fast multipole method, vortex-in-cell method, hybrid method) and parallel computer implementations. Examples relating to wing/aircraft trailing wake vortices are presented: 2-D and 3-D, inviscid and viscous, direct numerical simulation and large eddy simulation. We consider wake roll-ups, vortex tube dynamics, 3-D instabilities and the complexity/turbulence they produce. A vortex system in ground effects is also presented.

Winckelmans, G., Cocle, R., Dufresne, L., Capart, R., Bricteux, L., Daeninck, G., Lonfils, T., Duponcheel, M., Desenfans, O. and Georges, L.

"DIRECT NUMERICAL SIMULATION AND LARGE-EDDY SIMULATION OF WAKE VORTICES: GOING FROM LABORATORY CONDITIONS TO FLIGHT CONDITIONS"

European Conf. on Computational Fluid Dynamics, ECCOMAS CFD 2006, Delft, The Netherlands

This paper aims at presenting DNS and LES as applied to the simulation of vortex wakes: in laboratory conditions (moderate to medium Reynolds numbers) and up to real aircraft conditions (high to very high Reynolds numbers). Only incompressible flows are considered. DNS and LES are able to capture complex 3-D physics provided one uses high quality numerical methods: methods with negligible numerical dissipation (i.e., methods that conserve energy in absence of viscosity and/or subgrid modelling) and with low dispersion errors (to properly transport complex vortical structures). Methods that can do that are: spectral methods, high order finite difference methods, and vortex-in-cell methods. As the problems of interest are of large spatial extent and contain vortices with small cores, it is also essential that the methods be efficiently parallelized. The recent multiscale models, that act solely on the high wavenumber modes of the LES, are seen to be most appropriate.

Winckelmans, G., Desenfans, O., Barbaresco, F., Deltour, J.-C., Pham, K., Frech, M., Gerz, T., Holzaepfel, F., van Baren, G., Speijker, L., Verhoogt, T. and Vidal, A.

"THE ATC-WAKE PREDICTOR SYSTEM AND ITS POTENTIAL USE TO INCREASE THE CAPACITY AT AIRPORTS"

Proc. Joint International Symposium on Sensors and Systems for Airport Surveillance, JISSA 2005, Paris, June 20-21, 2005.

The ATC-Wake project is funded by the EC under the 'Information Society Technology' Programme. Main objective is the development of an Air Traffic Control Wake Vortex Safety and Capacity Integrated Platform (IP). This IP is used to evaluate interoperability with existing ATC systems, to assess possible safety and capacity improvements, and to evaluate operational usability and acceptability for air traffic controllers. It constitutes an essential step for installation of an 'integrated ATC decision support system' at airports, enabling air traffic controllers to safely apply new optimized weather-based aircraft spacing. The system integrates four new wake-vortex related subsystems: a Separation Mode Planner component (based on a weather forecasting and nowcasting system), a Predictor component (based on weather and wake sensors), a Monitoring and Alerting component (which notifies the air traffic controllers in case of a discrepancy between prediction and detection information), as well as Human Machine Interfaces to the controllers. Used in combination with new wake vortex safety regulation, the ATC-Wake System will provide both tactical and strategic benefits, while maintaining the required level of safety. This paper focuses on the ATC-Wake Predictor, which predicts for individual aircraft the wake vortex behavior in the pre-defined arrival or departure area(s). Prediction is performed using probabilistic wake vortex prediction models fed by real-time meteorological data (most recent nowcast data as well as ground or down-linked airborne measurements) from the time the aircraft reaches a critical arrival area entry until it lands and from the take-off until it leaves the critical departure area.

The prediction quality being directly related to input data quality (meteorological and radar data), a safety buffer is applied to satisfy accuracy requirements of Air Traffic Controllers and/or regulatory authorities. The prediction is updated in short intervals (6 seconds) and the information is provided to ATC through a HMI in the form of a Wake Vortex Vector. It is also vaulted/assessed by wake vortex measurements (performed by the Detector).

Winckelmans, G., Duquesne, T., Treve, V., Desenfans, O. and Bricteux, L.

"SUMMARY DESCRIPTION OF THE MODELS USED IN THE VORTEX FORECAST SYSTEM (VFS)"

Universite Catholique de Louvain (UCL), Internal Report, April 2005

This document provides a brief description of the Vortex Forecast System (VFS) principles and the different models used. The VFS is a deterministic and operational wake vortex predictor (transport and decay) previously developed by an international team (partners from Russia (SABIGO), Canada and Belgium) under contract with Transport Canada (TC) and its Transportation Development Center (TDC). The VFS as it was at the end of the TC/TDC funded project is described in [1]. It is continuously enhanced, also by research conducted at Universite Catholique de Louvain (UCL), Belgium, in the Division TERM (group of Prof. G. Winckelmans). This document presents the VFS version as of April 1, 2005, thus including the improvements added by UCL after completion of the TC/TDC funded project. It was written for 'open communication' purposes: so as to clearly explain the global approach and the models implemented so far.

Winckelmans, G., Treve, V. and Desenfans, O.

"REAL-TIME SAFETY ADVISING SYSTEM IN REDUCED WV SEPARATIONS OPERATION, AS DEVELOPED IN ATC-WAKE"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

The ATC-Wake project started two years ago. The main objective of this project is to develop and build a wake vortex safety and capacity Integrated Platform (IP). This platform will be used to evaluate interoperability with existing ATC systems, to assess possible safety and capacity improvements, to evaluate operational usability and acceptability, and to make a technological implementation plan. This platform is an essential step that will lead to installation of an integrated ATC decision support system at airports, enabling air traffic controllers to apply new optimized weather-based aircraft spacing. According to the user and system requirements defined during the first phase of the project, two main subsystems are developed. The first subsystem, called the 'Separation Mode Planner' (SMP), is dedicated to the forecasting of a safe landing rate about 40 minutes in advance (planning phase). This time constraint is imposed by the fact that, at most major airports, an Arrival MANager system (AMAN) is used to organize the traffic en-route before the entrance in the TMA. The SMP is mainly based on weather forecasting coupled to safety assessment of the various conceivable separation distances. The second subsystem, called the 'Predictor' constitutes the real-time part of the ATC-Wake system (tactical

phase). Here 'Predictor' is not just 'wake vortex prediction' (using VFS and P2P); it means the real-time subsystem used to assess, during the tactical phase, the suitability of the separations previously proposed by the SMP. This system merges, on one hand, input data from the weather monitoring/nowcasting systems and from the airport surveillance systems, and, on the other hand, databases describing airport layout and aircraft characteristics. In the 'virtual IP' developed so far in ATC-Wake, the various data provider systems are 'emulated': using the results of an airport simulation (TAAM simulation by Eurocontrol) connected to a radar emulator (from Thales) and a weather database (DLR databases of Wake-OP and Wake-TOUL campaigns). The 'Predictor' determines, in real-time, the part of the glide slope potentially affected by wake vortices. The information is provided on the air traffic controller screen (using a 'wake vortex vector') through a human machine interface (specially developed by NLR and evaluated through tower simulator sessions). We here propose to give a global presentation of the 'Predictor' subsystem: principles and functionalities (as described above), and demonstration by using the virtual environment (emulators) of the future ATC-Wake IP.

Winkler, S. and Perras, G.

"AN ANALYSIS OF WAKE VORTEX LIDAR MEASUREMENTS AT LAGUARDIA AIRPORT"

ATC-318, November 2004, MIT Lincoln Lab., Lexington, MA

Most of the research into the wake vortex hazard has concentrated on the in-trail encounter scenario for arrivals. At LaGuardia Airport, wake vortex spacings are applied to arrivals on runway 22 following a heavy departure on the intersecting runway 31, resulting in delay and increased workload for controllers. Previous analysis of this problem led to a recommendation for a measurement campaign to collect data on the behavior of wake vortices generated by departing heavy aircraft. In April of 2004, MIT Lincoln Laboratory deployed its wake vortex lidar system to measure such wakes at LaGuardia. Additionally, wind speed and turbulence data were collected with the hope of correlating wake behavior with the local atmospheric conditions. Analysis of the lidar data indicates that the system was able to acquire and track vortices from departures, a task not proven prior to this deployment. Further, vortices were seen to transport toward the threshold of runway 22, verifying an assumption based on analysis of the winds that wake transport is not a solution in this case. The quantity and type of data collected were insufficient to formulate a clear relationship between atmospheric turbulence and vortex decay. However, it may be possible to develop such a model by exploiting the data gathered during previous lidar deployments.

"WAKE VORTEX FIELD MEASUREMENT PROGRAM AT DENVER, CO DATA GUIDE"

Report F19628-00-C-0002, March 2004, MIT Lincoln Lab, Lexington, MA.

The FAA and NASA direct a joint wake vortex program that draws on the expertise of several organizations. In support of this program, MIT Lincoln Laboratory operates a mobile continuous-wave lidar.

Winter, H.

"RESEARCH AND DEVELOPMENT PROGRAM FOR A WAKE VORTEX WARNING SYSTEM IN GERMANY"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 3-1 - 3-7

The necessity to use Wake Vortex (WV) separations for aircraft on their final approach to an airport significantly reduces the available runway landing capacity. In 1984 the German Bundesministerium für Verkehr (BMV) initiated a research program to investigate the possibilities for a reduction of the required WV separations at the airport of Frankfurt. Theoretical studies and measurements taken at the Frankfurt airport have led to the definition of a WV Warning System (WVWS) for this airport. Since 1989 DLR is working on a project to study the potential for capacity improvement at the Frankfurt airport. Amongst several improvements for capacity enhancement, the WVWS was considered and analyzed for capacity benefits. These considerations have led to the definition of a project for the implementation of a WVWS at the Frankfurt airport. In the capacity enhancement study it was found that automation of approach, taxi and departure control is an important precondition for the improvement of the overall capacity situation of an airport like Frankfurt.

"CARTESIAN ADAPTIVE MESH REFINEMENT FOR ROTORCRAFT WAKE RESOLUTION"

AIAA Paper No. 2010-4554, June 2010, Chicago, Illinois.

We explore the use of high-order algorithms within a block-structured Cartesian adaptive mesh refinement solver to capture shed wakes from rotary-wing vehicles. The adaptive Cartesian solver is used as an off-body solver, in conjunction with a viscous near-body unstructured solver to capture wall boundary layer effects. The off-body solver automatically adapts to resolve time-dependent flow features, refining and coarsening throughout the unsteady simulation, with mesh refinement targeting regions of high vorticity. Accuracy and performance of the adaptive solver are tested for resolving the tip vortices from a wing at angle of attack and the wake of a quarter-scale V-22 helicopter rotor in hover conditions..

Witha, B., Steinfeld, G., Dorenkamper, M. and Heinemann, D.

"LARGE-EDDY SIMULATION OF MULTIPLE WAKES IN OFFSHORE WIND FARMS"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012108-1 - 012108-10.

In this study, high-resolution large-eddy simulations of two German offshore wind farms are performed with the LES model PALM in which the turbines are parameterized with an actuator disk approach. The simulation of a single wind farm is realized by a stationary model domain with a

turbulent inflow. Different atmospheric stratifications from slightly stable to unstable have been simulated and their effect on the wake characteristics is investigated. The results show a clear development of the flow within wind farms with large differences between single, double, and triple wakes. The wake deficit is increasing up to the second wake for the neutral and stable boundary layer and up to the third wake in the convective case before reaching a nearly constant value. This is explained with the turbulence intensity being much higher behind the second and subsequent turbines compared to the wake of the first turbine. With increasing atmospheric stability, the wake deficits are shown to be stronger due to reduced turbulence.

"FUNDAMENTAL TURBULENCE MEASUREMENT WITH UNMANNED AERIAL VEHICLES"

AIAA Paper 2016-3584, June 2016, Washington, DC.

This paper addresses the potential of using unmanned aerial vehicles for conducting research in the atmospheric boundary layer. A method of computing wind speed from a moving velocity sensor data is provided. The approach is demonstrated for both five-hole probes and hot-wire probes. Included in the procedure is a technique which was shown to provide an invertible, a posteriori calibration for hot-wire voltage data, demonstrated using data from a mid-afternoon flight of an unmanned aerial vehicle equipped with a single-sensor hot-wire probe. Several bulk and small-scale characteristics from small, fixed-wing unmanned vehicle flights in the convective boundary layer are calculated, and show the potential for extracting a range of both large-scale and small-scale turbulence statistics.

Wittmer, K. S.

"TURBULENT FLOWFIELD DOWNSTREAM OF A PERPENDICULAR AIRFOIL-VORTEX INTERACTION"

PhD Thesis, October 1996, Virginia Polytechnic Institute and State University, Blacksburg, VA.

Experiments were performed to document the turbulent flowfield produced downstream of an airfoil encountering an intense streamwise vortex. This type of perpendicular airfoil-vortex interaction commonly occurs in helicopter rotor flows. The experiments presented here thus provide useful information for the prediction of helicopter noise, particularly BWI noise. Three-component velocity and turbulence measurements were made in unprecedented detail using a computerized miniature four-sensor hot-wire probe system; revealing much about the structure and behavior of this flow over a range of conditions. The interaction between the vortex and the airfoil wake leaves the vortex surrounded by a large region of intense turbulence unlike the turbulence surrounding an isolated vortex. Even for close separations, the vortex core passes the airfoil virtually unchanged. However, vorticity of opposite sign is shed by the airfoil in response to the angle of attack distribution induced by the vortex resulting in an unstable circulation distribution according to Rayleigh's criterion. Simple theoretical models adequately describe the shed vorticity distribution of the airfoil and the unstable circulation distribution it imparts on the vortex. As the flow develops, the vortex continuously distorts the airfoil wake. The strain rates imparted by the vortex on the spanwise vorticity contained in the

airfoil wake result in an anisotropic, turbulence producing stress field. For several chord lengths downstream, the vortex core remains laminar and little change is seen in the unstable circulation distribution. While the vortex core is laminar, turbulent fluctuations measured in the core are the result of inactive wandering motions and the characteristic length and velocity scales of the flat portion of the vortex wake appear to be appropriate scales for the fluctuations. Eventually, the vortex core becomes turbulent as indicated by an increase in high frequency velocity fluctuation levels of more than an order of magnitude. Subsequently, the circulation distribution reorganizes to a stable distribution. A loss in core circulation occurs due to a decrease in the peak tangential velocity which is proportionately larger than the increase in the vortex core radius. The peak tangential velocity decreases to the point where it is exceeded by the axial velocity deficit -- another unstable situation. These effects increase with decreased separation between the vortex and the airfoil, but appear to be largely independent of airfoil angle of attack and only weakly dependent upon vortex strength.

Wittmer, K. S. and Deavenport, W. J.

"INTERACTION OF A STREAMWISE VORTEX WITH A FULL-SPAN BLADE"

AIAA Paper No. 95-2214, San Diego, CA, June 1995

The perpendicular interaction of a streamwise vortex with an infinite span blade was studied in incompressible flow. Three-component velocity and turbulence measurements were made using a sub-miniature four sensor hot-wire probe. Vortex core parameters (radius, peak tangential velocity, circulation, and centerline axial velocity deficit) were determined as functions of blade-vortex separation, streamwise position, blade angle of attack, vortex strength, and vortex size. Only a portion of this data set is presented here. The interaction of the vortex with the blade causes substantial changes in the vortex parameters for separations less than 0.375 chords. Core radius increases while peak tangential velocity decreases with the effect being greater for smaller separations. Simultaneously increasing the vortex generator and interaction blade angles of attack (for a fixed separation distance) also causes a dramatic weakening of the vortex core when compared to the undisturbed values. The scale and intensity of the turbulent region is seen to increase dramatically. The downstream development of the flow shows that the interaction of the blade wake with the vortex is the cause of the changes in the core parameters. Instability in the vortex core appears to be the catalyst for the magnification of the size and intensity of the turbulent flowfield downstream of the interaction.

"FLOW IN THE WAKE OF WIND TURBINES: TURBULENCE SPECTRAL ANALYSIS BY WIND TUNNEL TESTS"

American Journal of Environmental Engineering, Vol. 6, No. 4A, 2016, pp. 109-115.

The interaction between the incident wind and wind turbines in a wind farm causes mean velocity deficit and increased levels of turbulence in the wake. The turbulent flow is characterized by the superposition of wind turbine wakes. In this work, the technique of turbulence spectral evaluation for

reduced scale models in a boundary layer wind tunnel is presented, and different measurements of velocity fluctuations are analyzed. The results allow evaluating the spectrum for different frequency ranges and the differences of the spectral behavior between the incident wind and the turbine wake flow.

"ANALYSIS OF EXCESS WAKE VORTEX SEPARATION ON ARRIVAL DELAY"

AIAA Paper 2013-4424, August 2013, Los Angeles, CA.

An analysis is performed to estimate the delay in the terminal area due to excess leading/trailing aircraft wake vortex spacing. This analysis makes use of a large database of recorded traffic from early 2010 at several of the busiest Terminal Radar Approach Control Facilities (TRACONs) in the United States. To facilitate delay estimates, two arrival compression models are developed and applied to the recorded arrival traffic. A key feature of the compression modeling is the use of just two discrete points in the trajectory: TRACON entry and runway threshold crossing, eliminating the need for the resource intensive procedure of trajectory reconstruction. The analysis has two parts and each part focuses on two runways that are dedicated entirely to arrivals: KATL 27L and KDEN 35R. The first part is a sensitivity study exploring two strategies for compressing the arrivals: path reduction with original average true airspeeds and path reduction with (often times) faster average true airspeeds. This sensitivity study results in a range of delay savings on the order of tens of seconds per flight. The rest of the analysis uses the path compression model (original average true airspeeds), showing the uneven variation of daily delay savings at KATL 27L. Cumulative distribution functions capture the excess spacing reductions. They show a 10 percent increase (relative to the observed excess spacing) in arrivals landing with an excess spacing of 0.5 nmi or less at KATL 27L and a 25 percent increase at KDEN 35R.

Wold, G. R.

"AIRCRAFT CONTROL IN WAKE VORTEX WIND SHEAR"

NASA Langley Research Center, FAA/NASA Joint University Program for Air Transportation Research, 1993-1994, pp. 76-81

In the past, there have been several fatal incidents attributable to wake vortex encounters, involving both general aviation and commercial aircraft. In fact, the wake vortex hazard is the single dominant safety issue determining the aircraft spacing requirements at airports. As the amount of air traffic increases, the number of dangerous encounters is likely only to increase. It is therefore imperative that a means be found to reduce the danger. That is the purpose of this research: to use nonlinear inverse dynamic control methods in the design of an aircraft control system which can improve the safety margin in a wake vortex encounter.

"TIP-VORTEX DYNAMICS OF A PITCHING ROTOR BLADE-TIP MODEL"

AIAA Journal, Vol. 54, No. 10, October 2016, pp. 2947-2960.

The tip vortex of a finite rotor blade-tip model undergoing pitch oscillation is investigated by means of a wind-tunnel study. The motion and flow parameters as well as the model geometry were adapted to rotorcraft applications, including test cases with fully attached flow, light dynamic stall, and deep dynamic stall. High-speed particle image velocimetry was used to study the spatiotemporal behavior of the tip wake at different streamwise positions. Combined with surface pressure measurements, the data establish a connection between the sectional lift of the model and the vortex parameters (for example, swirl velocity and circulation), including dynamic phenomena like hysteresis and vortex breakdown during stalled flow conditions. For pitch oscillations below static stall limit, only small hysteresis effects were observed, and the vortex structure is like static reference measurements. Beyond static stall, the tip vortex retains its general structure in a time-averaged or phase-averaged frame, but the instantaneous flowfields reveal an increasing influence of turbulence. Dynamic stall cases exhibit a circulation overshoot beyond static levels during the upstroke and a disorganized and less-compact vortex structure during the downstroke.

"THE PILOTS VIEW ON WAKE VORTICES - CAPACITY VS. SAFETY"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001.

Capacity-problems in terms of 'movements per hour' are becoming a major driver for the economic performance of airports, ATM systems and airlines. The ICAO standard separation rules were developed in the early 70's, when the phenomenon of wake vortices made people aware of the danger when entering the wakes of a preceding aircraft. Today the values of these standard separations are discussed whether they are still adequate or not in specific situations. The dominant vortex hazard is the rolling moment induced on a directly following aircraft wing by the vortex motion. Because of the complexities of a vortex encounter, a simple parameter, the ratio of the maximum induced rolling moment to the maximum roll control authority of the aircraft, has generally been used to characterize the wake vortex hazard. The actual projects of a future VLTA (very large transport aircraft) are addressing the wake vortex problems during the whole design process as they want to prevent the birth of a 'super heavy' aircraft class thus neutralizing the capacity gain of large passenger decks by requiring additional track miles to separate the succeeding traffic. Since 1998 the IFALPA Wake Vortex policy has been passed as a result from many inputs from the national ALPA's. The topics that are addressed herein are: 1. a general commitment to serious efforts allowing a safe reduction of the standard wake-turbulence separation minima, 2. support for the results of international research activities contributing the development of any wake vortex warning/avoidance system, 3. the demand for airborne wake vortex detection systems, and 4. the demand for ground-based wake vortex advisory and warning systems.

"CALCULATION OF TURBULENCE INTENSITY BASED ON SPECTRUM WIDTH DATA OF A DOPPLER LIDAR"

Fourth Symposium on Lidar Atmospheric Applications, Paper P1.2, January 2009, Phoenix, Arizona.

The possibility of calculating EDR by using spectrum width data of a LIDAR with good digitization power for the spectral data (256-bit FFT) is demonstrated in this study based on the LIDAR system at Haneda Airport. The EDR values computed from this approach are found to have good correlation with those determined from structure function approach and the corrected spectrum width values. The spectrum width approach only requires the determination of one parameter, namely, the outer scale of turbulence, by iteration method in an implicit equation, instead of determining two parameters in the structure function approach. As such, this approach is computationally more efficient and thus more suitable for real-time implementation. For two cases of turbulent airflow associated with hangers at Haneda Airport, the turbulent wind areas are captured successfully in the EDR maps. Following the upgrade of the signal processors of the LIDARs at HKIA, a larger dataset would be used to evaluate the spectrum width approach of EDR computation.

"TIP VORTEX FORMATION AND EVOLUTION TO THE NEAR WAKE OF A ROTOR IN FORWARD FLIGHT"

57th American Helicopter Society Forum, June 2001, Washington, DC, Vol. 1, pp. 193-204.

Realistic models of the formation, structure and evolution of tip vortices are essential to predict rotor blade aeroacoustics. Velocity measurements are reported here on tip vortex formation and evolution to the near wake from a teetering, untwisted, square-tipped, two-bladed NACA0015 rotor in low-speed forward flight. Given assured periodicity and appropriate measurement techniques, vortex formation results confirm observations made in the 1980s. Circumferential velocity profiles are observed as early as $x/c = 0.47$, growing in strength and core radius up to x/c of 1.06. The profiles of circumferential velocity manifest the rollup of discrete vortex filaments. The effect of seed particle dynamics on the accuracy of vortex measurements in the near wake is studied to verify accuracy. The wake structure and the tip vortex properties up to 488 degrees of wake age are presented. Harmonic variations are seen in the tip vortex core axial velocity. A strong spanwise velocity is seen on the pressure and suction sides of the blade. The core axial velocity appears to approach tip speed at origin, and the core circumferential velocity remains constant for a large distance after formation. The equations of motion describing seed particle motion in a 2D vortex were numerically integrated to quantify the velocity error of LDV measurements of the near-wake vortex characteristics due to seed particle dynamics. For a vortex strength of 0.75 meter squared per second typical of rotor tests at a tip Mach number of 0.15, the error in circumferential velocity error due to lag of particles between 1 and 5 microns, is seen to have an upper bound of 2 percent.

Wong, O., Mahalingam, R., Tongchipakdee, C. and Komerath, N. M.

"THE NEAR WAKE OF A 2-BLADED ROTOR IN FORWARD FLIGHT"

AHS Aeromechanics Specialist's Meeting, Nov. 2000, Atlanta, Georgia.

The velocity fields in the near wake and the blade tip flowfield of a square-tipped, rectangular planform, 2-bladed teetering rotor have been measured, in low-speed forward flight. A technique for establishing periodicity of the flowfield from laser velocimeter data is shown. The vortex trajectories and wake structure in low-speed forward flight are shown to a vortex age of 488 degrees. Harmonic variations of the axial velocity distributions in the tip vortices are observed. The issue of wake rollup and transition from near to far wake is addressed. It is seen that with periodicity ensured, phase-resolved measurements prove the persistence of the vortex to large ages, as well as the absence of turbulence inside the core of the rotor tip vortex.

"VERIFICATION OF NWP TURBULENCE INTENSITY GUIDANCE USING EDDY DISSIPATION RATE FROM AIRCRAFT DATA"

24th Conference on Weather and Forecasting & 20th Conference on Numerical Weather Prediction, January 2011, Seattle, WA.

At the Hong Kong Observatory (HKO), the World Area Forecast System (WAFS) gridded forecast products from the two World Area Forecast Centres (WAFS) in London and Washington have been

made available to airlines and pilot users since August 2008 for evaluation. The WAFS trial gridded forecast products including clear-air turbulence (CAT) potential, in-cloud turbulence, icing and cumulonimbus clouds (CB) are provided up to T+36h at a forecast interval of 6 hours, based on the Unified Model (UM) of the UK Met Office (WAFS London) and the Global Forecast System (GFS) of NOAA/NCEP (WAFS Washington) respectively. This paper discusses the use of eddy dissipation rate (EDR) from commercial jets to verify the performance of NWP turbulence intensity products from the two WAFCs. Wind measurements recorded by flight data recorder are pre-processed by a band-pass filter algorithm to generate EDR. Contingency table approach is adopted to determine the hit, miss and false alarm of the clear air turbulence (CAT) potential from NWP models under different EDR thresholds. To assess the performance of model guidance, relative operating characteristic (ROC) curves are produced using different model CAT potential thresholds to determine the hit rate and false alarm. Additionally, the verification is applied to the turbulence intensity guidance from the Non-Hydrostatic Model (NHM), a new operational mesoscale NWP system in HKO. It is found that similar level of forecast skill on the moderate turbulence can also be obtained from NHM.

Wood, D. H.

"EFFECT OF TIP VORTEX GEOMETRY ON THE FLOW THROUGH THE BLADES OF HOVERING ROTORS"

Journal of Aircraft, Vol. 38, No. 3, May-June 2001, pp. 583-584.

It is concluded that the change in pitch of the tip vortex wake contraction is responsible for the average velocity through a hovering rotor being greater than the value from simple momentum theory. The effect of wake contraction is to reduce this discrepancy.

Wood, D. H.

"THE SECOND CURVATURE CORRECTION FOR THE STRAIGHT SEGMENT APPROXIMATION OF PERIODIC VORTEX WAKES"

Wind Energy Science, Vol. 3, 2018, pp. 345-352.

The periodic, helical vortex wakes of wind turbines, propellers, and helicopters are often approximated using straight vortex segments which cannot reproduce the binormal velocity associated with the local curvature. This leads to the need for the first curvature correction, which is well known and understood. It is less well known that under some circumstances, the binormal velocity determined from straight segments needs a second correction when the periodicity returns the vortex to the proximity of the point at which the velocity is required. This paper analyzes the second correction by modelling the helical far wake of a wind turbine as an infinite row of equispaced vortex rings of constant radius and circulation. The ring spacing is proportional to the helix pitch. The second correction is required at small vortex pitch, which is typical of the operating conditions of large modern turbines. Then the velocity induced by the periodic wake can greatly exceed the local curvature contribution. The second correction is quadratic in the inverse of the number of segments per ring and

linear in the inverse spacing. An approximate expression is developed for the second correction and shown to reduce the errors by an order of magnitude.

Wood, D. H. and Li, D.

"ASSESSMENT OF THE ACCURACY OF REPRESENTING A HELICAL VORTEX BY STRAIGHT SEGMENTS"

AIAA Journal, Vol. 40, No. 4, April 2002, pp. 647-651

The accuracy of representing a helical vortex, as found in the wakes of helicopters, wind turbines, and propellers, by a sequence of straight segments is considered. The accuracy is assessed by comparison with recent results for the induced velocity of a helix of constant pitch and radius. This comparison is motivated by the small values of the vortex pitch behind wind turbines and hovering rotors; small pitch leads to errors associated with the proximity of subsequent turns of the helix to the control point at which the velocity is required. Three cases are considered. The first, the velocity on the helix axis, has an analytic solution, which is used to demonstrate that the general accuracy of the straight segment approximation is second order, as has been found in previous comparisons with the velocity field of a vortex ring. For the second case, where the control point has the same radius as the vortex, the segments aligned with the control point are mainly responsible for the error. The error varies from first to third order as the number of segments per revolution of the helix is increased. Third, the self-induced velocity is determined to within an accuracy comparable with the effects of the vortex structure, of which little is presently known in general. The effects of vortex curvature are not significant and easily dealt with.

Wood, D. H. and Meyer, C.

"TWO METHODS FOR CALCULATING THE VELOCITIES INDUCED BY A CONSTANT DIAMETER FAR-WAKE"

J. Aircraft, Vol. 28, No. 8, August 1991, pp. 526-531

This paper describes two methods for calculating the velocities induced by the constant diameter helical vortices that occur in the far-wakes of helicopter rotors in hover or vertical flight, propellers, and horizontal-axis wind turbines. The velocities involve infinite integrals which, in general, cannot be integrated analytically. In the first method, each integral is evaluated numerically up to a finite limit and the remaining integral is approximated by an analytical function. The integrand of each function, or 'remainder' is found by summation over all of the vortices shed at the same radius. Numerical experiments show the remainders have a computational efficiency like those derived previously. The main features of the present remainders are simplicity and versatility. Furthermore, the remainders can replace numerical integration in some special cases. In the second method, the range of integration is made finite by transforming the integrand into one containing an infinite sum. The sum is approximated using the Euler-Maclaurin formula, and the resulting integral is evaluated numerically. The method is more cumbersome than the first but is robust, very accurate, and should be particularly useful at small vortex pitch.

Wood, V. T. and White, L. W.

"A NEW PARAMETRIC MODEL OF VORTEX TANGENTIAL-WIND PROFILES: DEVELOPMENT, TESTING AND VERIFICATION"

Journal of Atmospheric Science, Vol. 68, Issue 5, May 2011, pp. 990-1006.

A new parametric model of vortex tangential-wind profiles is presented that is primarily designed to depict realistic-looking tangential wind profiles such as those in intense atmospheric vortices arising in dust devils, waterspouts, tornadoes, mesocyclones and tropical cyclones. The profile employs five key parameters: maximum tangential wind, radius of maximum tangential wind, and three power-law exponents that shape different portions of the velocity profile. In particular, a new parameter is included controlling the broadly or sharply peaked profile in the annular zone of tangential velocity maximum. Different combinations of varying the model parameters are considered to investigate and understand their effects on the physical behaviors of tangential wind and corresponding vertical vorticity profiles. Additionally, the parametric tangential velocity and vorticity profiles are favorably compared to those of an idealized Rankine model and those of a theoretical stagnant core vortex model in which no tangential velocity exists within a core boundary and a potential flow occurs outside the core. Furthermore, the parametric profiles are evaluated against and compared to those of two other idealized vortex models (Burgers-Rott and Sullivan). The comparative profiles indicate very good agreements with low root-mean-square errors of a few tenths of a meter per second and high correlation coefficients of nearly one. Thus, the veracity of the parametric model is demonstrated.

Wood, V. T. and White, L. W.

"A NEW PARAMETRIC MODEL OF VORTEX TANGENTIAL-WIND PROFILE: TESTING AND VERIFICATION"

25th AMS Conference on Severe Local Storms, Poster Paper 10.12, Oct. 2010, Denver, CO.

The wind field around an intense atmospheric vortex such as a dust devil, tornado and mesocyclone can be accurately depicted using a parametric wind-profile model if the driving parameters are accurately determined. We developed a new parametric model to depict a realistic-looking tangential-wind profile that closely resembles that of any vortex. The profile employs five key parameters: maximum tangential wind, radius of maximum tangential wind and three power-law exponents that shape different parts of the velocity profile, including a new one that controls the broadly- or sharply-peaked profile in the annular zone of tangential velocity maximum. The objective of the paper is to test and verify the effectiveness and versatility of the new parametric wind-profile model by using numerical and analytical tangential wind measurements. The unsteady Burgers-Rott vortex model and the tornado numerical tangential-wind outputs of Trapp represent evolving simulated vortices. The analytical and numerical tangential speeds in the form of radial profiles radiating from the center of the vortex provide useful data and verify the parametric model.

"WAKE TURBULENCE DETECTION AND ECONOMIC IMPACT OF PROPOSED IMPROVEMENTS"

SAE Paper 77-0583, Washington, DC, May 1977

Increased separations of aircraft following heavy jets, which have been mandated because of the threat posed by aircraft trailing wake vortices, have aggravated the problem of air traffic delays at some of the busier airports. An extensive vortex measurement program at three major airports has provided the data base for the design of a Vortex Advisory System which will permit reduction of the vortex-imposed separations under certain measurable wind conditions. This system which promises to effect an appreciable reduction in traffic delay is currently undergoing testing at Chicago's O'Hare International Airport.

Wood, W. D., editor

"FAA/NASA PROCEEDINGS WORKSHOP ON WAKE VORTEX ALLEVIATION AND AVOIDANCE"

FAA-RD-79-105, October 1979, DOT Transportation Systems Center, Cambridge, MA

This document is a record of the joint FAA/NASA Workshop on Wake Vortex Alleviation and Avoidance conducted at the DOT Transportation Systems Center, November 28-29, 1978. The workshop was sponsored by the Federal Aviation Administration to apprise the appropriate specialists of the state of the art and to formulate program recommendations for wake vortex alleviation at the source, for wake avoidance systems, and for operations, and safety regulations.

Wood, W. D., Hallock, J. N. and Spitzer, E. A.

"WAKE VORTEX PROGRAM"

IEEE Northeast Electronics Research and Engineering Meeting, Boston, MA, 1973

The objective of the DOT/TSC wake vortex program is the increase in airport capacity without compromising the safety of operations. The paper shows how vortex dynamics and sensors coupled with user requirements lead to the description of three basic vortex avoidance systems: a warning system, an advisory system, and an Air Traffic Control integrated system which satisfies both the safety and the capacity aspects.

Woodfield, A. A.

"ROLL AND LIFT DISTURBANCES DUE TO WAKE VORTICES"

Report 9504, July 1995, Chief Scientist's Division, Civil Aviation Authority, London, UK.

This report presents a model of the effect on an aircraft of encountering a vortex wake. Methods for calculating the ratios of the induced rolling moment to the aircraft's roll control capability and of the lift change to the aircraft's weight are given. It is recommended that these methods should be used as the basis for a model of dynamic motion during a complete encounter and recovery that can be used to quantify hazards.

Woodfield, A. A.

"REVIEW OF PILOT REPORTS OF WAKE VORTEX ENCOUNTERS FOLLOWING IMPLEMENTATION OF RVSM IN EUROPEAN AIRSPACE, JANUARY to OCTOBER 2002"

Report No. 200301, February 2003, Woodfield Aviation Research, Bedford, U.

EuroControl implemented Reduced Vertical Separation Minima (RVSM) in January 2002, and from that time until October 2002 some 26 reports of possible wake vortex encounters were received. Ten of these events occurred below RVSM airspace and a further 5 were clearly encounters with Clear Air Turbulence (CAT). The remaining 11 are probably wake vortex encounters, but in 3 of these one of the aircraft involved is climbing or descending and thus the encounter is not a consequence of the implementation of RVSM. One of these climb/descent events is below RVSM flight levels. This leaves 8 events where a wake vortex was encountered under RVSM conditions, and 2 under climb/descent conditions at RVSM heights. The number of RVSM operations in European airspace over the period is not known to the author, but it is likely that they are at least in the tens of thousands per month. Thus, the reporting rate is very small. The report reviews all 10 wake vortex encounters above FL245, but clearly separates the events with both aircraft cruising with RVSM vertical separation (1,000 ft.) from those involving climbs or descents.

Woodfield, A. A.

"EN-ROUTE ENCOUNTERS WITH WAKE VORTICES, AND THE IMPLICATIONS OF REDUCED VERTICAL SEPARATION MINIMA (RVSM)"

Report No. 9901, March 1999, Woodfield Aviation Research, Bedford, United Kingdom.

Wake vortices are shed downstream by all aircraft and can be a potential hazard in en-route flight conditions as well as in the terminal area close to the ground. Introduction of Reduced Vertical Separation Minima (RVSM) bring aircraft closer together and it is important to assess whether or not this will significantly increase the risk of a hazardous encounter with wake vortices. Operations under RVSM in Oceanic airspace provide some practical experience with which to make an initial assessment of the likely effects of introducing RVSM in the more complex environment of European space. Heavy or Medium aircraft changing flight level within less than 2-3 minutes and through that of an encountering aircraft generate the greatest risk of a hazardous encounter. Data from reports to the UK CAA and NATS of wake vortex encounters in Oceanic airspace under RVSM are studied, and some earlier data from en-route wake vortex encounters. It is noted that there were no significant wake vortex encounter incidents in the first nine months of RVSM operations over the North Atlantic, which is estimated to cover about 100,000 flights. However, there were several nuisance encounters and a contingency procedure was introduced to allow lateral upwind track offsets to move an aircraft safely away from continuing nuisance encounters with a wake. This seems to have eliminated wake vortex incident reports, although there is no doubt that nuisance encounters still occur. Relevant features in European airspace that do not occur in Oceanic airspace are a wider mix of aircraft sizes, a greater number of aircraft changing flight levels, the presence of traffic on reciprocal tracks in airways, the

intersection of airways, and the presence of up and down draughts at high altitudes because of winds passing over mountain ranges. These effects have been considered and it is concluded that the presence of mountain ranges and the wider mix of aircraft sizes will increase the probability of encountering wake vortices with RVSM compared with Oceanic airspace, but the encounters should remain a nuisance rather than a hazard. When wake vortex encounters occur and persist then a change of flight level, heading, or a track offset of 1 n.m. will usually prevent further encounters.

Woodfield, A. A.

"UPDATE OF WAKE VORTEX DECAY AND MOTION PREDICTIONS AND THEIR IMPLICATIONS FOR CRUISE CONDITIONS"

Report No. 200102, August 2001, Woodfield Aviation Research, Bedford, United Kingdom

Assessments of potential changes in the risk of hazardous wake vortex encounters in cruise from reducing vertical separation minima (RVSM) require methods for estimating wake vortex vertical motion and decay. An empirical method developed by Greene in 1986 has been used for some years, but there has been concern that some of the assumptions and empirical constants may not be appropriate for extending estimates to high altitude cruise conditions. The author of this report has derived a similar method called the Unified Vortex Mass (UVM) method. Comparison of estimates from the UVM method and a small sample of encounter reports shows good agreement with the decay profile derived from that suggested by Sarpkaya and measurements of wake vortex condensation trails by Bisgood. Overall, the vortex descent at a potentially hazardous vorticity strength is somewhat greater than that estimated by Greene's method. For the largest aircraft considered (B-747-400), vortex descent increases from 410 ft. to 510 ft., but this is not sufficient to change the conclusion from previous analysis that the introduction of RVSM is unlikely to increase the probability of hazardous wake vortex encounters. With the UVM method it is now possible to estimate the effects of vertical draughts on vortex motion. Modest downdraughts will increase the probability of encountering strong vortices, although the main hazard from significant downdraughts will be collision hazards following involuntary height changes, which can occur because aircraft are often operating near their performance limits in cruise.

Wooller, J. and Firmin, M. C. P.

"AN EXPERIMENTAL INVESTIGATION INTO THE DETERMINATION OF LIFT FROM WAKE TRAVERSES AT SUPERSONIC SPEEDS"

C. P. No. 801, 1965, Aeronautical Research Council, Great Britain

Two theoretical results are derived by an approximate method for relating the lift on an object to the properties of the flow in its wake. An experimental investigation was devised, firstly to compare the flow properties with those indicated by horseshoe-vortex and linearized theories, and secondly, to compare the lift derived from those properties with the lift measured by a conventional strain-gauge balance. Results are presented which indicate a maximum difference of 6% between the

measurements for the lift, provided the traverses enclose the complete viscous wake, but improved theory and apparatus are necessary if the lift is to be obtained more precisely by wake traverse methods.

"CONSTANT FALSE ALARM RATE DETECTION OF WAKE VORTICES WITH APPLICATION TO A PULSED DOPPLER LIDAR SYSTEM"

Proceedings 1999 Conf. on Radar Into the Next Millenium., Piscataway, N. J., pp. 90-95

A 2-micron pulsed Doppler lidar system is being evaluated as a means of remotely detecting wingtip-induced vortices, i.e., wake vortices, in the approach corridor at an airport runway. The lidar system is placed beside the runway approach corridor and scanned in elevation. A structured signal processor estimates the Doppler spectra of the time sampled lidar return. A constant false alarm rate (CFAR) algorithm is applied to field test data and used to estimate the Doppler velocity profile of the cross section of space scanned by the lidar system and the size and strength of the wake vortices. The resulting CFAR detector exhibits the ability to distinguish between different aircraft sizes by the vortex strength.

Wren, J. E. and Baxa, Jr., E. G.

"CONSTANT FALSE ALARM RATE DETECTION OF WAKE VORTICES WITH APPLICATION TO A PULSED DOPPLER LIDAR SYSTEM"

IEEE National Radar Conference - Proceedings, 1999, pp. 90-95

In this paper, a 2-micron pulsed Doppler lidar system is being evaluated as a means of remotely detecting wingtip-induced vortices, i.e., wake vortices, in the approach corridor at an airport runway. The lidar system is placed beside the runway approach corridor and scanned in elevation. A structured signal processor estimates the Doppler spectra of the time sampled lidar return. A Constant False Alarm Rate (CFAR) algorithm is applied to field test data and used to estimate the Doppler velocity profile of the cross section of space scanned by the lidar system and the size and strength of the wake vortices. The resulting CFAR detector exhibits the ability to distinguish between different aircraft sizes by the vortex strength.

Wright, C.

"EXPERIMENTAL STUDY OF THE STRUCTURE AND DEVELOPMENT OF A WINGTIP VORTEX IN THE NEAR-FIELD"

ICAS-2002-8.2.3, Toronto, Canada, September 2002.

The purpose of the wind tunnel measurements was to study the effect of a flat wing end-cap and a round end-cap on the near field of the vortex pair. A NACA 0015 wing at 4-, 8-, and 12-degree angle of

attack was used. The scaled Reynolds number was approximately 1 million. Flow visualization (laser light and smoke) and velocity measurements (triple sensor hot wire probe) were employed.

Wright, C. T.

"EXPERIMENTAL STUDY OF THE STRUCTURE OF A WINGTIP VORTEX"

MS Thesis, 2000, Utah State University, Logan, UT.

A complete look at the near-field development and subsequent roll-up of a wingtip vortex from a NACA 0015 wing section is investigated. Two separate but equally important surveys of the vortex structure in the region adjacent to the wingtip and approximately one chord length downstream of the trailing edge are performed. The two surveys provide qualitative flow visualization and quantitative velocity measurement data. The near-field development and subsequent roll-up of the vortex structure are strongly influenced by the angle-of-attack and the end-cap treatment of the wing section. The velocity field near the wingtip of the NACA 0015 wing section was measured with a triple-sensor hot wire probe and compared to flow visualization images produced with titanium tetrachloride smoke injection and laser illumination. The flat end-cap results indicate the formation of multiple, relatively strong vortex structures as opposed to the formation of a single vortex produced with the round end-cap. The multiple vortices generated by the flat end-cap are seen to rotate around a common center in a helical pattern until they eventually merge into a single vortex. Compared to a non-dimensional loading parameter, the results of the flow visualization data show a 'jet-like' axial velocity profile for loading parameter values on the order of 0.1 and a 'wake-like' profile for much lower loading parameter values.

Wu, J. and Menon, S.

"NUMERICAL STUDIES OF NEAR-FIELD PLUME-VORTEX INTERACTIONS"

AIAA Paper No. 1998-2902, Albuquerque, NM, June 1998

In this study, fluid mixing and chemical reactions in the near-field wake of an aircraft has been investigated. The plume-vortex regime is studied using a 3D parallel LES code. Simulations of engine plume interaction with the wing-tip vortex of B737 and B747 have been carried out and some comparisons with data have been used to demonstrate the ability of the LES method. Inclusion of detailed gas phase kinetics and simple heterogeneous processes have been carried out to evaluate the effect of turbulent mixing on the chemical processes in the plume-vortex regime. Finally, to determine the impact of temporal assumptions (often used in such flow simulations) comparison with spatial simulations are carried out. Many features of the computed flow field show reasonable agreement with experimental data. The entrainment of the engine plumes into the wing-tip vortex and also the partial detrainment of the plume were numerically captured and analyzed. The impact of fluid mechanics on the chemical process has been estimated. Results indicate that a significant difference between spatial and temporal simulation exists (especially in the predicted SO₃ concentration). This has important implications for the prediction of sulfuric acid aerosols in the wake and may partly

explain the discrepancy between past numerical studies and the data. Analysis of the results also show that spatial simulation is more suitable for the near-field interaction process. For example, it was determined that detrainment (observed in the B747 contrail) was only captured using the spatial model.

"THEORY FOR AERODYNAMIC FORCE AND MOMENT IN VISCOUS FLOWS"

AIAA Journal, Vol. 19, No. 4, April 1981, pp. 432-441.

A general theory for aerodynamic forces and moments, developed through a rigorous analysis of the viscous flow equations, is presented. General formulas relating aerodynamic forces and moments to rates of change of vorticity moments in the fluid and the solid regions are presented. Analytical results for several problems are presented to demonstrate the application of the theory in interpreting complex aerodynamic phenomena and in computational fluid dynamics.

"UNSTEADY AERODYNAMICS OF NON-RIGID BODIES -- A NOVEL APPROACH"

AIAA Paper No. 1988-0565, Reno, NV, January 1988

A procedure to evaluate unsteady aerodynamic forces on non-rigid lifting bodies undergoing prescribed time-dependent motions is described. The kinematic aspect of the incompressible viscous flows in the form of an integral representation for the velocity vector is utilized to obtain an explicit expression for the surface vortex sheet representing the vorticity contents of the boundary layers. Knowing the surface vortex sheet strength and the strengths and locations of the wake vortices, a general theory of aerodynamics is then used to evaluate the unsteady aerodynamic forces.

"A GENERALIZED WAKE-INTEGRAL APPROACH FOR DRAG DETERMINATION IN THREE-DIMENSIONAL FLOWS"

AIAA Paper No. 1979-0279, New Orleans, LA, January 1979

A generalized theory relating the drag on a three-dimensional lifting body in a wind tunnel to properties of the vortical wake downstream of the body is presented. In the well-known theory of Betz, the profile drag is expressed as a wake integral, i.e., an integral over only the vortical wake region of a downstream section. The present theory shows that, under quite general circumstances, the induced drag is also determined accurately by a wake integral. The theory offers some insight to the interplay between the drag components and the wake characteristics. Results of an exploratory experimental study are presented in the paper. They show that wake measurements at sections near the lifting body can determine the induced drag with good accuracy.

"WAKE-INTEGRAL DETERMINATION OF AERODYNAMIC DRAG, LIFT AND MOMENT IN THREE-DIMENSIONAL FLOWS"

AIAA Paper No. 2002-0555, Reno, NV, January 2000.

New wake-integral expressions for the determination of aerodynamic load on finite wings and rotors are established using a vorticity-moment theorem. Compared to previous wake-integral expressions based on the momentum theory, the new expressions connect the wake flow properties more directly to the aerodynamic load. They offer enhanced physical understanding of the flow mechanisms responsible for the production of aerodynamic force and moment and are simpler and more efficient to use. Wind-tunnel experiments are performed to validate the wake-integral expressions for the thrust and the torque on rotors in slow climb. A three-dimensional particle-image velocimetry system is used to obtain velocity values in the near-wake of a model rotor. Thrust and torque values determined using the wake data are presented and compared with balance-measured values.

"A FLOW VISUALIZATION STUDY OF THE EFFECT OF WING-TIP JETS ON WAKE VORTEX DEVELOPMENT"

In Flow Visualization III, Proceedings of the Third International Symposium, Ann Arbor, MI, September 1983, Hemisphere Publishing Corp., 1985, pp. 387-391

The use of discrete wing-tip jets to improve the wing performance and to modify the tip vortex roll up has been investigated. A complicated three-dimensional vortex interaction in the vicinity of the wing tip flow field becomes more clear through the flow visualization study in a water tunnel. The existence of many induced secondary vortices was discovered. This finding leads to a theoretical model for analyzing the interacting vortices flow field. Flow visualization also helped in pointing out the direction for future study.

"AERODYNAMIC INTERACTIONS OF WINGTIP FLOW WITH DISCRETE WINGTIP JETS"

AIAA Paper No. 1984-2206, Seattle, WA, August 1984

Wind and water tunnel data and calculations of the effects on wing aerodynamic performance by the presence of discrete wing tip jets are reported. A NACA 0012-64 airfoil equipped for interchangeable tips that provided various blowing configurations was used in the tests. Data were gathered on forces and moments at three spanwise locations and dye injection provided flow visualization. A relatively small jet had a large effect on the spanwise pressure distribution. Three separate types of boundary vortices were produced by the tip jets: spin-off vortices extending into the potential flow region, auxiliary vortices parallel to the main flow, and entrained vortices in the jet and wingtip vortices. Wake

vortices were dispersed while total circulation increased, thereby effectively enhancing the aspect ratio and overall wing performance.

Wu, J. M., Vakili, A. D., Shi, Z. and Mo, J. D.

"PHENOMENA OF DISCRETE WINGTIP JETS"

Report 88-06, August 1988, University of Tennessee Space Institute, Tullahoma, TN.

Detailed flow phenomena of discrete wingtip jets blowing from a rectangular wing with squared edges and round tips are investigated in the water- and wind-tunnel experiments. Phenomena on a single asymmetric jet blowing from a flat-plate in crossflow were incorporated into the present wingtip jet study. The local flow field perturbation introduced by the tip jet blowing closely resembles that of the asymmetric jet from the flat-plate. The wingtip jet has influenced the global surface pressure distribution over the wing and improved the lift loading. A simple mathematical model is developed for practical calculation of wing loading.

"GUIDING PRINCIPLES FOR VORTEX FLOW CONTROLS"

AIAA Paper No. 1991-0617, Reno, NV, January 1991

In the practice of vortex flow controls, the most important factor is that the persistency and obstinacy of a concentrated vortex depend on its stability and dissipation. In this paper, the modern nonlinear stability theory for circulation-preserving flows is summarized, and the dissipation for general viscous flows is analyzed in terms of the evolution of total enstrophy. These analyses provide a theoretical base for understanding relevant physics of vortex flows, and lead to some guiding principles and methods for their controls. Case studies taken from various theoretical and/or experimental works of vortex controls, due to the present authors as well as others, confirm the feasibility of the recommended principles and methods.

"AXIAL STRETCHING AND VORTEX DEFINITION"

Physics of Fluids, Vol. 17, March 2005, pp. 038108-1 to 038108-4

Four existing invariant criteria for defining a vortex are diagnosed analytically and demonstrated by the Burgers and Sullivan vortices. Two of the criteria are found disqualified as generally applicable, and one underestimates the core radius. The diagnosis leads to a general requirement for any possible criterion: it should be able to identify the vortex axis and allow for arbitrary axial strain.

"AIRCRAFT WAKE VORTEX MEASUREMENT WITH COHERENT DOPPLER LIDAR"

27th ILRC International Laser Radar Conf., July 2015, New York City, NY.

Aircraft vortices are generated by the lift-producing surfaces of the aircraft. The variability of near-surface conditions can change the drop rate and cause the cell of the wake vortex to twist and contort unpredictably. The pulsed Coherent Doppler Lidar Detection and Ranging is an indispensable access to real aircraft vortices behavior which transmitting a laser beam and detecting the radiation backscattered by atmospheric aerosol particles. Experiments for Coherent Doppler Lidar measurement of aircraft wake vortices has been successfully carried out at the Beijing Capital International Airport (BCIA). In this paper, the authors discuss the Lidar system, the observation modes carried out in the measurements at BCIA and the characteristics of vortices.

Wu, S., Yin, J., Li, R., Wang, X., Liu, B. and Liu, J.

"OBSERVATIONS AND ANALYSIS OF TURBULENT WAKE OF WIND TURBINE BY COHERENT DOPPLER LIDAR"

27th ILRC International Laser Radar Conf., July 2015, New York City, NY.

Turbulent wake of wind turbine will reduce the power output of wind farm. The access to real turbulent wake of wind turbine blades with different spatial and temporal scales is provided by the pulsed Coherent Doppler Lidar (CDL) which operates by transmitting a laser beam and detecting the radiation backscattered by atmospheric aerosol particles. In this paper, the authors discuss the possibility of using lidar measurements to characterize the complicated wind field, specifically wind velocity deficit by the turbine wake.

"CHARACTERIZATION OF AIRCRAFT DYNAMIC WAKE VORTICES AND ATMOSPHERIC TURBULENCE BY COHERENT DOPPLER LIDAR"

19th Coherent Laser Radar Conference (CLRC), Paper Th5, June 2018, Okinawa, Japan.

Wake vortex are large rolling air masses generated by aircraft because of lift. The behavior of that wake vortex is a major issue in aeronautical research. They are strongest and most hazardous on congested airfields during take-off and landing, i.e. near the ground. It is held that serious interactions between wake vortex and the ground can significantly affect the evolution of wake vortex, thus making them difficult to predict. To investigate the real approach to mitigate wake vortex using 1.55-micron coherent Doppler lidar and to study the wake vortex near ground effect (NGE), the wake vortex observation project was carried out during Jan-Mar 2017 at Beijing International Airport (BCIA). This paper focuses on the NGE analyze based on 2017 BCIA experiment (2017BCIAE) observation.

Wu, S., Zhai, X., Liu, B. and Liu, J.

"CHARACTERIZATION OF AIRCRAFT DYNAMIC WAKE VORTICES AND ATMOSPHERIC TURBULENCE BY COHERENT DOPPLER LIDAR"

28th International Laser Radar Conference, June 2017, Bucharest, Romania, published in EPJ Web of Conferences, Vol. 176, 2018, pp. 06001-1 to 06001-4.

Field observations for the wake vortices by Coherent Doppler Lidar (CDL) have been carried out at the Beijing International Airport (BCIA) and Tianjin Binhai International Airport (TBIA) to investigate the wake vortices evolution characteristics and the near-ground effect. This paper introduces the dynamic wake vortices and atmospheric turbulence monitoring technique, successfully demonstrating that the CDL can capture the key characteristics of wake vortices in real-time, including wake vortices intensity, spatial-temporal evolution and so forth.

"WIND TURBINE WAKE CHARACTERIZING USING COHERENT WIND LIDAR"

18th Coherent Laser Radar Conference, June 2016, Boulder, CO.

Wind power is growing fast as one of the most promising renewable energy sources. When the wind turbine generator (WTG) extracts power from the wind, the wake evolves and leads to a considerable reduction in the efficiency of the actual power generation. The wake effect also leads to the increase of fatigue loads that reduce the life time of WTGs. In this work, a Pulsed Coherent Doppler Lidar (PCDL) is used to characterize the WTG wakes, which has high updating rate of 4 Hz and variable spatial resolution from 15 to 60 m. Field experiments were performed in the onshore and offshore wind parks from 2013 to 2015. Techniques based on a single Doppler Lidar were employed for elucidating main features of turbine wakes, including velocity deficit, wake dimension, velocity profile, 2D wind vector, turbulence dissipation rate and turbulence intensity under different conditions of surface roughness.

"DESIGN OF AIRPORT WAKE VORTEX MONITORING SYSTEM BASED ON 1.5-MICRON PULSED COHERENT DOPPLER LIDAR"

Optoelectronics Letters, Vol. 7, No. 4, July 2011, pp. 298-303.

To shun the vortex hazard, the airport wake vortex monitoring system based on 1.5-micron pulsed coherent Doppler lidar is designed successfully in this paper. Based on realistic analytical model, the wake vortex generated by airbus A340 under typical flight condition is simulated. Then the principle of airport wake vortex monitoring is introduced, and the work flow of the monitoring system is also presented. Moreover, based on the mechanism of vortex coherent detection and typical system parameters, both detection SNR and detection precision are obtained through numerical simulations. When the system outputs 2J energy, the coherent detection SNR at 10 km distance is up to 23.452, and detection precision can reach 0.328 m/s. With the wake vortex monitoring experiment of A340, some

vortex parameters are estimated. Due to these results comparatively coinciding with the previous simulation conclusions, the ability of Doppler lidar for full-scale wake vortex characterization and real time measurement is demonstrated. The study shows that the wake vortex detection based on 1.5-micron pulsed coherent Doppler lidar has the advantage of high accuracy and far distance, and the designed airport wake vortex monitoring system has proved to be effective and feasible, which has significant development and application prospect in the aspect of assuring flight security and increasing airport capacity.

Wu, Y.-H., Hu, Y.-H., Dai, D.-C., Xu, S.-L. and Li, J.-M.

"RESEARCH ON THE TECHNIQUE OF AIRCRAFT WAKE VORTEX DETECTION BASED ON 1.5 MICRON DOPPLER LIDAR"

Acta Photonica Sinica, Vol. 40, No. 6, June 2011, pp. 811-817.

To shun the wake vortex hazard and assure the flight security, the technique of wake vortex detection by Lidar was studied. The basic principle of wake vortex detection was introduced, and both the detection mode and the system parameters of Lidar were also given. Based on the designed scheme of wake vortex detection by Lidar, the relationships between Doppler spectrum value and the parameters of aircraft type, flight and environment were studied. The radial velocity distribution law of wake vortex was acquired, and the Doppler spectrum model of its laser echo was built. Moreover, the optimal parameters estimation algorithm was selected for wake vortex characterization. Based on the performed wake vortex detection experiment of A340, both the feasibility of wake vortex detection by Lidar and the validity of parameters estimation algorithm of wake vortex were verified. The research results show that the laser echo created of wake vortex is inversely proportional to the cube of radial velocity, but is directly proportional to the square of circulation. [In Chinese.]

"INFLUENCE OF PRECESSION ON VELOCITY MEASUREMENTS IN A STRONG LABORATORY VORTEX"

Experiments in Fluids, Vol. 27, 1999, pp. 181-188.

A strong laboratory vortex is generated in a cylindrical cell using a rotating disk and stretched by pumping the fluid out through a hole in the center of the top of the cell. The velocity field is measured by means of laser Doppler anemometry and Doppler ultrasonic anemometry which are both non-intrusive methods. The vortex exhibits a slight precession which induces temporal fluctuations of the velocity at the measurement point. Due to the centrifugal force, the tracers concentrate in a tubular region around the vortex, leading to spatial variations of the measurement counting rate. Under these two effects, the probability density function of the one point velocity exhibits a strong non-Gaussian behaviour. In order to access the details of the velocity profile of the vortex in its own system of reference, the influence of the vortex precession, of the spatial variations of the concentration in tracers and of the intrinsic measurement dispersion is investigated and a model is proposed. It allows

to recover statistically the characteristics of the vortex and to deduce the trajectory of its centre from the instantaneous velocity profiles.

Wurzbach, R.

"THE VELOCITY FIELD BEHIND A LIFT GENERATING WING OF FINITE SPAN"

Zeitschrift fur Flugwiss, Vol. 5, No. 12, December 1957, pp. 360-365

When calculating the velocities induced by a wing of finite span, the process of rolling-up the vortex sheet formed behind the wing, and its displacement are considerably simplified. For estimating the field of induced velocities, a method is given which considers the rolling-up and the displacement of the vortex sheet. [In German.]

"3D-SIMULATION OF THE TURBULENT WAKE BEHIND A WIND TURBINE"

Journal of Physics, Conference Series, Vol. 75, 2007, pp. 1-8.

The paper relates to the simulation of the airflow around a wind turbine (WT) of the type ENERCON E66 with emphasis on the turbulent wake. The simulations were undertaken with the Computational Fluid Dynamics software ANSYS FLUENT 6.3 using the LES technique for turbulence modeling. It is the aim of the work to capture the full three-dimensional turbulent flow behind a WT in a sufficient spatial and temporal resolution to generate information for wind loads of WTs in wind farm configuration. This information shall help to optimize wind farm layouts in the future. Using an incoming wind field that matches the requirements of the IEC-61400 for wind fields used in load calculations it was possible to simulate a full meandering turbulent wake. The turbulent features of the WT wake could be reproduced with numerical methods not using further assumptions but solely based on the WT geometry and the solution of the governing physical equations.

Wynanski, I.

"METHOD AND APPARATUS FOR DELAYING THE SEPARATION OF FLOW FROM A SOLID SURFACE"

US Patent 5,209,438, May 1993

An active perturbation-producing element on the solid surface is driven to induce oscillations in the boundary layer of the fluid stream about an axis substantially perpendicular to the solid surface, to enhance the mixing of the boundary layer in the fluid stream. The method is particularly applicable for increasing the lift of a wing, but may also be used for increasing the divergence angle of a diffuser.

"DEVELOPMENT OF APPROACH AND DEPARTURE AIRCRAFT SPEED PROFILES"

Journal of Aircraft, Vol. 54, No. 1, January-February 2017, pp. 94-103.

Information on the suggested aircraft speeds can be obtained from flight manuals, but the actual airspeeds flown by an aircraft will vary based on the aircraft landing weight, airport altitude, wind conditions, and other Air-Traffic-Control related factors. The recent advent of new tools and an abundance of new, highly accurate aircraft surveillance data have enabled a reevaluation of past airspeed profile assumptions. The resulting analysis provides a stronger representation for airspeeds flown on final approach and initial departure by the aircraft types comprising a large percentage of U.S. Instrument Flight Rules operations. Furthermore, the time to fly is calculated to determine how long it takes the trailer aircraft to fly the distance to the point where the leader generates a particular portion of the wake. Although this work is performed to provide improved inputs for Recategorization Phase II analyses, the airspeed profiles derived from aircraft surveillance data will also be valuable to other Air Traffic Control applications (such as the Advanced Traffic Proximity Alert, the Interval Management-Paired Approach, Time-Based Flow Management, and the Integrated Departure Arrival Capability) that require accurate knowledge of how aircraft approach and departure airspeeds vary in actual operations.

"QUANTITATIVE ESTIMATION OF WAKE VORTEX SAFETY USING THE P2P MODEL"

6th USA/Europe ATM R&D Seminar, April 2005, Paper 57, Baltimore, MD

Wake vortex encounter risk is a major safety issue in aircraft final approach phase. The evaluation of the risk is crucial when the industry takes the effort to reduce aircraft spacing for the purpose of capacity gain. This paper proposes a hybrid analytical method to assess the wake vortex encounter risk during the final approach phase. The hybrid method uses probabilistic method to calculate the risk based on the probabilistic distributions of aircraft positions and vortex characteristics obtained from Monte Carlo simulations. The proposed method will be more computational efficient than pure simulations to evaluate the probability of a rare event, such as a serious vortex encounter. In addition, it can provide insights about risk distributions with respect to time and location. The estimation given by the model is conservative, which provides effective safety margin to the risk evaluation in a highly stochastic environment.

"TIME-STEPPING FREE-WAKE METHODOLOGY FOR ROTOR FLOW FIELD SIMULATION IN GROUND EFFECT"

Aircraft Engineering and Aerospace Technology, Vol. 87, No. 5, 2015, pp. 418-426.

The purpose of this paper is to provide an approach to predict rotor thrust and hub moments under in ground effect (IGE) in transient flight. Target of the research is developing a new integrated methodology that can be applied in the simulation of rotor flow field IGE. Free-wake model and panel method are two methods used to predict ground influence on rotor flow field. However, these methods can result in unphysical phenomena, such as wake vortex moving below the ground during simulation and fluctuation taking place on vortices near the ground, which is named noise problem. Thus, a new tactic called 'constant volume rectification' is developed to rectify the unreal vortex location, and a third-order time-stepping algorithm called CB3D (Center difference and Backward difference 3rd-order scheme with numerical Dissipation) with strengthened stability is proposed to replace the existing second-order time-stepping algorithm CB2D (Center difference and Backward difference 2nd-order scheme with numerical Dissipation) to inhibit the development of discrete error. The new free-wake model is effective and stable in predicting the characteristics of the rotor flow field in steady and transient flights under IGE. The newly developed CB3D scheme is more stable and more suitable for wake prediction of rotor under IGE than the CB2D scheme. At different advance ratios, the predicted flow regimes of recirculation and ground vortex agree well with the test images. In the accelerating condition, the predicted variations of rotor thrust and hub moments with advance ratios are consistent with the corresponding experimental results. It is found that the slow movement of wake geometry with advance ratio in the accelerating condition is the cause of the delay in the variation tendency of rotor forces compared to that in steady condition.

Xin, J., Li, P. and Chen, R.

"FREE-WAKE ANALYSIS OF HOVERING ROTOR IN GROUND EFFECT"

Acta Aeronautica et Astronautica Sinica, Vol. 33, No. 12, December 2012, pp. 2161-2170.

A free-wake based model with fine convergence is developed to predict the wake geometry of a hovering rotor operating in ground effect (IGE). The vortex line is discretized into straight-line filaments, and the influence of the ground is modeled using a surface panel method. Since earlier studies show it is hard for the free-wake to converge when the rotor is hovering at a low height, the work of this study incorporates several modification measures to improve the convergence of the model, such as rectifying the wake vortices below the ground plane proportionally and distributing the ground panels circularly, which reduced the calculation amount of the model at the same time. The model is validated with prediction instances in which the rotor is placed at different heights. A comparison of the determined wake geometries with experimental data shows good agreement and proves the proposed model possesses good accuracy. [In Chinese.]

"AIRCRAFT ROUTE OPTIMIZATION FOR FORMATION FLIGHT"

Journal of Aircraft, Vol. 51, No. 2, March-April 2014, pp. 490-501.

We quantify the fuel and cost benefits of applying extended formation flight to commercial airline operations. Central to this study is the development of a bi-level, mixed-integer real formation flight optimization framework. The framework has two main components: 1) a continuous-domain aircraft mission performance optimization and 2) an integer optimization component that selects the best combination of optimized missions to form a formation flight schedule. The mission performance reflects the effects of rolled-up wakes, formation heterogeneity, and formation-induced compressibility. The results show that an airline can use formation flight to reduce fuel burn by 5.8 percent or direct operating cost by 2.0 percent in a long-haul international schedule. The savings increase to 7.7 percent in fuel or 2.6 percent in cost for a large-scale, transatlantic airline alliance schedule. These results include the effects of a conservative fuel reserve for formation flight. Sensitivity studies show that a modest reduction in the cruise Mach number may be sufficient to manage the impact of formation-induced compressibility effects on system-level formation flight performance. We demonstrate that the potential savings from extended formation flight (an operational improvement using existing aircraft) can approach those claimed for advanced vehicle technologies and unconventional configurations.

"EXTRICATION OF WAKE VORTEX PARAMETERS BASED ON LIDAR ECHO"

Acta Photonica Sinica, Vol. 42, No. 1, January 2013, pp. 54-58.

To realize the monitoring of the aircraft wake vortex effectively, solve the puzzles of flight safety and runway capacity limitation, an algorithm of wake vortex parameter extrication based on Lidar echo is proposed. The physical model of circulation and radial velocity distribution is studied, and the structure of wake vortex is described. Based on the features of the vortex parameters, the flowchart of parameter extrication is given, as echo signal processing for noise reduction, threshold selection for velocity envelopes to resolve the velocity distribution and parameter (core radius, core position, circulation) extrication. Moreover, the calculation example of extrication algorithm is carried out by taking a certain type of aircraft for example which is compared with the model simulation. The experimental result verifies the effectiveness of the extrication algorithm. [In Chinese.]

"RETRIEVAL OF 3D WIND FIELD FROM LIDAR VELOCITY DATA"

14th Coherent Laser Radar Conference, July 2007, Snowmass, Co.

The Hong Kong Observatory (HKO) operates a Doppler LIDAR at the Hong Kong International Airport (HKIA) for airflow monitoring and windshear alerting. Complex airflow occasionally occurs in the vicinity of HKIA due to terrain disruption. To better visualize the wind in the airport area, 2D wind retrieval based on the LIDAR's radial velocity measurement is conducted. This paper is an extension of the work by using a more sophisticated technique to retrieve the 3D wind field around HKIA.

Xu, X., Zhao, H., Wang, Z.

"OVERVIEW OF WAKE VORTEX SEPARATION REDUCTION SYSTEMS"

Acta Aeronautica et Astronautica Sinica, Vol. 31, Issue 4, 2010, pp. 655-662

Flight delay is nowadays one of the most critical curbing factors in aviation industry. While the efficiency of air transportation is improved by air traffic flow management, massive research work on wake vortex separation reduction is also performed by researchers all around the world. One of the technologies developed to date is to modify flight procedure aiming at the reduction of the wake vortex separation of closely spaced parallel runways; and another is to build wake turbulence prediction models to anticipate the dissipation and transportation of wake vortex. Thus, a wake turbulence separation consultative matrix is calculated to acquire more landing and take-off slots. The wake vortex separation reduction systems can alleviate flight delay and increase terminal capacity. They are assorted into two categories according to different principles adopted in design, i.e., wake vortex separation system based on offset approach procedure and wake vortex separation system based on dynamic prediction. The theory, algorithm and components of each system are thoroughly analyzed. The performance of the systems is compared and the advantages and drawbacks of each system are discussed.

Xue, Y., Xu, H.-J. and Wang, X.

"BUILD PROBABILITY DISTRIBUTION MAPS OF FLIGHT RISK DURING WAKE ENCOUNTERING"

Journal of Aircraft, Vol. 52, No. 3, May-June 2015, pp. 805-818.

Under the background of increasing wake vortex problems, flight risk probabilities during wake encountering are evaluated using complex system theory and multivariate extreme value theory. First, three-dimensional extreme flight parameters required for assessing the risk are extracted using Monte Carlo simulation. The one-dimensional extreme parameters are verified to have the same distribution type of thick tail as the test data. Second, the four adaptive weight parameters copula is proposed for modeling the distributions of three-dimensional extreme parameters. The result of the fitting test shows the four adaptive weight parameters copula has higher accuracy than the other cupola. Third, the flight risk probability in every corresponding grid point is evaluated by taking the four adaptive weight parameters copula to model the extreme parameters in the wake field. At last, the visual two-dimensional and three-dimensional distribution maps of flight risk probability are built, and the topology characteristics of risk distributions at different stages are analyzed. The maximum flight risk probability during wake encountering is about 13.5 percent. The work is an effective complement to the aircraft system safety assessment method. It also has some reference values for research on wake navigation control, risk aversion, airport safety interval improvement, environmental risks visualization, and so on.

Yamada, K. and Suzuki, K.

"DYNAMICAL SYSTEM ANALYSIS ON THE ONSET OF RECIRCULATING FLOW REGION ASSOCIATED WITH VORTEX BREAKDOWN"

AIAA Paper 2016-4347, June 2016, Washington, DC.

In this study, the onset of axisymmetric vortex breakdown in a closed cylinder is extensively investigated numerically by solving the incompressible axisymmetric Navier-Stokes equations. A longitudinal vortex tube, which is generated around the center axis of the cylinder, goes to burst after the radial expansion of the vortex tube and the appearance of a pair of stagnation points on the axis, by which a recirculating flow region is bounded. Such process is examined from the aspects of the velocity profile along the axis and the eigensystem of the velocity gradient tensor around the stagnation points, varying the Reynolds number and the aspect ratio of the cylinder.

"SIMULATION OF AIRCRAFT WAKE VORTEX USING PRESSURE-BASED UNIFIED NUMERICAL APPROACH FOR INCOMPRESSIBLE AND COMPRESSIBLE FLOWS"

AIAA Paper No. 2004-0077, Reno, NV, January 2004

A wake vortex simulation using CFD methodology based on a new pressure-based unified approach is presented. A numerical method is developed to attain calculation for both in incompressible and compressible flows regime with a low numerical diffusive property and for high prediction accuracy of pressure gradient. This scheme is constructed by splitting the full Navier-Stokes equation into an advection role by velocity and a propagation role by acoustic wave. In the advection phase, concept of the advective upwind splitting method (AUSM) is adapted to non-conservative advection equations. For the acoustic phase, SMAC-like Poisson's equation is derived to reduce a numerical error. Newly developed scheme shows good agreement except strong shock capturing capability for validation problems including incompressible, compressible and vortical flow calculations. Finally, wake vortex simulation for NACA0012 rectangular wing is investigated. The computation results show availability of new approach for wake vortex flow predictions.

"DETAILED FLOW VISUALIZATION AROUND COMPLEX BODIES"

Proceedings of 9th International Symposium on Flow Visualization, Edinburgh, Scotland, August 2000, pp. 327-1-327-8

Flows around geometrically complex bodies, such as whole airplane models and sports car models, have been measured in a small wind tunnel especially designed for detailed and precise measurements with a full-automatic controlled traverse gear. Lots of data were obtained using a micro five-hole Pitot tube to make clear the flow mechanisms around the bodies with help of computer graphic software for three-dimensional flow analyses. Pressure and velocity fields were visualized in the three-dimensional space, vortex and even separated/reverse flow regions were detected from the resultant visualization

pictures. The present technique gives 'quantitative' visualization of the flows around complex bodies and enables us to make 'invisible' quantities clearly visible. Three-dimensional streamlines or particle paths were also obtained from experimental data.

Yamasuge, H., Yoshikawa, E., Ushio, T., Ishii, S., Aoki, M. and Hashimoto, K.

"EXPERIMENTAL VERIFICATION OF WIND LIDAR WITH LONG-DURATION FREQUENCY-MODULATED PULSE"

19th Coherent Laser Radar Conference (CLRC), Paper P17, June 2018, Okinawa, Japan.

In our previous research, a new wind lidar which accomplishes high power and high range resolution by transmitting laser pulses with long duration and frequency modulation was proposed. In the proposed wind lidar, analytical performance evaluation under ideal conditions indicated that accuracies of wind ranging and velocimetry increases in proportion to the square root of pulse duration. In this research, we investigated accuracies of modulated pulse shaping that is one of the issues to realize the proposed wind lidar. We developed an experimental system which directly returns generated laser pulses to its receiver, and digitally measured the returned waveform. Although, in the returned signal, the returned waveform is distorted compared to its ideal waveform, the result of matched filter processing showed sufficient performances that the mainlobe width was almost maintained, and peak power was reduced very little by -0.3 dB as compared with the ideal waveform.

Yamauchi, G. K., Johnson, W. and Wadcock, A. J.

"VORTEX WAKE GEOMETRY OF A MODEL TILT ROTOR IN FORWARD FLIGHT"

American Helicopter Society International Meeting on Advanced Rotorcraft Technology and Life Saving Activities, Tochigi, Japan, November 2002

The vortex wake trajectory from one rotor of a 0.25-scale V-22 tiltrotor model was measured for four test conditions in the NASA Ames 40- by 80-Foot Wind Tunnel. Vortex wake images were acquired using a laser light sheet and video camera. Wake trajectories were constructed by extracting vortex positions from the video images. Wake trajectories were also calculated using the comprehensive analysis CAMRAD II. Measured and calculated wake geometries exhibit similar trends when advance ratio is varied at fixed thrust or when thrust is varied at fixed advance ratio.

Yamauchi, G. K., Burley, C. L., Mercker, E. and Pengel, K.

"FLOW MEASUREMENTS OF AN ISOLATED MODEL TILT ROTOR"

55th Annual Forum, American Helicopter Society, Montreal, Canada, May 1999

Wake measurements on the advancing side of a 0.25-scale V-22 isolated tilt rotor are presented and discussed. Three-dimensional wake geometry data were obtained using the Laser Light Sheet (LLS) technique. The position of wake segments relative to the rotor blade were acquired for a range of

thrust and shaft angles. The rotation sense of the wake segments was determined. The lower thrust condition generated negative tip loading over a larger portion of the rotor disk than the higher thrust condition. At a higher thrust condition for the same shaft angle, the number of observed negative circulation vortices decreased. Two-dimensional velocity measurements were obtained using the Particle Image Velocimetry (PIV) technique. Three methods for averaging the PIV velocity data are discussed. Two of the methods account for vortex wander; both methods, however, require further refinement to determine which method provides more accurate results. The third method, which does not account for vortex wander, should only be used to obtain general features of the flow. For the vortices examined, approximately 100 PIV samples were determined to be sufficient for computing the average vortex core size and core circulation. The core size and core circulation of the negative vortices were smaller than the positive circulation vortices. The core tangential velocity appears to have a nearly linear relationship to the core size for the vortices examined. The fraction of total circulation in the core for both negative and positive vortices was found to be consistent with the Scully and Oseen vortex models.

"NUMERICAL SIMULATION AND EXPERIMENTAL VERIFICATION ON DOWNWASH AIR FLOW OF SIX-ROTOR AGRICULTURAL UNMANNED AERIAL VEHICLE IN HOVER"

International Journal of Agricultural & Biological Engineering, Vol. 10, No. 4, 2017, pp. 41-53.

Recently, multi-rotor unmanned aerial vehicle (UAV) becomes more and more significantly irreplaceable in the field of plant protection against diseases, pests, and weeds of crops. The easy takeoff and landing performance, hover function and high spraying efficiency of UAV are urgently required to spray pesticide for crop timely and effectively, especially in dispersed plots and hilly mountains. In such situations, the current researches about UAV spray application mainly focus on studying the influence of the UAV spraying parameters on the droplet deposition, such as operation height, operation velocity and wind velocity. The deposition and distribution of pesticide droplets on crops which depends on installation position of nozzle and airflow distribution characteristics of UAV are directly related to the control effect of pesticide and crop growth in different growth periods. As a preliminary step, this study focuses on the dynamic development law and distribution characteristics of the downwash air flow for the SLK-5 six-rotor agricultural UAV. Based on compressible Reynolds-averaged Navier-Stokes (RANS) equations with an RNG k- ϵ turbulence model and dynamic mesh technology, the efficient three-dimensional computational fluid dynamics (CFD) method was established to analyze the flow field distribution characteristics of UAV in hover. Then the unsteady interaction flow field of the wing was investigated in detail. The downwash wind speed of the marked points for the SLK-5 UAV in hover was also tested by weather tracker. It was found that the maximum velocity value of the downwash flow was close to 10 m/s; the z-direction velocity was the main body of the wind velocity in the downwash airflow, and the comparison of the wind velocity experiment test and simulation showed that the relative error was less than 12% between the experimental and simulated values of the z-direction velocity at the marked points. Then the flow characteristics of the longitudinal and cross section were analyzed in detail, the results obtained can be used as a reference for drift and sedimentation studies for multi-rotor unmanned aerial vehicle.

"WING TIP VORTEX STRUCTURE BEHIND AN AIRFOIL WITH FLAPS AT THE TIP"

Science China Physics, Mechanics and Astronomy, Vol. 54, No. 4, April 2011, pp. 743-747.

In this work, the wing tip vortex structure behind a NACA 0015 airfoil with and without small flaps was studied using a Particle Image Velocimetry (PIV) system. The experiment was carried out in a low-speed wind tunnel with a test section of 0.5m x 0.5m. The Reynolds number defined by the chord length of the wing (C) was 81000. The angle of attack was fixed at 10 degrees. The PIV measurements were made from 0 to $2C$, measured from the trailing edge of the model. The dihedral angle of three flaps was -15, 0 and 15 degrees, respectively. Compared with the clean model, the one with three flaps significantly changed the wing tip vortex structure, the vorticity, and the core of the wing tip vortex. The occurrence of three flaps decreased the gradient of pressure on the two sides of the wing tip, which depressed wing tip vortex formation to some extent. Vortices shed from three flaps influence the evolution of the wingtip vortex generated by the base airfoil. The interaction of those vortices resulted in a weakening of the wing tip vortex.

"EULER SOLUTIONS OF FLOW AROUND A RECTANGULAR WING WITH SQUARE TIP"

AIAA Paper No. 2007-896, Reno, NV, January 2007

Low speed flows about a high-lift rectangular wing with square lateral tip are computed by a three-dimensional compressible Euler flow solver. Flow separation around the square tip of the wing is studied. The flow is, otherwise, attached to the surface of the wing. The pressure distributions over the upper and lower surfaces of the wing, especially on the outer portion of the wing and the generation and evolution of the tip vortices in the near field of the wing are computed by the Euler method and validated by a comprehensive wind-tunnel test data in the literature. The effects of the wind-tunnel wall are not considered in the computations.

"LARGE EDDY SIMULATIONS OF DECAYING ROTATING TURBULENCE"

Physics of Fluids, Vol. 16, No. 11, November 2004, pp. 4088-4104

Large eddy simulations of homogeneous isotropic turbulence subjected to system rotation were performed using the truncated Navier-Stokes method. In the method the Navier-Stokes equations are solved through a sequence of direct numerical simulation runs and a periodic processing of small scales to provide the necessary dissipation. The method is evaluated by comparing simulation results with theoretical analysis, direct numerical simulations, as well as with other large eddy simulation results. Obtained results demonstrate several advantages of the method over traditional large eddy simulations

models. The method captures important features of rotating turbulence: the energy decay is inhibited, the energy spectrum departs from the classical k to the $-5/3$ form, and initially isotropic turbulence becomes anisotropic. For increasing rotation rate three distinct regimes are observed. At low rotation rates, the influence of rotation is weak and flow behaves like for nonrotating cases. At intermediate rotation rates strong coupling between rotation and nonlinear interactions has a significant influence on turbulence. At high rotation rates viscous effects dominate over nonlinear effects. Furthermore, for high Reynolds numbers, small Rossby numbers, and large elapsed time, the k to the -3 energy spectrum is observed due to the anisotropy identified by various indicators, rather than k to the -2 form found under the assumption of isotropy.

"AN EXPERIMENTAL INVESTIGATION ON THE WAKE INTERFERENCE OF WIND TURBINES SITED OVER COMPLEX TERRAINS"

AIAA Paper No. 2012-1069, January 2012, Nashville, TN.

An experimental study was conducted to investigate the interferences of wind turbines sited over hilly terrains to elucidate underlying physics to explore/optimize design paradigms of wind turbines sited over complex terrains for higher power yield and better durability. The experiments were conducted in a large wind tunnel with wind turbine models sited over a flat terrain (baseline case) and a 2D-ridge with non-homogenous atmospheric boundary layer winds. In addition to measuring dynamic wind loads (both forces and moments) and the power outputs of the wind turbine models, a high-resolution digital Particle Image Velocimetry system was used to conduct detailed flow field measurements to quantify the flow characteristics of the surface winds and wake interferences among multiple wind turbines over flat (baseline case) and complex terrains. The detailed flow field measurements were correlated with the wind load measurements and power outputs of the wind turbine models to elucidate the underlying physics associated with turbine power generation and fatigue loads acting on the wind turbines.

"RECENT IMPROVEMENTS TO A HYBRID METHOD FOR ROTORS IN FORWARD FLIGHT"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 804-812

A hybrid Navier-Stokes/full potential solver has been developed for the efficient prediction of three-dimensional unsteady viscous flow phenomena that occur over helicopter rotors in forward flight. The method combines a Navier-Stokes analysis near the blade, modeling the viscous flow and near wake with a potential flow analysis in the far field, modeling inviscid isentropic flow. A grid motion module has been developed to account for the blade motion and elastic deformations. Free and prescribed wake models have been developed to account for the tip vortex effects once the vortex leaves the viscous flow region and enters the potential flow region. Sample results are presented for a two-

bladed AH-1G rotor in descent and for a UH-60A rotor in high-speed forward flight. Comparisons with experiments, flight test data, and other numerical simulations are given.

Yang, Z., Sarkar, P. and Hu, H.

"VISUALIZATION OF THE TIP VORTICES IN A WIND TURBINE WAKE"

Journal of Visualization, Vol. 15, 2012, pp. 39-44

In the present study, an experimental study was conducted to characterize the formation and the evolution of the helical tip vortices and turbulent flow structures in the wake of a horizontal axis wind turbine model placed in an atmospheric boundary layer wind. A high-resolution particle image velocimetry system was used to make detailed flow field measurements to quantify the time evolution of the helical tip vortices in relation to the position of the rotating turbine blades in order to elucidate the underlying physics associated with turbine power generation and fatigue loads acting on the wind turbine.

"TWO DIMENSIONAL VORTICES MERGING ANALYSIS"

AIAA Paper No. 2007-4366, Miami, FL, June 2007.

This paper focuses on the interaction of co-rotating vortices, like those in the near-wake of transport aircraft. The fundamental process of vortex merging is analyzed and modeled in detail in a two-dimensional context. Vortex merging criterion and its physical origin was also discussed. Finally, bifurcation theory was used to determine the merging criterion. Numerical simulation of vortex merging was studied through N-S equation and the LES turbulence model was employed; spectral method was used to initialize the flow field. In the temporal direction, the 2nd order method was accepted. The distance between two vortices cores at different time stage was also given in present paper, the result was in good agreement with DNS result. The process of vortex merging was divided into four stages. The duration of four stages were also given in present paper. The so-called 'rebound' phenomenon was described and analyzed theoretically. The relationship between duration and Reynolds number was discussed. At last, the final flow field characteristic was predicted, including vortex core size characteristic.

Yao, Z. X. and Liu, D. D.

"VORTEX DYNAMICS OF BLADE-BLADE INTERACTION"

AIAA Paper No. 1994-0737, Reno, NV, January 1994.

A time domain method has been developed for treatments of vortex dynamics in all classes of blade-blade interaction problems. A new 'vortex impingement' condition is introduced to the discrete vortex tracking scheme and was found most effective in handling the vortex-airfoil interaction, the wake-airfoil

interaction (WAI), and the blade-blade interaction (BBI) problems. Various computed examples are presented for different classes of interaction problems ranging from single airfoil to airfoils in tandem in indicial or oscillatory motions. Present results are verified with all classical solutions and are found in good agreement with almost all existing solutions. From the present BBI study, it is concluded that any front blade movement will induce a strong interaction between the wake and the rear airfoil; hence, it alters drastically the lift response and the wake structure. Any rear blade movement only induces a weak interaction; hence, it remains comparatively ineffective to the response. Comparative study of WAI and BBI results indicates that the airfoil interference effect is relatively insignificant as opposed to that of the wake-airfoil interaction.

"VORTEX/WAKE FLOW STUDIES FOR AIRFOILS IN UNSTEADY MOTIONS"

AIAA Paper No. 1989-2225, Seattle, WA, August 1989

A time-domain method has been developed to account for vortex-airfoil-wake interaction problems. The present method is based on a high-order panel scheme on the airfoil coupling with the discrete vortex tracking technique for treatments of the wake and assigned free vortex. Computation examples include complete checks of classical problems, high angle of attack histogram, and various vortex-airfoil interaction problems. New results for the impulsively-started airfoils in tandem are also presented. The present method is found to be a robust one in handling the vortex-airfoil-wake interaction problems. Finally, issues involving conservation of vorticity condition and vortex models will be discussed.

Yaras, M. I.

"EFFECTS OF ATMOSPHERIC CONDITIONS AND GROUND PROXIMITY ON THE DYNAMICS OF AIRCRAFT WAKE VORTICES: A STUDY OF THE 1994-1995 MEMPHIS FIELD MEASUREMENTS"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998.

This paper studies aircraft wake data acquired by the MIT Lincoln Laboratory and NASA Langley Research Center at the Memphis, TN international airport during December 1994 and August 1995. The objective is to identify the dominant mechanisms affecting the transport and decay of aircraft wake vortices. Specifically, the effects of atmospheric stratification, wind shear, atmospheric turbulence and ground proximity on the far-wake development are examined. The wake-vortex trajectories are observed to closely follow the ideal descent path under calm and near-neutral atmospheric conditions and away from the ground. Increased variability in the vertical wake trajectory is noted under high ambient turbulence (normalized turbulence levels more than 0.5) with observations of descending as well as rising vortices for the same turbulence energy. Interaction of the wake vortices with nonuniform ambient vorticity associated with a ground-jet crosswind profile is observed to arrest their vertical descent leading to a rebound. No discernable changes are observed in wake-vortex transport and decay over a normalized Brunt-Vaisala frequency range of 0.2 to 0.5. Wake-vortex rebound due to

viscous ground interaction is observed to occur about one time unit after the arrest of the initial vertical descent. For wake vortices generated sufficiently close to the ground, the rebound is immediate. An effect of stratification on the rebound process is not observed over a range of normalized Brunt-Vaisala frequencies of 0.07 to 0.35. Furthermore, neither winds aligned with the wake axis nor wind shear in this direction appear to influence the rebound process.

Yaras, M. I.

"NUMERICAL SIMULATIONS OF AIRCRAFT WAKE-VORTEX DYNAMICS IN NONUNIFORM WINDSHEAR AND GROUND PROXIMITY"

AIAA Paper No. 2002-0940, Reno, NV, January 2002

The work presented herein examines the interaction of aircraft wake vortices with nonuniform ambient shear in proximity of the ground. The investigation is based on two- and three-dimensional numerical simulations using a grid-based Reynolds-averaged Navier-Stokes solver. The simulations are tailored to establish the extent of simplifications in mathematical modeling that can be realized while maintaining acceptable accuracy. The results are intended to provide the ground work for the development of real-time algorithms that may be used at airports in dynamic spacing of aircraft during landing and take-off. Through comparison with field data as well as simulations based on a one-equation turbulence model, the assumption of a constant eddy viscosity is shown to be adequate for modeling the turbulent diffusion of wake vortices in low-turbulence ambient conditions. Nonlinear interactions are demonstrated in the instance of simultaneous influence of ambient shear and ground proximity on the wake-vortex dynamics. Furthermore, neither axial motion within the core of the wake vortices nor nonuniform headwind shear are shown to have significant influence on the kinematics of the wake/crosswind-shear interaction, lending support for two-dimensional modeling of this flow if three-dimensional instability effects are accounted for separately. Finally, the results help to establish the levels of accuracy and resolution of wind measurements that are required for reliable prediction of wake-vortex dynamics in nonuniformly sheared ambient conditions.

Yaras, M. I.

"EFFECTS OF ATMOSPHERIC CONDITIONS AND GROUND PROXIMITY ON THE DYNAMICS OF AIRCRAFT WAKE VORTICES: A STUDY OF THE 1994-95 MEMPHIS FIELD MEASUREMENTS"

TP-13372E, March 1999, Carleton University, Ottawa, Ontario

To identify the mechanisms affecting the transport and decay of aircraft wake vortices, the effects of atmospheric stratification, wind shear, atmospheric turbulence and ground proximity were examined using the data collected at Memphis International Airport in December 1994 and August 1995. Of the atmospheric parameters considered, large-scale atmospheric turbulence and non-uniform wind shear were observed to substantially influence the wake transport and decay. The extent of rebound following viscous interaction with the ground was like published results of laboratory tests conducted at much lower Reynolds numbers.

"AIRCRAFT WAKE VORTEX TAKEOFF TESTS AT O'HARE INTERNATIONAL AIRPORT"

DOT/FAA/RD-94-25, August 1994, Volpe National Transportation Systems Center, Cambridge, MA.

Three wake vortex measurement systems (anemometer, acoustic doppler, and laser doppler) were used to collect wake vortex data from aircraft departing Runway 22L at Chicago's O'Hare airport for nine months in 1980. The data were analyzed to determine vortex decay and vortex transport probabilities. The results support the classification of all B-707 and DC-8 aircraft in the large wake vortex class. The acoustic doppler system was found to be significantly more sensitive than the ground anemometer system to vortices transported long distances laterally by a crosswind. The most efficient lateral transport was noted for crosswinds greater than seven knots. The horizontal and vertical ground wind signatures of a wake vortex are compared.

Yaroshevsky, V. A.

"THE CALCULATION OF VORTEX WAKE KINETIC ENERGY AND THE EFFECT OF CIRCULATION DISTRIBUTION ON SOME CHARACTERISTICS OF WAKE"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 26-33

The vortex wake rolls up into two parallel vortex cords at a short distance (about 10-15 wingspans downstream the aircraft). Considering the well-known assumption that the rotational kinetic energy of the wake in the nearfield is produced by the work of induced drag, it is possible to calculate the size of so-called core radius of each vortex. A very simple law has been found for the accurate calculation of this kinetic energy. The paper analyzes the effect of circulation distribution on some important characteristics of vortex wake: core radius, maximum induced velocity in the near field, rate of vortex-pair height loss, mean time of vortex-pair life, rate of vortex core growth.

Yasue, M., Vehlow, C. A. and Ham, N. D.

"GUST RESPONSE AND ITS ALLEVIATION FOR A HINGELESS HELICOPTER ROTOR IN CRUISING FLIGHT"

Fourth European Rotorcraft and Powered Lift Aircraft Forum, Paper No. 28, September 1978, Stresa, Italy, pp. 28-1 - 28-39.

The vertical gust response and its alleviation for hingeless helicopter rotor blades in cruising flight is studied theoretically and experimentally. An evaluation is performed of the effectiveness of torsional stiffness variation in conjunction with chordwise center-of-gravity shift in alleviating the blade flapping response to decrease the root bending moment. The theoretical analysis utilizes the equations of motion of hingeless rotor blades exposed to vertical gusts in forward flight for the flapping, lagging, and elastic and rigid pitch degrees of freedom. The equations include the effect of steady-state deflections

in the trim conditions and various hingeless rotor configurations such as precone, droop and torque offset as well as chordwise center-of-gravity shift and aerodynamic center offset. The experimental program involves the wind tunnel tests of a five-foot diameter rotor subject to a sinusoidal waveform gust. Testing involves variation of the blade chordwise center-of-gravity location, the blade torsional stiffness, rotor advance ratio, and vertical gust frequency.

Yates, J. E.

"INTERACTION WITH AND PRODUCTION OF SOUND BY VORTEX FLOWS"

AIAA Paper No. 77-1352, Atlanta, Georgia, April 1977.

A general theory of aeroacoustics of homentropic fluid media is presented. The definition of sound (unsteady compressible flow) and the concept of Bernoulli enthalpy are the fundamental building blocks of the theory. It is proved that a Coriolis acceleration is necessary to obtain a transfer of energy from the vortical to the acoustic mode. With the Lighthill hypothesis the theory is formally equivalent to the Lighthill or Ribner theory in the low Mach number limit. The present theory is complete in that all the basic aeroacoustic interactions can be investigated, in particular, the excitation of a fluid flow by sound. The interaction of sound with vortex flows is studied in detail. A formula for vortex core scattering is derived with a plane wave analysis. A general theory of acoustic interaction with multiple weakly interacting line vortices is presented. The theory is applied to estimate the interference noise between an engine and an aircraft vortex wake. For the DC-9 in a standard take-off configuration the interference noise is estimated to be 3 or 4 dB at the engine peak Strouhal number. The noise produced by a corotating vortex pair is calculated with the present theory. For low Mach number (M less than 0.1) the sound power varies as M to the 7th power in accordance with known results for compact 2-D flows. For M greater than 0.1 but less than 0.3 the power radiated is 10 to 15 dB less than the compact M to the 7th power law, even though the basic source is still quadrupole. For M greater than 0.3 higher order multipoles contribute to the sound power.

Yates, J. E.

"APPLICATION OF THE BERNOULLI ENTHALPY CONCEPT TO THE STUDY OF VORTEX NOISE AND JET IMPINGEMENT NOISE"

NASA CR-2987, April 1978, Aeronautical Research Associates of Princeton, Princeton, NJ.

A complete theory of aeroacoustics of homentropic fluid media is developed and compared with previous theories. The theory is applied to study the interaction of sound with vortex flows, for the DC-9 in a standard take-off configuration. The maximum engine-wake interference noise is estimated to be 3 or 4 dB in the ground plane. It is shown that the noise produced by a corotating vortex pair departs significantly (10 to 15 dB reductions) from the compact M scaling law for eddy Mach numbers (M) greater than 0.1. An estimate of jet impingement noise is given (~ 10 dB increase in sound power) that is in qualitative agreement with experimental results. The increased noise results primarily from the nonuniform acceleration of turbulent eddies through the stagnation point flow. It is shown that the

corotating vortex pair can be excited or de-excited by an externally applied sound field. The model is used to qualitatively explain experimental results on excited jets.

Yates, J. E.

"CALCULATION OF INITIAL VORTEX ROLL-UP IN AIRCRAFT WAKES"

J. Aircraft, Vol. 11, No. 7, July 1974, pp. 397-400.

The initial in-plane acceleration of a vortex sheet in two-dimensional incompressible flow is calculated. The theory is used to estimate the strength and location of the discrete vortices that roll-up behind an aircraft wing. Numerical results are presented for a C-141 takeoff and a DC-9 landing configuration. The results verify a hypothesis of Donaldson for estimating the strength and location of the discrete vortices that is required in a Betz-type roll-up calculation. The present theory also provides an estimate of the relative rates of vortex roll up.

Yates, J. E.

"A STUDY OF SCATTERING, PRODUCTION, AND STIMULATED EMISSION OF SOUND BY VORTEX FLOWS"

NASA Contractor Report 3139, May 1979, Aeronautical Research Associates of Princeton, Princeton, NJ.

The basic theory of aeroacoustics of homentropic fluid media is applied to the problem of sound scattering, production, and stimulated emission. A general theory of scattering from low speed three-dimensional vortex flows is presented. Specific results are given for the horseshoe vortex and vortex ring. The noise of an elementary corotating vortex pair in various flows is calculated. It is shown that a potential flow and shear flow can substantially increase the basic pair noise. Small reverse shears can annihilate vortex pairs and eliminate the pair noise mechanism. The pair results are used to explain qualitatively the operation of noise suppression devices. The stimulated emission of a single vortex pair and four and six vortex arrays is demonstrated. The results for six vortices illustrate how external pure tones can amplify the broadband noise of a jet in agreement with recent experimental evidence.

Yates, L. A. and Chapman, G. T.

"STREAMLINES, VORTICITY LINES, AND VORTICES"

AIAA Paper No. 1991-0731, Reno, NV, January 199.

The properties of vortical flows are studied using both theoretical analysis and computational flow fields. The consequences of two definitions of the vortex core, a minimum in the streamline curvature and a maximum in the normalized helicity, are examined. Analysis indicates that several criteria must be met if the cores defined by these two methods are to coincide. In certain regions of the flow, computational flow fields indicate that these two definitions are coincident, that the velocity and vorticity fields are aligned at the core, and that extrema in the velocity magnitude, vorticity magnitude, pressure, and density occur at the core.

Ye, Q.-Y. and Chu, C. K.

"UNSTEADY EVOLUTIONS OF VORTEX RINGS"

Phys. Fluids, Vol. 7, No. 4, April 1995, pp. 795-801

Unsteady evolutions of vortex rings with linearly distributed vorticity and various core parameters are considered in an unbounded, inviscid fluid. The instability of a Norbury vortex with a moderate core thickness parameter is also investigated. Contour integral expressions based on the Biot-Savart law for the velocity field induced by a vortex ring are derived. Numerical results show that all vortex rings except the Norbury vortices will undergo an unsteady evolution process to reach an asymptotic state. The process may be roughly divided into two major stages: initial large deformation stage and later asymptotic oscillating stage. Vortex filamentation is often observed during the first stage. In the second stage, the vortex oscillates periodically with nearly constant amplitude; its core closely resembles a Norbury vortex having the same circulation and impulse, but the dynamic properties and kinetic energies are different.

Yeh, D. T. and Plotkin, A.

"VORTEX PANEL CALCULATION OF WAKE ROLLUP BEHIND A LARGE ASPECT RATIO WING"

AIAA Paper No. 1985-1561, Cincinnati, OH, July 1985

A higher order (linear vortex) panel method is used to calculate the three-dimensional wake rollup behind large aspect ratio symmetric wings in steady inviscid incompressible flow. Triangular shaped panels are chosen to increase the geometric flexibility of the wake sheet. The wing spanwise circulation distribution is obtained from lifting line theory and the wake geometry is then evaluated in an iterative fashion by satisfying conservation of circulation, flow tangency as well as zero pressure jump for all wake panel surfaces in the near wake region (two spans in length). The far wake is modeled by straight semi-infinite vortex filaments that are in the uniform stream direction. Numerical results are shown to compare favorably with those in the literature. The capability of the method to model a rectangular wing with a deflected flap is also studied.

Yemenici, O., Uzol, N. S. and Uzol, O.

"INVESTIGATION OF ROTOR-ROTOR INTERACTIONS FOR TWO HELICOPTERS IN FORWARD FLIGHT USING FREE-VORTEX WAKE METHODOLOGY"

AIAA Paper No. 2010-4558, July 2010, Chicago, Illinois.

This paper presents an investigation of the aerodynamic interactions between two UH-1H helicopter rotors in forward flight. The wake flow structure and performance characteristics of the rotors are investigated when the rear rotor is operating within the wake of the front rotor. A 3-D unsteady vortex-panel method potential flow solver based on a free-vortex-wake methodology is used for this purpose.

The solver is validated using the experimental data from the Caradonna-Tung experiments. The interactional analyses are performed for 10 different positions of the rear rotor with respect to the front rotor. The wake of the front rotor, which is generated due to the mutual interactions of the wake and tip vortices, is significantly asymmetric and non-uniform. Therefore, the rear rotor operates within a complex and vortical free-stream flow. The interaction of the incoming wake flow and the rear rotor generates a large, asymmetric wake region downstream of the rear rotor. The wake-rotor interactions cause substantial variations in the forces generated by the rear rotor. These variations also depend on the lateral variations of the rear rotor with respect to the front one.

Yen, K. T.

"THE AERODYNAMICS OF A JET IN A CROSSFLOW"

NADC-78291-6, December 1978, Naval Air Development Center, Warminster, PA

The aerodynamics of a jet in a crossflow considered as the key problem in transition aerodynamics for VSTOL aircraft has been reviewed. Experimental results on the flow structure of the jet, the contrarotating vortices, the jet entrainment phenomenon, and the surface pressure distributions have been analyzed. The influences on these characteristics by the jet parameters such as the velocity ratio, injection angle and jet orifice shape have been considered based on available measurements. In the theoretical area, particular attention has been directed to the methods of prediction and analysis, and the fundamental physical bases of these methods. Current developments in transition aerodynamics, and some recent work on the formation of contrarotating vortices and the wake flow are described.

Yen, S. C. and Hsu, C. M.

"INVESTIGATION ON VORTEX SHEDDING OF A SWEEP-BACK WING"

Experimental Thermal and Fluid Science, Vol. 31, 2007, pp. 849-855.

Effects of Reynolds number and angle of attack on the vortex shedding of a finite swept-back wing are experimentally studied. The cross-sectional profile of the wing is NACA 0012, and the sweep-back angle is 15 degrees. The time series signals detected by hot-wire in the wake region shows four distinct behaviors: laminar, subcritical, transitional, and supercritical. The derived Strouhal number curves are significantly different in these four behaviors. In addition, the statistical properties of turbulence, that is, the power spectrum density function, probability density function, correlation coefficient, Lagrangian integral time scales, and length scales are also presented in this paper.

Yeshala, N., Egolf, T. A., Vasilescu, R. and Sankar, L. N.

"APPLICATION OF HIGHER ORDER SPATIALLY ACCURATE SCHEMES TO ROTORS IN HOVER"

AIAA Paper No. 2006-2818, San Francisco, CA, June 2006.

The accuracy of the calculation of the tip vortex magnitude and the trajectory is very important in rotor calculations, especially in hover where it is the source of the induced velocity that in turn affects the aerodynamic loads. Lower order schemes do not give results of required accuracy due to the excessive diffusive error on practical grids. As a result, the use of spatially accurate schemes, with less diffusion error, is of prime importance in increasing the accuracy of the solution. In this study, two spatially high order schemes (Weighted Essentially Non-Oscillatory 7th (WENO7) and its 5th order counterpart (WENO5) are studied. Results are presented for performance characteristics and flow field structures. It is found that WENO7 scheme outperforms the 5th order scheme, provided an adequately refined grid with modest stretching factors is used.

"MEASURING ATMOSPHERIC GUSTS AT LOW ALTITUDE"

AIAA Paper 2017-4076, June 2017, Denver, CO.

A small unmanned aerial vehicle was developed with the specific objective to explore atmospheric wind gusts at low altitudes of less than 200 m above ground. The small unmanned aerial vehicle is equipped with an air-data system that has been adapted for this specific application. The air-data system estimates the local wind gusts in the order 0.5 m/s by evaluating inputs from a five-hole probe, an inertial measurement unit, and a system that evaluates the differential carrier frequency phase shift of the GPS signal. The subsequently derived wind gust profiles will be used to improve gust models for the design and operation of small unmanned aerial vehicles. At this point, several successful test flights have been performed using the small unmanned aerial vehicle. Preliminary results of the wind profile and gusts encountered are presented in this paper.

Yeung, A. F. K. and Lee, B. H. K.

"PARTICLE IMAGE VELOCIMETRY STUDY OF WING-TIP VORTICES"

J. Aircraft, Vol. 36, No. 2, March-April 1999, pp. 482-484

Velocity measurements of wing-tip vortices have been obtained successfully in the Institute for Aerospace Research 9 m X 9 m wind tunnel using the Particle Image Velocimetry (PIV) technique. At 14-deg. angle of attack, the wing-tip vortices have been found to be highly unsteady, and the PIV technique has been shown to be an effective tool in obtaining instantaneous measurements of such unsteady flows. Further work is underway to refine its operation and extend its applicability under a wider range of flow conditions.

"PIV STUDY OF WING TIP VORTICES IN THE IAR 9M X 9M WIND TUNNEL"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 91-93

The wing tip vortex of an unswept wing has been studied in the Institute for Aerospace Research (IAR) 9m by 9m wind tunnel using the particle image velocimetry (PIV) technique. The model used was a 14-inch chord, 5-foot (half-) span wing having a NACA0015 profile and mounted vertically on the floor of the test section. The angle of attack was set at 14 degrees. Protected by a Plexiglas casing and mounted on a tripod inside the test section, the PIV camera was placed approximately 6 chord lengths downstream of the measurement plane. The image covers a physical area of 320mm x 240mm, the largest measurement area with acceptable velocity measurements for the present flow configuration and seeding arrangements. The PIV system was used to measure the crossflow components of the wing tip vortex at approximately ten chord lengths downstream of the airfoil. The preliminary results presented in this paper were obtained at a wind speed of 15 mph (6.7 m/s) and a chord Reynolds number of 130,000. Vaporized bay oil, released in the settling chamber through a small nozzle, was used as the seeding material. For the present flow condition, the smoke nozzle was approximately 17 ft above the floor of the 82-ft diameter settling chamber.

"WAKE VORTEX CONTROL USING MODIFIED FLAPS"

Applied Mechanics and Materials, Vols. 365-366, 2013, pp. 827-834.

The present paper is on the experimental investigation of a potentially effective method to alleviate the strength of aircraft wake vortex. The research work was carried out in a water-towing tank which equipped with a 2-D PIV system. By using modified flaps attached to the baseline-airfoil, the Rayleigh-Ludwig instability of the wake vortex was activated, resulting in a premature dissipation of the wake vortex. The experimental results of PIV measurement exhibited that the circulation of the wake vortex was reduced to over 50 percent for the optimal case at 45 wingspans downstream with suitable settings, which proved the effectiveness of the modified-flap treatment in alleviating the wake vortex under labor conditions.

Yi, H., Jinwen, Y. and Feng, B.

"THE INSTABILITY OF A FOUR-VORTEX WAKE SYSTEM IN A WATER TOWING TANK"

Advanced Materials Research, Vols. 756-759, 2013, pp. 1484-1488.

A simplified rectangular baseline-airfoil model attached with tailored flaps was designed to study the Rayleigh-Ludwig instability by tailoring a four-vortex wake system. By means of PIV measurement in a water towing tank, the interaction process and circulation evolution of the wake system were obtained systematically. The circulation remains was reduced to ca. 40 percent after 43 wingspans which proved the application potentials of this method in alleviating the wake vortex.

"NUMERICAL MODELING OF THE IMPULSIVE ORTHOGONAL CUTTING OF A TRAILING VORTEX"

Shock Waves, Vol. 23, 2013, pp. 369-379.

This paper presents inviscid compressible simulations for the impulsive blocking of a vortex, with nonzero axial velocity along its core, by a flat plate orthogonal to the vortex axis. This is a simplified model of the blade-vortex interaction between the tail rotor of a helicopter and the trailing vortex system formed by the main rotor system. There are two important elements to this phenomenon. One is the vortex response, including a physical description for the evolution of complex vortical structures near the plate surface, and the second is the resultant pressure wave structure and the manner of its propagation away from the plate surface. This paper focuses more on the vortex structure, and how this is affected by compressibility and the initial transient shock structures that form at the plate surface.

"VORTEX MOTION, SOUND RADIATION, AND COMPLEX TIME SINGULARITIES"

Phys. Fluids, Vol. A 2, No. 2, February 1990, pp. 214-21.

The equation of motion for interacting point vortices can be embedded in a system of ordinary differential equations with polynomial couplings and thus subjected to the 'Painleve test' for integrability. The arrays of singularities produced by this analysis confirm well known results on integrability and chaos in few-vortex systems, and are shown by further numerical experiments to predict qualitative features of the low Mach number sound radiation from the vortex system. The correspondence between singularity distribution, vortex trajectory pattern, time series of far-field pressure, and sound spectrum are illustrated and discussed based on a parametric numerical survey of some simple three- and four-vortex motions. The results suggest a physical interpretation of the Painleve singularities.

"WAKE VORTEX OBSERVATION CAMPAIGN BY ULTRA FAST-SCANNING LIDAR IN NARITA AIRPORT, JAPAN"

ICAS 2014, September 2014, St. Petersburg, Russia.

The Japan Aerospace Exploration Agency (JAXA) is conducting a wake vortex observation campaign at Narita airport, Japan to evaluate the probabilistic properties of wake vortex behaviors. Based on the probabilistic properties derived from many observation data, the current safe wake vortex separation minima can be revised and airport capacity is increased without any loss of safety. In our observation campaign, an ultra-fast scanning lidar is used to obtain a large number of wake vortex behaviors with high accuracy and temporal resolution. This paper presents an overview of our observation campaign, collected data, and initial analyses.

"AIRCRAFT WAKE VORTEX RETRIEVAL METHOD ON LIDAR LATERAL RANGE-HEIGHT INDICATOR OBSERVATION"

AIAA Journal, Vol. 55, No. 7, July 2017, pp. 2269-2278.

An aircraft wake vortex retrieval method that estimates the horizontal and vertical positions and radii-averaged circulations of wake vortices from lidar-measured Doppler spectra on a lateral range-height indicator is proposed. The method formulates relationships between state variables and measured Doppler spectra for each individual wake vortex and iteratively optimizes the state variables so as to match the measured Doppler spectra. Because the state variables consist of a position, the parameters of an assumed two-dimensional vortex model, and a local background wind, high retrieval accuracy is achieved without adverse influences from errors in the pre-estimation of position or background wind. The separate formulation of each wake vortex enables the method to flexibly handle nonideal cases, for example where only one wake vortex of a pair remains or a long-persistent wake vortex and a newly generated pair of wake vortices coexist on a single range-height indicator. The retrieval results were evaluated against reference flight data from 864 flights collected during a wake vortex observation campaign conducted by the Japan Aerospace Exploration Agency at Narita International airport. The evaluation was performed by an approach using self- and cross-evaluation models, which allowed the evaluation of many retrievals considering time variation of the wake vortex parameters. As a result, the proposed method was found to retrieve horizontal position with a bias error of 0.2 m and a standard error of 4.8 m; vertical position with bias and standard errors of -1.7 and 3.5 m, respectively; and radii-averaged circulation with bias and standard errors of +31.5 and 32.3 square m per s, respectively.

"DETECTION AND ESTIMATION OF WAKE VORTEX ON ULTRA FAST-SCANNING PULSED-DOPPLER LIDAR"

ICAS 2004, Paper 2004-0186, September 2014, St. Petersburg, Russia.

An algorithm for the detection and estimation of a wake vortex using a lateral Range Height Indicator (RHI) observation of a pulsed-Doppler lidar is proposed. By estimating physical parameters from measured Doppler spectra, the proposed method achieves high accuracy and robustness even in low Carrier-to-Noise Ratio (CNR) conditions. This paper describes the methodology and presents an initial evaluation with data collected in a wake vortex observation campaign at Narita Airport, Japan.

"RELATIONSHIP BETWEEN AEOLIAN TONE AND WAKE VORTEX FROM INCLINED FLAT BLADE"

Journal of Fluid Science and Technology, Vol. 4, No. 3, 2009, pp. 775-785.

The three-dimensional structure of the wake vortex was investigated in relating to the aeolian tone from the inclined blade. It was pointed out that the aeolian tone is largest not at zero, but at ten degrees of the inclined angle. The correlation length of the wake vortex in span becomes large at small inclined angles. The large-scale structures of the wake vortex are generated in zero and ten degrees of inclined angle. The shape of the structure is influenced with the span-wise velocity in the dead air region. There are small scale spots of the pressure fluctuation at the trailing edge. The spots are interacted each other and make a large cluster of the pressure fluctuation. It is proposed that the scale of it is decided by the timing of the wake vortex formation. And the shape of the wake vortex structure is closely related with the scale of it. The correlation length of the wake vortex is calculated from the shape of the structure. The estimation of aeolian tone by using the length with Fukano's model is well coincided to experiments.

"MODERN COMPUTATIONAL FLUID DYNAMICS/STRUCTURAL DYNAMICS SIMULATION FOR A HELICOPTER IN DESCENT"

Journal of Aircraft, Vol. 50, No. 5, September-October 2013, pp. 1450-1464.

In this work, several computational-fluid-dynamics-based approaches are employed to validate the airloads, trim angles, blade elastic motions, vortex positions, and structural loads of a rotor in low-speed, descending flight. To this end, two different comprehensive codes, CAMRAD II and DYMORE, are coupled with a computational fluid dynamics code, KFLOW, using a loose coupling methodology. A computational fluid dynamics approach using the measured blade motions is also carried out for the validation. For both clarity and consistency required in the relative comparison between different methods, an identical computational fluid dynamics grid system is used for the study. A fuselage effect is considered in the analysis. The predicted results are correlated against the measured data. CAMRAD II coupling shows good prediction for low-frequency loadings, elastic motions, and structural lag bending and torsion moments. DYMORE coupling demonstrates good matches on trim control angles, blade vortex interaction airloads, and structural flap bending but less satisfactory for lag motions. Initial results indicate poor correlation on aeropitching moments. This discrepancy is seen to be fixed when considering the actual pressure sensor locations used in the test. The blade-vortex miss distance at a desired instant is also evaluated. About 25 percent larger miss distance is obtained with a higher harmonic control input.

Young, L. A.

"ROTOR VORTEX FILAMENTS: LIVING ON THE SLIPSTREAM'S EDGE"

NASA TM- 110431, January 1997, Ames Research Center, Moffett Field, CA

The purpose of this paper is to gain a better understanding of rotor wake evolution in hover and axial flow by deriving an analytical solution for the time dependent behavior of vortex filament circulation and core size. This solution is applicable only for vortex filaments in the rotor far-wake. A primarily

inviscid vortex/shear layer interaction (where the slipstream boundary is modeled as a shear layer) has been identified in this analytical treatment. This vortex/shear layer interaction results in decreasing vortex filament circulation and core size with time. The inviscid vortex/shear layer interaction is shown, in a first-order treatment, to be of greater magnitude than viscous diffusion effects. The rate of contraction, and ultimate collapse, of the vortex filament core is found to be directly proportional to the rotor inflow velocity. This new insight into vortex filament decay promises to help reconcile several disparate observations made in the literature and will, hopefully, promote new advances in theoretical modeling of rotor wakes.

Young, L. A.

"A FAMILY OF VORTICES TO STUDY AXISYMMETRIC VORTEX BREAKDOWN AND RECONNECTION"

AIAA Paper No. 2007-4447, Miami, FL, June 2007

A new analytic model describing a family of vortices has been developed to study some of the axisymmetric vortex breakdown and reconnection fluid dynamic processes underlying body-vortex interactions that are frequently manifested in rotorcraft and propeller-driven fixed-wing aircraft wakes. The family of vortices incorporates a wide range of prescribed initial vorticity distributions -- including single or dual-core vorticity distributions. The result is analytical solutions for the vorticity and velocities for each member of the family of vortices. This model is of sufficient generality to further illustrate the dependence of vortex reconnection and breakdown on initial vorticity distribution as was suggested by earlier analytical work. This family of vortices, though laminar in nature, is anticipated to provide valuable insight into the vortical evolution of large-scale rotor and propeller wakes.

Young, L. A.

"INFLUENCE OF INITIAL VORTICITY DISTRIBUTION ON AXISYMMETRIC VORTEX BREAKDOWN AND RECONNECTION"

AIAA Paper No. 2007-1283, Reno, NV, January 2007

An analytical treatment has been developed to study some of the axisymmetric vortex breakdown and reconnection fluid dynamic processes underlying body-vortex interactions that are frequently manifested in rotorcraft and propeller-driven fixed-wing aircraft wakes. In particular, the presence of negative vorticity in the inner core of a vortex filament (one example of which is examined in this paper) subsequent to 'cutting' by a solid body has a profound influence on the vortex reconnection, leading to analog flow behavior like vortex breakdown phenomena described in the literature. Initial vorticity distributions (three specific examples which are examined) without an inner core of negative vorticity do not exhibit vortex breakdown and instead manifest diffusion-like properties while undergoing vortex reconnection. Though this work focuses on laminar vortical flow, this work is anticipated to provide valuable insight into rotary-wing aerodynamics as well as other types of vortical flow phenomena.

Young, L. A.

"VORTEX CORE SIZE IN THE ROTOR NEAR-WAKE"

NASA/TM-2003-212275, June 2003, NASA Ames Research Center, Moffett Field, CA

Using a kinetic energy conservation approach, several simple analytic expressions are derived for estimating the core size of tip vortices in the near-wake of rotors in hover and axial-flow flight. The influence of thrust, induced power losses, advance ratio, and vortex structure on rotor vortex core size is assessed. Experimental data from the literature is compared to the analytical results derived in this paper.

Young, L. A.

"MODELING OF A TURBULENT LINE VORTEX"

AIAA Paper 2008-3801, June 2008, Seattle, WA.

There is considerable interest in turbulence modeling of vortical structure. The most fundamental of all such structures is the line, or columnar, vortex. Many laminar flow solutions of line vortices have been reported in the literature. Only a few analytical treatments have been presented for turbulent line vortex modeling. More contemporary predictive work has focused on performing highly refined higher-order CFD predictions of vortices for specific areas of interest -- in particular, examining wing/blade-tip trailed vortex roll-up or far-field wake temporal evolution. In almost all cases, the turbulence closure models are not necessarily well suited for the high gradients and rotational effects typical of wing/rotor trailed tip vortices. Recently, though, there have been several computational studies of turbulent vortices that have adopted highly sophisticated direct numerical simulations of the unsteady Navier-Stokes momentum equations. This work has been very promising in terms of understanding not only the mean flow behavior of turbulent vortices but their higher-order characteristics as well. Nonetheless, there remains much still to learn about turbulent vortices in general. In particular, the transition flow mechanism from laminar to fully turbulent vortex states is still largely undetermined. A new analytical approach is suggested in this paper. The result is progress towards a turbulent line vortex model that captures many of the flow features previously observed, predicted, and/or conjectured about this fundamental building block of the vortical fluid flow, including, most importantly, the transition from laminar to turbulent flow states.

Young, L. A.

"VORTEX FILAMENT EVOLUTION SUBJECT TO PULSED/PERIODIC DISRUPTION"

AIAA Paper No. 2008-367, Reno, NV, January 2008

There is considerable interest within the fixed- and rotary-wing research communities as to discovering how fixed- and rotary-wing trailed tip vortices might be modified or controlled. The reasons for attempting such vortical flow control are many but success to date has been very modest. This is primarily the case because the vortical flow physics are still not adequately understood. A new

analytic model describing the flow behavior resulting from pulsed or periodic disruption to line vortices is described. Such vortex filament disruption is manifested in three different forms: spatial cuts or breaks, embedded inner core negative vorticity, and/or sinusoidal varying circulation. These are three possible strategies by which vortex filament strength and geometry can perhaps be modified through passive or active control mechanisms. Finally, an additional analysis is presented that examines the feasibility of destabilizing vortical structures, thereby representing a fourth potential approach for active flow control. The presented work describes a wide array of unsteady flow phenomena that are highly pertinent to the question of active control of trailed rotary- and fixed-wing vortices.

Young, L. A., Yamauchi, G. K. and Rajagopalan, G.

"SIMULATED ROTOR WAKE INTERACTIONS RESULTING FROM CIVIL TILTROTOR AIRCRAFT OPERATIONS NEAR VERTIPORT TERMINALS"

AIAA Paper 2013-0801, January 2013, Grapevine, TX.

A mid-fidelity computational fluid dynamics tool called RotCFD -- specifically developed to aid in rotorcraft conceptual design efforts -- has been applied to the study of rotor wake interactions of civil tiltrotor aircraft in the immediate vicinity of vertiport/airport ground infrastructure. This issue has grown in importance as previous NASA studies have suggested that civil tiltrotor aircraft can potentially have a significant impact on commercial transport aviation. Current NASA reference designs for such civil tiltrotor aircraft are focused on a size category of 90-120 passengers. Notional concepts of operations include simultaneous non-interfering flight into and out of congested airports having vertiports, that is, prepared VTOL takeoff and landing zones, or underutilized short runways for STOL operation. Such large gross-weight vehicles will be generating very high induced velocities. Inevitably, the interaction of the rotor wake with ground infrastructure such as terminal buildings and jetways must be considered both from an operational as well as design perspective.

Youssef, K. S.

"NUMERICAL INVESTIGATION OF THE WAKE OF A RECTANGULAR WING"

PhD Thesis, March 1998, Virginia Polytechnic Institute and State University, Blacksburg, VA.

Wakes of lifting bodies contain vortex sheets that roll up into strong streamwise vortices. The long-time behavior of such vortices depends on the turbulence in the wake and the stability characteristics of the vortices themselves. In the near wake of a rectangular wing the flow field consists of a spiraling wake that winds around a pair of vortex cores. The study of the turbulence structure and life of wing tip vortices is of great importance to air traffic control in congested airports. In this dissertation a computer code is developed for the temporal as well as spatial simulations of trailing vortices. A sixth-order compact finite-difference method is used in the cross plane. The streamwise derivatives are represented either by a Fourier series for temporal simulations (periodic flow) or by a sixth-order compact scheme for spatial simulations. The time marching scheme is a third-order Runge-Kutta

method. The code is used to study the nonlinear development of temporal helical instability waves in a trailing vortex. Contours of a passive scalar are used to study the entrainment process that redistributes angular and axial momenta between the core and its surroundings. Such a process leads to quenching of the instability waves in the vortex core. The code is also used to predict the spatial development of mean flow in the wake of a rectangular wing. New treatment of the outflow boundary condition on the pressure is formulated so that a strong streamwise vortex can exit the computational domain without distortion. Temporal large-eddy simulation (LES) is performed to study the development of large-scale structure in the wake and their interaction with the tip vortex. A modified MacCormack scheme developed by Gottlieb and Turkel (1976) has been used to solve the LES equations. A model of the initial conditions in the near wake of a rectangular wing is devised to investigate mechanisms of turbulence production in the spiral wake around the core of a tip vortex. The model consists of a streamwise vortex sheet whose strength is found from Prandtl lifting line theory. A Gaussian streamwise velocity profile is superimposed on the field of the vortex sheet. This profile represents the spanwise vorticity. The integrated spanwise vorticity of this profile is zero. A novel feature of this study is that the mean flow contains both streamwise and spanwise vorticity. The model is then used to initialize the flow field for temporal LES of the instabilities of the spanwise vorticity during roll up. The results show that the sinuous mode prevails in the spiral wake around the core. The strength and streamwise length scale of the instability vary along the span because of the continuous variation of the wake thickness due to stretching by the tip vortex. The large-scale structures produced by the instability of the spiral wake cause the formation of undulations on the core -- consistent with the hypothesis of Davenport et al. (1996).

Youssef, K. S., Ragab, S. A., Devenport, W. J. and Gawad, A. F. A.

"LARGE EDDY SIMULATION OF THE NEAR WAKE OF A RECTANGULAR WING"

AIAA Paper No. 1998-0317, Reno, NV, January 1998

A model of the initial conditions in the near wake of a rectangular wing is devised to investigate mechanisms of turbulence production in the spiral wake around the core of a tip vortex. The model consists of a streamwise vortex sheet whose strength is found from Prandtl lifting line theory. Spanwise vorticity is represented by a Gaussian streamwise velocity profile that is superimposed on the field of the vortex sheet. The integrated spanwise vorticity of this profile is zero. The model is then used to initialize the flow field for temporal large-eddy simulation of the instabilities of the spanwise vorticity during roll up. The results show that the sinuous mode prevails in the spiral wake around the core. The strength and streamwise length scale of the instability vary along the wake because of the continuous variation in its thickness. The large-scale structures produced by the instability of the spiral wake cause the formation of undulations on the core.

"VISUALIZATION AND MEASUREMENT FOR WINGTIP VORTEX"

Proceedings of 6th Triennial Int'l. Symposium on Fluid Control, Measurement and Visualization, Flucome 2000, August 2000, Sherbrooke, Canada.

The structure of wingtip vortex and the affections of taps on wingtip vortex are studied experimentally. Four different kinds of taps are mounted on the tip of a wing respectively during the experiment. The vortex structure and the damping process of the wingtip vortex are visualized by use of hydrogen bubbles in a towing tank. The azimuthal velocity within the cross sections which correspond to different downstream positions are measured through LDV in a water tunnel. The results from the visualization and measurements indicate that the taps will obviously affect the structure of the wingtip vortex at initial stage but not when the vortex goes downstream. The taps have little affection on the damping process of wingtip vortex.

Yu, Z., Chapelier, J.-B. and Scalo, C.

"COHERENT-VORTICITY PRESERVING LARGE-EDDY SIMULATION OF VORTEX RINGS UNDER LARGE PERTURBATIONS"

AIAA Paper 2018-4035, June 2018, Atlanta, GA.

In this paper, a numerical study of the dynamics of a perturbed vortex ring is conducted using Coherent-vorticity Preserving (CvP) Large-Eddy simulation spanning circulation-based Reynolds numbers in the range 7,000-700,000. The vortex line corresponding to the vortex ring is defined using a parametric equation and perturbed with amplitude in the range of 10-20 percent of the radius. Two types of perturbations are tested: sinusoidal (mode 10) and multi-mode. The Biot-Savart law is employed to define the corresponding induced velocity field. High levels of perturbation yield a transient bursting stage of the original vortex ring and the formation of a new one. The generation of dipoles and different types of vortex reconnection are accurately captured by the CvP-LES. Vortex bursting is observed with large amplitude perturbations at the beginning of simulations. The ejection of dipoles at the inner and outer sides extracts vorticity from the vortex ring which loses its coherence immediately. Dipoles keep growing and the vortex core intensifies in the form of tangled vortex threads up to breakdown, leaving stable dipoles. Dipoles go through a viscous cancellation process and the vortex core is then slightly restored. The reasons of the persistence of coherent structures in all types of perturbations are analyzed. An axial flow, i.e. a flow along the vortex line is detected with multi-mode perturbation simulations, which is driven by the pressure gradient resulting from ejected dipoles and develops from nonuniform locations of pressure sources.

Yu, Z., Qu, Y. and Zhang, Y.

"SAFE CONTROL OF TRAILING UAV IN CLOSE FORMATION FLIGHT AGAINST ACTUATOR FAULT AND WAKE VORTEX EFFECT"

Aerospace Science and Technology, Vol. 77, 2018, pp. 189-205.

In the close formation flight, the wake vortex induced by the leading aircraft will have adverse effects on the safe flight of the trailing unmanned aerial vehicle (UAV). Hence, this paper investigates a

difficult problem of safe control for the trailing UAV against actuator faults, input saturation, and wake vortex effect. By using disturbance observers, external wake vortex, disturbances, and internal actuator faults are estimated. Then, with the help of estimated knowledge of disturbance, backstepping control laws are developed for the longitudinal dynamics and the lateral-directional dynamics, respectively. One of the key features of the proposed strategy is that, the inherent problem, i.e., 'explosion of complexity' in conventional backstepping control, is solved by the presented dynamic surface control scheme. Another key feature is that external wake vortex, disturbances, and internal actuator faults, input saturation are simultaneously considered. It is shown by Lyapunov stability analysis that the closed-loop system is uniformly ultimately bounded with safety requirements guaranteed even in the presence of wake vortex and actuator faults. The effectiveness of the proposed approach is further validated by simulation results.

Yuan, S. W.

"VORTEX CONTROL"

US Patent 3,936,013, February 1976.

This invention is for wings of all types, such as fixed wings for aircraft and hydrofoil boats, and rotary blades (or wings) for helicopters and turbines, to be equipped with a slotted tube, or a tube with series of holes extending outwardly in the spanwise direction near the trailing edge of the wing tip for blowing jets of fluid (such as air or water) in the direction opposite to the lift of the wing, thereby achieving flow in the form of a jet sheet to abate, diffuse and break up the undesirable wing-tip or blade-tip vortices.

Yuan, S. W.

"VORTEX POLLUTION-WING-TIP VORTICES: THE HAZARD AND THE REMEDY"

Aeronautical Soc. of India Journal, Vol. 23, May 1971, pp. 67-70

A device has been developed for controlling wing tip vortices, and its effectiveness has been verified by wind-tunnel testing. Multiple apertures (or a continuous slot) extending along the chordwise direction of the wing tip are used for blowing tangential jets of gas at preselected locations. Rows of vortices are thus produced to counterbalance the undesirable wing-tip vortices. The small amount of gas required can be bled off from the jet engine through a conduit, or it can be generated locally. The system improves lift efficiency and increases the volume of airport landing and takeoff operations by shortening the separation requirements dictated by vortex hazards.

Yuan, S. W.

"WING-TIP VORTICES CONTROL"

US Patent 3,692,259, September 1972.

This invention is for wings of all types, such as fixed wings for aircraft and hydrofoil boats, and rotary blades (or wings) for helicopters and turbines, to be equipped with a row of chordwise tangential jets along the edge or end surfaces of the wing tips for counter-balancing and controlling the wing-tip or blade-tip vortices.

Yuan, S. W. and Bloom, A. M.

"EXPERIMENTAL INVESTIGATION OF WING-TIP VORTEX ABATEMENT"

International Council of the Aeronautical Sciences, Paper 74-35, Haifa, Israel, 1974.

Detailed measurements of aerodynamic forces and downstream velocity distributions of a model airplane with and without vortex abatement device have been made. Time-mean-average velocity components were measured, using an triple-sensor hot film probe, at 1/2-chord and 5-chord distances behind the trailing edge of the wing. The results of these tests clearly indicate that not only does the vortex abatement device reduce greatly the size of the wing-tip vortex but also the strength of the vortex core. The effect of the vortex abatement device also results in a considerable increase in lift and decrease in drag.

Yue, L., Junwei, W., Zhirong, L. and Feng, B.

"EXPERIMENTAL INVESTIGATION OF WAKE VORTEX IN A WATER-TOWING-TANK"

Proceedings SPIE, Vol. 8417, 6th International Symposium on Advanced Optical Manufacturing and Testing Technologies, October 2012, pp. 84172Y-1 - 84172Y-8.

Wake vortex behind an aircraft would introduce great hazard to the following aircraft and threat to the flight safety. Generic model using two rectangular airfoils was employed for generating wake vortex system to investigate the method of wake vortex alleviation. The investigation was carried out in a water towing tank equipped with Particle Image Velocimetry system. Characteristics of double-vortex flow were analyzed for selected cases, proving that the intensity of the vortex is reduced with respect to the interaction between the wake vortices. The study exhibited that the R-L instability was most effectively triggered with parameter combinations of angles of attack 10 and 8 degrees and $b = 50\text{mm}$ respectively. As a result, the circulation of the wake vortices was alleviated by nearly 40 percent accordingly.

Yuen, H. C.

"WAVES ON VORTEX FILAMENTS"

Ph.D. Thesis, May 1973, California Institute of Technology, Pasadena, CA

Various problems concerning waves on vortex filaments are considered. The local force balance method introduced by Moore and Saffman for the calculation of the induced velocity at a point of a

vortex filament with arbitrary structure and shape is used to examine the effect of axial flow on the stability of trailing vortices and vortex rings. It is found that the effect is small in both cases.

Zaitsev, M. Y., Kop'ev, V. F. and Kotova, A. N.

"REPRESENTATION OF THE SOUND FIELD OF A TURBULENT VORTEX RING AS A SUPERPOSITION OF QUADRUPOLES"

Acoustical Physics, Vol. 47, No. 6, 2001, pp. 699-706

Results of an experimental study of the directivity of noise produced by a turbulent vortex ring ($Re = 100,000$) are presented. The acoustic measurements were performed in an anechoic chamber by a circular array of microphones with its center lying at the symmetry axis of the ring. A method of a synchronous processing of acoustic signals is proposed. This method allows one to separate different quadrupole components in the measured sound field of a turbulent vortex.

Zak, J. A.

"ATMOSPHERIC BOUNDARY LAYER SENSORS FOR APPLICATION IN A WAKE VORTEX ADVISORY SYSTEM"

NASA/CR-2003-212175, April 2003, Vigyan, Inc., Hampton, VA.

Remote sensing of the atmospheric boundary layer has advanced in recent years with the development of commercial off-the-shelf (COTS) radar, sodar, and lidar wind profiling technology. Radio acoustic sounding systems for vertical temperature profiles of high temporal scales (when compared to routine balloon soundings (radiosondes)) have also become increasingly available as COTS capabilities. Aircraft observations during landing and departures are another source of available boundary layer data. This report provides an updated assessment of available sensors, their performance specifications and rough order of magnitude costs for a potential future aircraft Wake Vortex Avoidance System (WakeVAS). Future capabilities are also discussed. Vertical profiles of wind, temperature, and turbulence are anticipated to be needed at airports in any dynamic wake avoidance system. Temporal and spatial resolution are dependent on the selection of approach and departure corridors to be protected. Recommendations are made for potential configurations of near-term sensor technologies and for testing some of the sensor systems to validate performance in field environments with adequate ground-truth.

Zak, J. A. and Rodgers, Jr., W. G.

"ATMOSPHERIC BOUNDARY LAYER WIND DATA DURING THE PERIOD JANUARY 1, 1998 THROUGH JANUARY 31, 1999 AT THE DALLAS-FORT WORTH AIRPORT. VOLUME 2 - DATA AND PROCESSING"

NASA/CR-2000-210323 Vol. 2, August 2000, Vigyan, Inc., Hampton, VA.

The NASA Langley Research Center's Aircraft Vortex Spacing System (AVOSS) requires accurate winds and turbulence to determine aircraft wake vortex behavior near the ground. Volume 1 described the wind input and quality analysis process. This volume documents the data available during the period January 1998 through January 1999 and the partitioning and concatenation of files for time of day, turbulence, non-duplication, cross wind profile quality and ceiling and visibility. It provides the resultant filtered files for the first three partitions as well as identification of ceiling/visibility conditions when they were below 5000 feet and 5 miles respectively. It also includes the wind profile quality flags to permit automatic selection of files for AVOSS application using selected ceiling/visibility and wind profile quality values and flags (or no flags).

Zak, J. A. and Rodgers, Jr., W. G.

"PREPROCESSING FOR EDDY DISSIPATION RATE AND TKE PROFILE GENERATION"

NASA CR-2001-210834, March 2001, NASA Langley Research Center, Hampton, VA

The Aircraft Vortex Spacing System (AVOSS), a set of algorithms to determine aircraft spacing according to wake vortex behavior prediction, requires turbulence profiles to appropriately determine arrival and departure aircraft spacing. The ambient atmospheric turbulence profile must always be produced, even if the result is an arbitrary (canned) profile. The original turbulence profile code was generated by North Carolina State University and used in a non-real time environment in the past. All the input parameters could be carefully selected and screened prior to input. Since this code must run in real-time using actual measurements in the field as input, it became imperative to begin a data checking and screening process as part of the real-time implementation. The process described herein is a step towards ensuring that the best possible turbulence profile is always provided to AVOSS. Data fill-ins, constant profiles and arbitrary profiles are used only as a last resort, but are essential to ensure uninterrupted application of AVOSS.

"OBSERVED CHANGES IN ATMOSPHERIC BOUNDARY LAYER PROPERTIES AT MEMPHIS INTERNATIONAL AIRPORT DURING AUGUST 1995"

NASA CR-4786, September 1997, pp. 68

As part of the NASA Terminal Area Productivity Program, Langley Research Center embarked on a series of field measurements of wake vortex characteristics and associated atmospheric boundary layer properties. One measurement period was at the Memphis International Airport in August 1995. Atmospheric temperature, humidity, winds, turbulence, radiation, and soil properties were measured from a variety of sensor systems and platforms including sodars, profilers, aircraft, and towers. This

research focused on (1) changes that occurred in tower data during sunrise and sunset transitions, (2) vertical variation of temperature and cross-head winds at selected times utilizing combinations of sensors, and (3) changes measured by an OV-10 aircraft during approaches and level flights. Significant but not unusual changes are documented and discussed in terms of expected boundary layer behavior. Questions on measurement and prediction of these changes from existing and near-term capabilities are discussed in the context of a future Aircraft Vortex Spacing System.

"DOCUMENTATION OF ATMOSPHERIC CONDITIONS DURING OBSERVED RISING AIRCRAFT WAKES"

NASA CR-4767, April 1997, ViGYAN, Inc., Hampton, VA

Flight tests were conducted in the fall of 1995 off the coast of Wallops Island, Virginia, to determine characteristics of wake vortices at flight altitudes. A NASA C-130 aircraft equipped with smoke generators produced visible wakes at altitudes ranging from 775 to 2225 m in a variety of atmospheric conditions, orientations (head wind, cross wind), and airspeeds. Meteorological and aircraft parameters were collected continuously from an OV-10A aircraft as it flew alongside and through the wake vortices at varying distances behind the C-130. Vortices were observed to rise at distances beyond a mile behind the C-130. The maximum altitude was 150 m above the C-130 in a near neutral atmosphere with significant turbulence. There were several cases when the vortices did not descend after a short initial period and remained near generation altitude in a variety of moderately stable atmospheres and wind shears.

"ATMOSPHERIC BOUNDARY LAYER WIND DATA DURING THE PERIOD JANUARY 1, 1998 THROUGH JANUARY 31, 1999 AT THE DALLAS-FORT WORTH AIRPORT - VOLUME 1 - QUALITY ASSESSMENT"

NASA/CR-2000-210323, Vol. 1, August 2000, Vigyan, Inc., Hampton, V.

The quality of the Aircraft Vortex Spacing System (AVOSS) is critically dependent on representative wind profiles in the atmospheric boundary layer. These winds observed from several sensor systems around the Dallas-Fort Worth airport were combined into single vertical wind profiles by an algorithm developed and implemented by MIT Lincoln Laboratory. This process, called the AVOSS Winds Analysis System (AWAS), is used by AVOSS for wake corridor predictions. During times when AWAS solutions were available, the quality of the resultant wind profiles and variance was judged from a series of plots combining all sensor observations and AWAS profiles during the period 1200 to 0400 UTC daily. First, input data was evaluated for continuity and consistency from criteria established. Next, the degree of agreement among all wind sensor systems was noted and cases of disagreement identified. Finally, the resultant AWAS solution was compared to the quality-assessed input data. When profiles differed by a specific amount from valid sensor consensus winds, times and altitudes were flagged. Volume one documents the process and quality of input sensor data. Volume two documents the data processing/sorting process and provides the resultant flagged files.

"OPERATIONAL PERFORMANCE OF SENSOR SYSTEMS USED TO DETERMINE ATMOSPHERIC BOUNDARY LAYER PROPERTIES AS PART OF THE NASA AIRCRAFT VORTEX SPACING SYSTEM PROJECT"

NASA CR-2001-210835, March 2001, NASA Langley Research Center, Hampton, VA.

There has been a renewed interest in the application of remote sensor technology to operational aviation and airport-related activities such as AVOSS. Radio Acoustic Sounding Systems (RASS), Doppler-acoustic sodars, UHF profilers and lidars have many advantages in measuring wind and temperature profiles in the lower atmospheric boundary layer since they can operate continuously and unattended; however, there are limitations in their operational use at airports. For example, profilers deteriorate (limited altitude coverage or missing) in moderate or greater rain and can be affected by airplane targets in their field of view. Sodars can handle precipitation better but are affected by the high noise environments of airports and strong winds. Morning temperature inversions typically limit performance of RASS, sodars and profilers. Fog affects sonic anemometers. Lidars can have difficulties in clouds, fog or heavy precipitation. Despite their limitations these sensors have proven useful to provide wind and temperature profiles for AVOSS. Capabilities and limitations of these and other sensors used in the AVOSS program are discussed, parameter settings for the sensor systems are documented, and recommendations are made for the most cost-effective group of sensors for the future. The potential use of specially tuned dynamic forecast models and measurements from landing and departing aircraft are addressed.

"OBSERVED AIRCRAFT RISING WAKES AT FLIGHT ALTITUDES"

Proceedings of the 8th Conference on Aviation, Range, and Aerospace Meteorology, Dallas, TX, January 1999

Flight tests were conducted in the fall of 1995 off the coast of Wallops Island, Virginia, to measure characteristics of wake vortices at flight altitudes. A NASA Wallops Flight Facility C-130 aircraft equipped with smoke generators produced visible wakes at altitudes ranging from 775 to 2225 m in a variety of atmospheric conditions, orientations (head wind, cross wind), and airspeeds. Meteorological data and aircraft parameters were collected from a Langley Research Center OV-10A aircraft as it flew alongside and through the wake vortices at varying distances behind the C-130. Meteorological data were also obtained from special balloon observations at Wallops Island. Differential GPS was used on each aircraft to obtain altitude profiles. Vortices were observed to rise at distances as close as 500 m behind the C-130. The wake was observed to be 150 m higher than the C-130 on one occasion at a distance of 11 km behind. The rising motion on this day was due to large vertical oscillations in the wakes. The atmospheric conditions were near neutral stratification with significant turbulence. There were several cases when the vortices did not descend after the first few minutes, and they remained near generation altitude in a variety of moderately stable atmospheres and wind shears. The FAA Wake Turbulence Training Aid is currently under revision to incorporate some of the data from this research.

"A NOTE ON VORTEX MERGING"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 78-83

Inviscid merging of two, initially circular regions of a constant vorticity distribution have been investigated numerically and analytically using integral invariants of vorticity distribution in two-dimensional ideal fluid flow. Main factors affecting the merging process have been identified. Bifurcation diagram is shown in the plane of governing parameters. Generation of a resulting circular vortex with the area equal to the sum of the original vortices area has been proven.

Zakharov, V. E.

"QUASI-TWO-DIMENSIONAL HYDRODYNAMICS AND INTERACTION OF VORTEX TUBES"

Lecture Notes in Physics, Vol. 536, 1999, pp. 369-385

One motivation relates to the classical problem of the 'blow-up' in the Euler equation. According to the most plausible scenario, in the point of blow-up the vorticity becomes infinite. As far as vorticity is a vector, this assumption presumes that the flow near the blow-up point is almost two-dimensional and the velocity field is concentrated mostly in the plane orthogonal to the vorticity vector. An elaboration of this regular tool for description of this type of flow looks very timely. Another motivation is the vortex dynamics. This is a subject which has a chance to become the backbone of the future theory of turbulence. Probably, there is no way to explain qualitatively and quantitatively the fundamental phenomenon of intermittency but a careful study of the dynamics of the vortex tubes or their systems in a real three-dimensional nonstationary flow.

Zalay, A. D.

"HOT-WIRE AND VORTICITY METER WAKE VORTEX SURVEYS"

AIAA Journal, Vol. 14, May 1976, pp. 694-696

The vorticity meter used in the experiments consists of a paddle-wheel sensor mounted on a rotating shaft and fitted with a jeweled bearing. Vorticity data for a trailing vortex obtained with the vorticity meter are presented in a graph, considering an injected and a basic vortex. The tangential and axial velocity profile of a trailing vortex, as determined with the aid of a three-component hot-wire anemometer system, is shown, and a comparison is conducted regarding the vortex circulation strength calculated from vorticity meter and hot-wire measurements.

Zalay, A. D.

"EXPERIMENTAL INVESTIGATION OF THE DECAY OF A VORTEX PAIR"

M.S. Thesis, June 1970, Mass. Institute of Technology, Cambridge, MA

Simulation, visualization, and qualitative measurements of the decay process of a pair of trailing vortices is outlined in this report. The vortex pair is generated in the laboratory by a tank piston arrangement. A titrated iodine starch solution and electrically pulsed plates are used to create a dark dye locally which is caught up in the vortex core and permits visualization of the decay process. Actual measurements of core size and velocity distribution are made by means of constant temperature hot wire probes and motion pictures. Experimentally measured wave lengths and wave amplitude growth rates for the vortex pair are compared against a linearized model of mutual and self-induction.

"INVESTIGATION OF VISCOUS LINE VORTICES WITH AND WITHOUT THE INJECTION OF CORE TURBULENCE"

RASA Report 74-01, February 1974, Rochester Applied Science Associates, Rochester, NY

An experimental research program was conducted to investigate the general characteristics of a line vortex trailed from a three-dimensional lifting surface, and to determine how its general velocity distribution, turbulence level, turbulent frequency content, and dissipation rates are affected by the injection of a jet of turbulent air and by a fixed turbulence generator. Three component hot-wire surveys indicated that injection of the vortex core reduced the peak tangential velocity, established a strong axial flow component, increased the core diameter, altered the turbulence spectrum, and enhanced the turbulence level in the viscous core.

"VORTEX WAKE RESEARCH"

Flight Mechanics Symposium on Flight in Turbulence, AGARD, CP-140, 1973, pp. 13-1 to 13-14

Recent NASA investigations of aircraft trailing vortices are reviewed. Some results obtained in flight on vortex characteristics, such as decay of maximum velocity and vortex drift, are presented for distances behind a generating C-5A airplane from 0.6 to 13.0 nautical miles. The lateral control activity of a CV-990 airplane probing the vortices generated by a C-5A airplane is illustrated and the effect of the C-5A aircraft configuration on this activity is indicated. The roll response at various distances behind a generating aircraft and the separation distance for limit controllability of small and medium size aircraft (Cessna 210, Learjet, DC-9, and CV-990) are related to the initial circulation of the generating aircraft. Some results are presented from near-field and far-field studies on accelerated vortex dissipation through the use of various devices such as mass ejection, spoilers, vortex generators, trailing drag devices, and so forth.

"EXPERIMENTAL STUDY OF TIP VORTEX FLOW FROM A PERIODICALLY PITCHED AIRFOIL SECTION"

AIAA Paper 2016-1846, January 2016, San Diego, CA.

An experimental investigation of a tip vortex from a NACA0012 airfoil is conducted in a low-speed wind tunnel at a chord Reynolds number of 40000. Initially, data for a stationary airfoil held at various angles-of-attack are gathered. Detailed surveys are done for two cases: angle of attack of 10 deg with attached flow and angle of attack of 25 deg with massive flow separation on the upper surface. Distributions of various properties are obtained using hot-wire anemometry. Data include mean velocity, streamwise vorticity and turbulent stresses at various streamwise locations. For all cases, the vortex core is seen to involve a mean velocity deficit. The deficit apparently traces to the airfoil wake, part of which gets wrapped by the tip vortex. At small angle of attack, the vortex is laminar within the measurement domain. The strength of the vortex increases with increasing angle of attack but undergoes a sudden drop around angle of attack greater than or equal to 16 deg. The drop in peak vorticity level is accompanied by transition and a sharp rise in turbulence within the core. Data are also acquired with the airfoil pitched sinusoidally. All oscillation cases pertain to a mean angle of attack of 15 deg while the amplitude and frequency are varied. An example of phase-averaged data for an amplitude of ± 10 deg and a reduced frequency of $k=0.2$ is discussed. All results are compared with available data from the literature shedding further light on the complex dynamics of the tip vortex.

"REAL RESEARCH OF DIFFERENT CLASS AIRPLANE VORTEX WAKES AT LOW ALTITUDES"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 45-1 - 45-12.

The paper is intended to investigate airplane wake vortex in real flight at low altitudes. The paper is aimed at obtaining real flight data for wake vortex generation, development and decay processes of an airplane flying at modes approaching the takeoff and landing ones. The acquired data are anticipated to be used in designing means of affecting the wake vortex structures to decrease their unfavorable effects on other flying airplanes, as well as in developing mathematical models of the airplane wake processes. To perform studies special techniques were worked out which allow synchronous measurements of spatial kinematic and geometrical wake characteristics, airplane flight and environmental parameters to be made. The techniques use the hot-wire method for measuring the instant velocity, a method of wake visualization and a stereophotogrammetric survey method. Using these methods, wake vortices of two classes of airplanes were studied: a medium-haul Tu-124 weighing about 35,000 Kgs and a light highly maneuverable L-39 with a weight of 3,500 Kgs. Flights were performed at altitudes below 400 m.

"FULL-SCALE STUDIES OF STRUCTURE AND DEVELOPMENT OF A VORTEX WAKE OF A MEDIUM TRUNK-ROUTE AIRCRAFT IN THE ATMOSPHERIC BOUNDARY LAYER"

Proceedings of International Council of the Aeronautical Sciences, 14th Congress, Toulouse, France, September 9-14, 1984, pp. 268-273.

This paper describes the developed complex technique, and the results of a full-scale investigation of a vortex wake of a medium trunk-route aircraft are presented. The results of the investigation are the basis for a schematic division of a vortex wake development process into five phases. Qualitative and quantitative characteristics are obtained for each phase of vortex wake development which define the wake structure. The investigation allowed determination of flight parameter and atmospheric condition effects on the vortex wake phase extent.

"PECULIARITIES OF AIRPLANE VORTEX WAKES AND CONDENSATION TRAILS INTERACTION AND THEIR MATHEMATICAL MODELING"

Proceedings of the 2nd International Conf. on Transport, Atmosphere and Climate (TAC-2), edited by Sausen, R., van Velthoven, P. F. J., Bruning, C. and Blum, A., June 2009, Aachen, Germany and Maastricht, The Netherlands, pp. 203-216.,

The unique photos, demonstrating air flow peculiarities in aircraft aerodynamic wake vortex, are presented in the report. On the bases of these materials analysis and basing on obtained in flight the quantitative data and calculation wake models results, there are presented the patterns of air flow development and structure in aircraft aerodynamic wake. It is shown that scheme of formed aircraft wake vortex structure could be presented as two independent air flow areas. These areas are separated by closed current surface. First -- more spacious area corresponds to practically plane spiral flows, consisting of two vortices of opposite direction. The second one is in the small area of vortices axis and corresponds to spatial flow with circumferential flow velocities, analogous to solid body rotation and with intensive alternating axial flows. Presented in the report are pictures, obtained in real flight conditions with the help of visualization, demonstrating interaction of wake vortex and contrail for aircraft of different types. It is shown that depending on engine location at the aircraft, the contrail could practically do not interact with aerodynamic wake, mainly being captured by external flow and dissipated at relatively small distances from aircraft. Contrail could also be captured by external vortex flow, then got to vortices nuclei and hold them rather long. Examples of mathematical modeling of a vortex wakes of the airplane, based on MDV utilization are presented in the report, in view of influence of engines jets and conditions of an atmosphere. As an example of wakes calculation for airplanes A-310, A-380 and SSJ-100, the qualitative agreement of results of calculations and visualization of streams in wakes is shown. It indicates a possibility of usage and perfection of this method of calculation for the purposes of model creation, account of wake vortices interaction with contrails both in near and far wake, down to their destruction.

"MATHEMATICAL MODEL OF AIRCRAFT WAKE VORTICES DEVELOPMENT FOR TAKE-OFF/LANDING PHASES FOR WAKE VORTEX SAFETY SYSTEMS"

ICAS 2014, September 2014, St. Petersburg, Russia.

One of the most important areas of research in aviation technology is an increase of air traffic control efficiency and flight safety provision in vicinity of airfields for take-off/landing flight phases, i.e. in conditions of possible entering of aircraft into wake vortices of other aircraft. Elaboration of wake vortex safety systems (WVSS) is rather effective solution of this problem. Math model of aircraft wake vortex is the main component of WVSS. The model should provide reliable information on intensity and spatial location of dangerous vortices areas. Calculation results should be available in real time scale. Presented in the paper is the detailed description of math model of aircraft wake vortices' development. Examples of calculations of wake vortices characteristics for various aircraft, flight conditions and atmospheric states are presented. It is noted that the model elaborated could be utilized in WVSS both for the take-off/landing flight phases and for cruise flight conditions during aircraft flight along flight routes.

"RARE EVENT SIMULATION FOR POTENTIAL WAKE ENCOUNTERS"

Proceedings of the 2017 Winter Simulation Conference, Institute for Operations Research and the Management Sciences, December 2017, Las Vegas, NV, pp. 2554-2565.

A flying aircraft produces two coherent rotating vortices of air in its trail. If another aircraft flies into one of these vortices, it can experience an un-commanded roll. Because of the potential risk, wake separation standards exist to significantly reduce the probability of such events. Thus, wake encounters are inherently rare. As new procedures and technologies are proposed to increase the capacity of the airspace, rare-event simulation is necessary to evaluate to the safety of proposed changes. This paper explores the performance of a rare-event splitting technique in the context of estimating probabilities of potential wake encounters. The goal is to identify good strategies for the splitting method while using a relatively simple model for the wakes. Suggestions for the choice of the level function and the locations of levels are given.

"INTERFERENCE OF VORTICES WITH SHOCKS IN AIRSCOOPS; DISSIPATION OF VORTEXES"

Fluid Mechanics-Soviet Research, Vol. 7, No. 4, July-August 1978, pp. 153-158.

The dissipation of vortex filaments upon crossing strong shock fronts is described. It is shown that a stagnation zone with a conical shock develops in the free stream. The flow in the detachment zone approaches that which occurs when a turbulent boundary layer is detached from a surface. It is shown that the interference of the vortex filament with the shock in air scoop can have a deleterious effect on performance.

"METHODS OF STUDYING AN AIRPLANE VORTEX WAKE STRUCTURE IN FLIGHTS AT LOW ALTITUDES"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 21-1 - 21-12.

Vortex wake is a source of hazards for airplanes flying into it, so vortex wake research is urgent. Actual (flight) wake data are the most reliable basis for developing methods to reduce its adverse effects. For civil aviation, of prime interest is the wake effects in flying at low altitudes: just over the runway (0 to 20 m), and in the takeoff and approach area (0 to 300 m). Vortex wake is a rather complex physical phenomenon, the research of which requires a special procedure. The procedure must provide for the following three groups of measurements: the wake characteristics recording, measuring the flight parameters of the airplane generating vortex wakes, and meteorological data acquisition in the wake development region. To estimate wake flow velocity vectors, hot film anemometers were used. To record the vortex core geometry, smoke visualization and stereophotogrammetric survey methods were used.

Zeman, O.

"PROGRESS IN THE MODELING OF PLANETARY BOUNDARY LAYERS"

Annual Review of Fluid Mechanics, Vol. 13, 1981, pp. 253-172.

Comparison of various turbulence-simulation techniques favors second-order modeling as the practical computational method in applications to planetary boundary layers. Still, the complexity of the dynamics of planetary boundary layers presents several challenging problems for second-order modeling. Some of these yet to be resolved are (1) Identification and separation of the surface effects from the effects due to large anisotropy or inhomogeneity on pressure terms (because the near-surface contributions to the pressure terms involve the surface pressure, these contributions could be measured). (2) The effect of stratification on turbulence dynamics near the critical Richardson number. How are the turbulence-energy spectrum and the dissipation rate altered in this stable limit with respect to the neutral conditions? (3) Modeling the effects of large eddy-surface interactions in convective boundary layers by exploring models that allow for anisotropy of turbulence scales and of dissipation partitioning among the energy components. (4) Apart from the theoretical (linear) models, the actual buoyancy contributions in the pressure terms are largely unknown. It would be useful to attempt to identify these buoyancy contributions with the aid of large-eddy or direct turbulence simulations.

Zeman, O.

"THE PERSISTENCE OF TRAILING VORTICES: A MODELING STUDY"

Phys. Fluids, Vol. 7, No. 1, January 1995, pp. 135-143

The principal subject of this paper is analysis and modeling of turbulent wing tip vortex flows in a far-field region of the vortex evolution. The choice of a Reynolds stress closure (RSC) to model the vortex turbulence is shown to be indispensable for representation of the flow rotation effects on turbulence. The principal result reported is the model-experiment comparison of the vortex growth rates for different vortex Reynolds numbers. The mean vortical flow generated by the wing tip very effectively suppresses the Reynolds shear stress, which mediates the extraction of energy from the mean flow by turbulence. In consequence, the vortex-core growth rate is controlled only by molecular viscosity and the vortex turbulence decays since the turbulence production rate is very nearly zero. This rather unexpected result is shown to be supported by experiments. Finally, it is shown that the computed turbulence structure is consistent with experimental data at the NASA Ames Research Center.

Zemtsop, C. P., Stollinger, M. K., Heinz, S. and Stanescu, D.

"LARGE-EDDY SIMULATION OF SWIRLING TURBULENT JET FLOWS IN ABSENCE OF VORTEX BREAKDOWN"

AIAA Journal, Vol. 47, No. 12, December 2009, pp. 3011-3021.

This paper reports the results of numerical investigations of swirling turbulent jet flows by large-eddy simulation. Reynolds-averaged Navier-Stokes simulations are used to generate mean inflow data. Fluctuations are added to the profiles of the means to produce instantaneous inflow data. The instantaneous inflow data are correlated such that the characteristic length and time scales of inflowing turbulent eddies are consistent with the corresponding Reynolds-averaged Navier-Stokes profiles imposed at the inlet. The resulting large-eddy simulation method is validated against experimental data of both swirling and nonswirling turbulent jets. The application of the validated large-eddy simulation method to studies of the mechanism of swirl effects shows the following. Swirl breaks apart the typical ring structures of nonswirling turbulent jets into two modes: a helical mode and streamwise braid structures. The interaction of these two modes generates unorganized turbulence that enhances the turbulent mixing. An analysis of the mixing enhancement by swirl shows a significant increase of the turbulent mixing efficiency of scalars with the swirl number (of up to 21.7 percent for the cases considered).

"THE INVESTIGATION OF DIFFERENT WING-LETS IMPACT ON WING TIP VORTEX"

Proceedings of the International Conference on Service Robotics Technologies (ICSRT 2018), March 2018, Chengdu, China, pp. 22-26.

In the present work, the formation of the wing-tip vortex from a rectangular NACA0015 wing with a square tip at Re (Reynolds number) = 200,000 and AOA (angle of attack) = 15 degrees were simulated, with a Spalart-Allmaras turbulence model by using of ANSYS FLUENT. Numerical results showed that the wing-lets can break up tip vortex effectively and increase the Lift coefficient, reduce the Drag coefficient. The present study suggested that under the same calculation cost, the most excellent

achievement was grasped with three wing-lets on NACA0015 airfoil at AOA = -15 degrees, the vorticity and drag coefficient reduced by 75% and 9%, respectively, and lift coefficient increased about 27%.

Zhang, B., Song, Z. and Li, J.

"LASER-ULTRASONIC METHOD FOR VORTEX MEASUREMENTS"

Proceedings Third Pacific International Conf. on Aerospace Science and Tech., Shaanxi Science and Tech. Publishing House, Xian, China, September 1997, pp. 5-53

A laser-ultrasonic method is used to measure the vortex flow in wind tunnel tests. The principle of the method is based on the measurement of the flow-induced travel time differences of the ultrasonic signals propagating between two or more laser beams. An advantage of this method is that there is no need to inject particles into the flow field. This method can measure any position in the flow field, including the vortex core. Therefore, the method is used to investigate vortex breakdown and the stability of vortices, and to determine the velocity, vorticity, circulation distribution, and inner structure of a vortex. A test result for the flow field of a ducted fan indicates that this method can obtain the velocity distribution and the swirling structure of this flow field.

Zhang, B., Tang, Q., Chen, L-P. and Xu, M.

"NUMERICAL SIMULATION OF WAKE VORTICES OF CROP SPRAYING AIRCRAFT CLOSE TO THE GROUND"

Biosystems Engineering, Volume 145, March 2016, Pages 52-64.

A study of the velocity field of the wake of a Thrush 510G carrying out spray application close to the ground was investigated. The aircraft normally operates in extreme ground effect and wake vortices play a major role in the dispersal and deposition of pesticide spray released behind the aircraft. The evolution of wake vortices over time, and their interaction with the ground were simulated using computational fluid dynamics (CFD) techniques. The simulation was initialized with meteorological data from a field experiment. Information given by CFD simulation included the trajectory of the wake vortices as well as circulation, which indicates the strength of vortex. This information provided insights into the velocity field in the wake, including the upwash near the wing tips and the downwash in between. The effect of turbulence intensity as well as crosswind on the wake vortices and the resulting velocity field were investigated.

Zhang, H. J., Zhou, Y. and Whitelaw, J. H.

"NEAR-FIELD WING-TIP VORTICES AND EXPONENTIAL VORTEX SOLUTION"

Journal of Aircraft, Vol. 43, No. 2, March-April 2006, pp. 445-449

Vortices shed from the tip of a rectangular half-span wing model (NACA 0012) have been investigated with particle image velocimetry at a chord Reynolds number between $3.4 \times 10,000$ and $26.6 \times 10,000$ and angles of attack = 8 and 16 deg over 0.2 to 5 chord lengths downstream of the model. It has been

found that the measured wing-tip vortex shows little dependence in the circumferential velocity and vorticity, when normalized by their local maximum, on the angle of attack, Reynolds number, and downstream distance from the wing. Furthermore, the radial distributions of circumferential velocity and vorticity coincide quite well with the exponential vortex solution, with only a slight departure outside the core region.

Zhang, M., Cheng, L. and Zhou, Y.

"CLOSE-LOOP CONTROL OF VORTEX - AIRFOIL INTERACTION NOISE"

Journal of Hydrodynamics, Vol. 18, Issue 3, Supplement 1, July 2006, pp. 430-437

Closed-loop controlled interactions between an airfoil and impinging vortices were experimentally investigated. This work aims to minimize the fluctuating flow pressure (p) at the leading edge of the airfoil, which is a major source of the blade-vortex interaction noises commonly seen in rotorcrafts. Piezo-ceramic actuators were used to create a local surface perturbation near the leading edge of the airfoil to alter the airfoil-vortex interaction. Two closed-loop control schemes were investigated, which deployed p and the streamwise fluctuating flow velocity (u) as the feedback signal, respectively. While the control effect on p was measured using a fast response pressure transducer, the oncoming vortical flow was monitored using a particle image velocimetry and a hot wire. It was found that the control scheme based on the feedback signal u led to a pronounced impairment in the strength of oncoming vortices and meanwhile a maximum reduction in p by 39%, outperforming the control scheme based on the feedback signal p . Physics behind the observations is discussed.

Zhang, S.

"NUMERICAL STUDY ON SOUND GENERATION IN THE INTERACTION OF TWO VORTICES"

AIAA Paper No. 2011-0053, January 2011, Orlando, FL.

This is an extension of our previous studies on the shock vortex interaction. Through solving two dimensional unsteady Navier-Stokes equation by a fifth order weighted essentially non-oscillatory schemes (WENO), we systematically studied the interaction between two vortices. Our goal is to reveal the mechanism of sound generation in the interaction between two co-rotating vortices or two counter-rotating vortices. It is found that the interaction of two vortices rely on their strengths and rotating directions. The interaction of two counter-rotating vortices with equal strength generates two vortex poles and three sound waves. While, the interaction between two equally strength co-rotating vortices result in the merging of two vortices at some condition. In the instant of the vortex merging, strong noise are generated. The interaction between two vortices with large difference in their strengths will result in the weak vortex rotating around the stronger one. And strong noise is generated continuously.

Zhang, S., Jiang, S., Zhang, Y.-T. and Shu, C.-W.

"THE MECHANISM OF SOUND GENERATION IN THE INTERACTION BETWEEN A SHOCK WAVE AND TWO COUNTER-ROTATING VORTICES"

Physics of Fluids, Vol. 21, 2009, pp. 076101-1 - 076101-9.

The interaction of a shock wave and two counter-rotating vortices is simulated systematically through solving the two-dimensional, unsteady, compressible Navier-Stokes equations using a fifth order weighted essentially nonoscillatory finite difference scheme. The main purpose of this study is to reveal the mechanism of sound generation in the interaction between a shock wave and two counter-rotating vortices. It is found that there are two regimes of sound generation in this interaction. The first regime corresponds to the shock interaction with two isolated vortices, in which the sound wave generated by the interaction between the shock wave and two counter-rotating vortices equals to the linear combination of the sound waves generated by the interactions between the same shock wave and each vortex. The second regime corresponds to the shock interaction with a coupled vortex pair, in which the sound wave comes from two processes. One is the vortex coupling, and the second is the interaction between the shock wave and the coupled vortex pair.

Zhang, S., Zhang, Y.-T. and Shu, C.-W.

"MULTISTAGE INTERACTION OF A SHOCK WAVE AND A STRONG VORTEX"

Physics of Fluids, Vol. 17, No. 11, November 2005, 116101-1 to 116101-13

The interaction between a shock wave and a strong vortex is simulated systematically through solving the two-dimensional, unsteady compressible Navier-Stokes equations using a fifth-order weighted essentially nonoscillatory finite difference scheme. Our main purpose in this study is to characterize the flow structure and the generation of sound waves of the shock-strong vortex interaction. The simulations show that the interaction of a shock wave and a strong vortex has a multistage feature. It contains the interaction of the shock wave and the initial vortex, of the reflected shock wave and the deformed vortex and of the shocklets and the deformed vortex. The shocklets are generated by the secondary interaction. Due to the complex reflected shock structure, there exist interactions between the reflected shock waves and the sound waves. Many pressure waves are embedded in the second and third sound waves.

"MULTI-GPU ACCELERATED WING TIP VORTEX EXTRACTION"

AIAA Paper No. 2011-3678, June 2011, Honolulu, Hawaii.

This paper presents a scientific visualization framework where strong vortical flow features, commonly appearing in turbulence flow, are extracted to support parameterization, automation, and interactive exploration of CFD solutions. Tip vortex near an aerodynamic wing is used as an example to demonstrate how this framework can be used to quantitatively analyze and innovatively visualize large amounts of CFD data. Multiple modern Graphics Processing Units (GPU) are adapted to accelerate both

computing and visualization, with interactive performance achieved even on extremely large mesh. Moreover, algorithmic considerations in precisions and memory management in multi-GPU computing environments suggest broader potential impacts on both simulation solver and post-processing software applications.

"NEAR-WAKE FLOW STRUCTURE DOWNWIND OF A WIND TURBINE IN A TURBULENT BOUNDARY LAYER"

Experimental Fluids, Vol. 52, 2012, pp. 1219-1235.

Wind turbines operate in the surface layer of the atmospheric boundary layer, where they are subjected to strong wind shear and relatively high turbulence levels. These incoming boundary layer flow characteristics are expected to affect the structure of wind turbine wakes. The near-wake region is characterized by a complex coupled vortex system (including helicoidal tip vortices), unsteadiness and strong turbulence heterogeneity. Limited information about the spatial distribution of turbulence in the near wake, the vortex behavior, and their influence on the downwind development of the far wake hinders our capability to predict wind turbine power production and fatigue loads in wind farms. This calls for a better understanding of the spatial distribution of the 3D flow and coherent turbulence structures in the near wake. Systematic wind-tunnel experiments were designed and carried out to characterize the structure of the near-wake flow downwind of a model wind turbine placed in a neutral boundary layer flow. A horizontal-axis, three-blade wind turbine model, with a rotor diameter of 13 cm and the hub height at 10.5 cm, occupied the lowest one-third of the boundary layer. High-resolution particle image velocimetry was used to measure the velocities in multiple vertical streamwise planes (x-z) and vertical span-wise planes (y-z). In particular, we identified localized regions of strong vorticity and swirling strength, which are the signature of helicoidal tip vortices. These vortices are most pronounced at the top-tip level and persist up to a distance of two to three rotor diameters downwind. The measurements also reveal strong flow rotation and a highly non-axisymmetric distribution of the mean flow and turbulence structure in the near wake. The results provide new insight into the physical mechanisms that govern the development of the near wake of a wind turbine immersed in a neutral boundary layer. They also serve as important data for the development and validation of numerical models.

"OFF-SURFACE AERODYNAMIC MEASUREMENTS OF A WING IN GROUND EFFECT"

Journal of Aircraft, Vol. 40, No. 4, July-August, 2003, pp. 716-725

The off-surface aerodynamic characteristics of a wing in ground effect are investigated using several methods including laser Doppler anemometry and particle image velocimetry. The study focuses on two aspects of the flow: turbulent wake and edge vortex. These features are closely associated with the behavior of the aerodynamic force in ground effect. The size of the wake increases in proximity to

the ground. A downward shift of the path of the wake is also observed. Discrete vortex shedding is seen to occur behind the wing. As the wing height is reduced, separation occurred on the suction surface of the wing, and the spanwise vortex shedding is found to couple with a flapping motion of the wake in the transverse direction. An edge vortex is also observed off the edge of the end plate of the wing, which contributes to force enhancement and helps to define the force behavior in the force enhancement region. The rate of change in the downforce vs height curve is linked to the strength of the edge vortex. The vortex breakdown signals a slowdown in the force enhancement. When the maximum downforce height is reached, the edge vortex breaks down completely.

Zhang, X. and Zerihan, J.

"EDGE VORTICES OF A DOUBLE-ELEMENT WING IN GROUND EFFECT"

Journal of Aircraft, Vol. 41, No. 5, September-October 2004, pp. 1127-1137

The influence of edge vortices generated by a generic double-element wing on force behaviors are discussed. The wing is equipped with end plates and operates in ground effect. The downforce-vs-height curve is divided into three distinct regions according to ground proximity and flap setting. As the wing is moved from a height in freestream to the ground plane, the downforce first experiences a rapid enhancement (region A). This process is accompanied by the presence of a concentrated vortex off the edge of the side plate and diffuser effect of the wing. At a critical height, the vortex breaks down and its contribution to the downforce is lost. This creates a change in the gradient of the downforce slope. The force enhancement process continues as the height of the wing is reduced (region B); the main diffuser effect is still present. The downforce is lost below a height where the maximum downforce is reached, due to large separation on the wing (region C). The importance of the edge vortices in defining the characteristics of the downforce curve is established.

"A COMPARISON OF IMPLICIT AND EXPLICIT SIMULATIONS OF VORTEX BREAKDOWN"

AIAA Paper 2019-1144, January 2019, San Diego, CA.

Vortex breakdown is an instability which occurs in swirling flows and is seen in both incompressible and compressible flow regimes. The choice of numerical algorithm to compute this flow is critical to resolving the relevant physical phenomena. In previous work, we described the procedure of combining a Barely Implicit Correction (BIC) algorithm with a fourth-order Flux-Corrected Transport (FCT) algorithm to eliminate the sound speed limit for explicit calculations of low-speed flows, and showed that BIC-FCT could predict the three major vortex breakdown modes (spiral, bubble and double-helix). Here, we show a direct comparison of the implicit BIC and explicit FCT algorithms by using the same time step within the explicit stability limit. The comparison is conducted on simulations of a three-dimensional, swirling jet flow with vortex breakdown, by examining the flow structures and examining the property fields. Differences are observed in the phase of the downstream spiral and double-helix

modes. Based on a pressure wave analysis, we attribute this phase shift to the difference of how the explicit FCT and implicit BIC treat an open outflow boundary.

"INTERACTION OF MULTIPLE VORTICES OVER A DOUBLE DELTA WING"

AIAA Paper 2015-2308, June 2015, Dallas, TX.

Interactions between strake and wing vortices over a 70-deg/50-deg double delta wing were studied experimentally in a wind tunnel using particle image velocimetry (PIV) measurements. The upstream effect of the wing vortex on the formation of the strake vortex was identified. A dual-vortex structure of the strake vortices is observed before the wing vortex develops. Prior to vortex breakdown, both wing and strake vortices were found meandering in relatively small regions. The correlation between the instantaneous locations of the vortices increases if the vortices become sufficiently close to each other. The proper orthogonal decomposition (POD) analysis of the instantaneous velocity fields suggested that, for both wing and strake vortices, the most energetic mode was displacement in the first helical mode. The most energetic mode reveals out-of-phase displacements when the vortices are close to each other.

"TIP VORTICES GENERATED BY A WING IN GROUND EFFECT"

11th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, July 2002

Tip vortices generated by a cambered, single element wing operating in ground effect were studied using a range of methods including particle image velocimetry (PIV), laser Doppler anemometry (LDA), surface pressures, force balance measurements, and surface flow visualization. The wing was placed suction surface down, leading to down-force and a complex system of trailing vortices evolving in proximity to the ground. The characters of the tip vortex led to changes in the aerodynamic force behavior in ground effect. The down-force was found affected by the presence of separation on the suction surface and the tip vortices. At larger ground heights, a concentrated tip vortex was produced off the edge of the endplate on the wing through separation, contributing to the down-force enhancement process. The tip vortex induced an upwash on the wing, leading to an effective reduction in the incidence of the wing and hence smaller extents of separation near the wing tip. However, vortex breakdown occurred as the wing was lowered to the ground, leading to a slowdown in the force enhancement.

"AFS-450 SIMULATION CAPABILITY DEVELOPMENT NATIONAL AIRSPACE SYSTEM STOCHASTIC SIMULATION PHASE III WAKE ENCOUNTER MODEL RESEARCH AND PLANNING"

DOT-RITA-RVT-72-10-02-1.0, February 2010, US DOT Volpe National Transportation Systems Center, Cambridge, MA.

The Volpe Center has developed the Vehicle Simulation Tool (VST) for the Flight Systems Laboratory (AFS-450) of the FAA. The VST is used for safety studies and validations of aircraft traffic during landing and/or takeoff operations. The Phase III development of the VST is planned to add the Wake Vortex Encounter (WVE) model to enhance the model capability for evaluating the influence of air traffic safety due to the interaction of aircraft and wake vortex. The prototype of the WVE tool has been developed to provide an off-line tool to create mathematical functions that statistically model aircraft responses during the wake encounter. The tool uses X-Plane as the high-fidelity aircraft flight simulator and collects the data of the aircraft state vector (altitude, roll angle, acceleration, etc.) during the flight. By using multi-variable Least Square Method, closed-form mathematical formulas are generated for the WVE model that are computationally efficient. This report presents the wake model research and planning for Phase III VST. The preliminary design and results of the WVE model are presented. Each aircraft in the model is considered as a source that generates wake and also as a following aircraft that may encounter the wake generated by other aircraft. The model interacts with the flight simulator (such as the VST) in two ways: (1) by taking aircraft flight data in real-time during the flight simulation, and (2) by post-processing the data file generated by the flight simulator which shows the time histories of aircraft locations. The reports generated by the WVE model will contain information of wake encounter time, location, wake encounter geometry, maximum and deviation of aircraft state change.

Zhang, Y. and McGovern, S.

"PARAMETRIC STUDY OF AIRCRAFT RESPONSE DUE TO WAKE VORTEX ENCOUNTER"

IEEE/AIAA 29th Digital Avionics Systems Conference, Oct. 2010, Salt Lake City, Utah.

A simulation-based tool which creates mathematical functions that statistically model aircraft responses during various user-selectable wake encounters is presented. A wake vortex is created due to aircraft wings moving through the viscous air. The methods currently available to minimize the influence of wake vortices on the trailing aircraft can often impact airport capacity. As such, it is of interest to quantify the effect of different size wakes at different encounter geometries and with different aircraft types, flight configurations, speeds, and altitudes. By collecting simulation results generated using a high-fidelity computational-fluid-dynamics-based aircraft flight model combined with industry, government, and academic wake models, numerous encounter aircraft responses (e.g., pitch,

roll, Gs, altitude deviation, etc.) can be calculated. Using the multi-variable least squares method, closed-form mathematical formulas can then be generated from the simulation results to allow for the calculation of other wake encounter situations. This paper presents the preliminary design and gives results from the simulation tool and the associated post-processing for generation of the wake encounter equations and their aircraft-type-specific coefficients. A simple case study is then presented to demonstrate some typical results.

"SIMULATION OF JET BLAST EFFECT ON LANDING AIRCRAFT"

Air Traffic Control Quarterly, Vol. 9, No. 3, 2001, pp. 211-227.

In this paper, we describe a computer simulation of the jet blast effect on an aircraft landing on an orthogonal runway. A phenomenological jet blast model is first presented, followed by a study of its effect on a landing aircraft passing through the blast region. The jet blast issued from the departing aircraft in motion is simplified as a cosine function, specified by peak velocity and width. The jet blast velocity is assumed to cause an additional sideslip velocity for the landing airplane, whose value is subsequently modified accordingly to the coupled governing flight dynamics equations. Numerical simulations are conducted for two different landing aircraft under the control of an automatic landing system.

Zhang, Y., Shortle, J. and Sherry, L.

"COMPARISON OF ARRIVAL TRACKS AT DIFFERENT AIRPORTS"

Proceedings of 4th International Conference on Research in Air Transportation, ICRAT 2010, June 2010, Budapest, Hungary.

This paper analyzes arrival track data at Chicago (ORD) and Atlanta (ATL) airports. We investigate distributions of vertical and lateral position at different distances from the runway threshold in instrument meteorological conditions (IMC) and visual meteorological conditions (VMC). In IMC, the observed standard deviations at different distances are similar between the two airports. The results reported in this paper are also like those reported at St. Louis (STL). Visual comparison of the observed distributions also shows a close similarity. This provides some indication that distributions observed at one airport in IMC may generalize to other airports. In VMC, there are some differences between the distributions. We also fit probability density functions to lateral and vertical positions. In general, the normal distribution provides the best fit among the normal, lognormal, gamma, and Weibull families. The quality of the fit is better in IMC closer to the runway threshold.

"SPECTRAL CHARACTERISTICS OF WAKE VORTEX SOUND DURING ROLL-UP"

NASA-CR-2003-212673, December 2003, NASA Langley Research Center, Hampton, VA

This report presents an analysis of the sound spectra generated by a trailing aircraft vortex during its rolling-up process. The study demonstrates that a rolling-up vortex could produce low frequency (less than 100 Hz) sound with very high intensity (60 dB above threshold of human hearing) at 200 feet from the vortex core. The spectrum then drops off rapidly thereafter. The study suggests that acoustic sensors operating at low frequency band could be profitably deployed for detecting the vortex sound during the rolling-up process.

Zhao, J.

"DYNAMIC WAKE DISTORTION MODEL FOR HELICOPTER MANEUVERING FLIGHT"

PhD Thesis, March 2005, Georgia Institute of Technology, Atlanta, GA.

A new rotor dynamic wake distortion model, which can be used to account for the rotor transient wake distortion effect on inflow across the rotor disk during helicopter maneuvering and transitional flight in both hover and forward flight conditions, is developed. The dynamic growths of the induced inflow perturbation across the rotor disk during different transient maneuvers, such as a step pitch or roll rate, a step climb rate and a step change of advance ratio are investigated by using a dynamic vortex tube analysis. Based on the vortex tube results, a rotor dynamic wake distortion model, which is expressed in terms of a set of ordinary differential equations, with rotor longitudinal and lateral wake curvatures, wake skew and wake spacing as states, is developed. Also, both the Pitt-Peters dynamic inflow model and the Peters-He finite state inflow model for axial or forward flight are augmented to account for rotor dynamic wake distortion effect during helicopter maneuvering flight. To model the aerodynamic interaction among main rotor, tail rotor and empennage caused by rotor wake curvature effect during helicopter maneuvering flight, a reduced order model based on a vortex tube analysis is developed. Both the augmented Pitt-Peters dynamic inflow model and the augmented Peters-He finite state inflow model, combined with the developed dynamic wake distortion model, together with the interaction model are implemented in a generic helicopter simulation program of UH-60 Black Hawk helicopter and the simulated vehicle control responses in both time domain and frequency domain are compared with flight test data of a UH-60 Black Hawk helicopter in both hover and low speed forward flight conditions.

"ENHANCEMENT OF VISCOUS VORTEX PARTICLE METHOD FOR FUNDAMENTAL ROTOR WAKE DYNAMICS SIMULATION"

AIAA Paper No. 2012-1196, January 2012, Nashville, Tennessee.

This paper describes the investigation of the fundamental physics of rotor wake dynamics, including the essential properties of the rotor tip vortices, such as the trajectory, the core size, the circulation strength, etc. The paper also discusses the simulation of the challenging rotor aerodynamic interference problems using the state-of-the-art viscous Vortex Particle Method (VPM). In order to

accurately model the complicated rotor wake problem, efforts were made to enhance the viscous vortex particle method, including the multi-resolution vorticity source generation, the VPM-VIC algorithm, and the far field boundary conditions. This paper also addresses the aerodynamic interaction to allow for the effects of the near field structures, such as the fuselage and the ship deck. Simulation results were compared with available measurements and excellent correlations were demonstrated.

"NEW HYBRID METHOD FOR PREDICTING THE FLOWFIELDS OF HELICOPTER ROTORS"

Journal of Aircraft, Vol. 43, No. 2, March-April 2006, pp. 372-380.

Based on a Navier-Stokes/full potential/free wake solver, a new hybrid method was developed for efficient predictions of the three-dimensional viscous flowfield of a helicopter rotor under both hover and forward flight conditions. The developed flow solver was composed of three modules: 1) a compressible Navier-Stokes analysis to model the viscous flow and near wake about the blade, 2) a compressible potential flow analysis to model the inviscid isentropic potential flow region far away from the rotor, and 3) a free wake model to account for tip vortex effects once the tip vortex leaves the viscous flow region and enters the potential flow region. In this hybrid method, a moving embedded grid methodology was adopted that accounts for rigid blade motions in rotation, flapping, and pitching. A dual-time method was employed to fulfill the calculation of the unsteady flowfields of helicopter rotors, and a third-order upwind scheme (MUSCL) and flux-splitting scheme without introducing artificial viscosity were used to calculate the flux. To search suitable donor elements in embedded grids to pass information between the viscous flow and potential flow zones, a new searching scheme was implemented. The sectional pressure distributions of a UH-60A helicopter rotor and an AH-1G model rotor in hover and forward flight, with and without the wake model, were calculated, and the developed hybrid model was validated by comparing with available experimental data. The simulated steady and unsteady lifting results of a model rotor with three different blade-tip planforms demonstrate the benefits of the curvilinear swept tip and constant swept tip in suppressing supercritical flows.

Zhelannikov, A. I.

"TO THE STUDY OF WAKE VORTEX BEHIND THE AIRBUS-380 CHARACTERISTICS AT TAKEOFF AND LANDING"

Civil Aviation High Technologies, Vol. 19, No. 6, 2016, pp. 51-57. [In Russian]

Every year new aircraft emerge in civil aviation. The wide-body A-380 aircraft with a take-off weight of up to 560 t has come to operation recently. The wake vortex behind such plane poses a real threat for other planes. Such wake is especially dangerous during weak cross wind at takeoff and landing. Vortex wake behind the A-380 plane characteristics research using the developed computing software has been executed in this article. Design-software complex includes two mathematical models, the

mathematical model of the close wake vortex and the mathematical model of the distant wake vortex. These mathematical models are based on the vortex method. A mathematical model of the close wake vortex is based on the analytical-experimental approach. At cruising flight regimes, it is a four-vortex system wake vortex, and at takeoff and landing regimes it is six- or eight-vortex system. A mathematical model of the far wake vortex is based on the exact solution of the Helmholtz equations. This allows consideration of the vortex diffusion and dissipation over time. The influence of the axial velocity in the mathematical model of the distant wake vortex is given by placing it in the center of the vortex flow. Its intensity is found from the experimental data. Calculated fields are perturbed velocities for the A-380 aircraft. Fields of the indignant speeds at a light cross wind of 0.5 m/s - 1.5 m/s in various time points are presented. The moments at which there is a wing vortex lag of the A-380 plane over very center of runway are shown. Calculation of aerodynamic characteristics of the MC-21-400 plane in the vortex trace of the A-380 plane is executed. It is shown when the MC-21-400 plane gets in to the center of a wing vortex, the arising moments of the roll are not parried.

Zhelannikov, A. I.

"FEATURES OF SPREAD OF VORTEX WAKE BEHIND AIRCRAFT AT TAKEOFF AND LANDING, IF CROSSWINDS"

Civil Aviation High Technologies, No. 223, 2016, pp. 5-11.

With commercially-developed software system, carried out research on the impact of crosswinds on the position of vortex wake at takeoff and landing of aircraft of various classes. Identified the threat, in terms of 'hovering' of wing vortex over the center of the runway, versus crosswind speed. During takeoff and landing aircraft, these vortices can be a danger to other aircraft. [In Russian..

"SUPERSONIC VORTEX BREAKDOWN CONTROL BY ENERGY DEPOSITION"

AIAA Paper No. 2005-1048, Reno, NV, January 2005

A possibility for using steady and periodic pulse energy deposition to stimulate a vortex breakdown in conditions of its interaction with an oblique shock wave is demonstrated on a basis of the numerical computations in the framework of the nonstationary Euler equations. The vortex/oblique shock wave interaction (VOSWI) at Mach numbers 3 and 5 is analyzed. It is shown that the formation of a subsonic wake downstream of an energy source lying on the vortex axis contributes to a more significant growth of the dimensions of the arising recirculation zone as compared to the cases when the vortex core remains supersonic. The growth of the streamwise velocity deficiency on the vortex axis contributes to an earlier vortex disintegration on the shock in conditions of energy deposition. An increased flow unsteadiness is revealed at the early stages of the vortex breakdown formation in conditions of periodic pulsed energy deposition, which stimulates the shock front waviness. The flowfield structure for different regimes of VOSWI with steady and periodic pulsed energy deposition is analyzed. The

analogies between the vortex breakdown and turbulent separation are specified on the basis of numerical and experimental data as well as theoretical analysis.

Zhelotovodov, A. A., Pimonov, E. A. and Knight, D. D.

"VORTEX BREAKDOWN SIMULATION BY THE STEADY AND PERIODIC PULSE ENERGY DEPOSITION IN A VICINITY OF SHOCK WAVE"

AIAA Paper No. 2006-0401, January 2006, Reno, NV.

The vortex/oblique shock wave interaction (VOSWI) at the Mach numbers 3 and 5 is analyzed on a basis of the numerical computations in a framework of the 3-D nonstationary Euler equations. A possibility of the vortex breakdown control using steady and periodic pulsed energy deposition is demonstrated in the cases of weak, moderate, and strong regimes of VOSWI. Influence of the energy sources of spherical and ellipsoidal geometry, their dimensions and location on the vortex axis as well as the energy deposition power and frequency is considered. The specific details of the realized flowfield structures are analyzed. The correlations for the plateau pressure level in the vortex breakdown zones and the near-wall boundary layer separation regions are considered.

Zhelotovodov, A. A., Pimonov, E. A. and Knight, D. D.

"NUMERICAL MODELING OF VORTEX/SHOCK WAVE INTERACTION AND ITS TRANSFORMATION BY LOCALIZED ENERGY DEPOSITION"

Shock Waves, Vol. 17, 2007, pp. 273-290.

Three-dimensional unsteady Euler simulations are presented for the interaction of a streamwise vortex with an oblique shock of angle 23.3 degrees at Mach 3 and 5. The flowfield features are analyzed for weak, moderate and strong interaction regimes. The details of the free recirculation zone at conditions of subsonic and supersonic flow on the vortex axis are considered. The vortex breakdown under conditions of a subsonic vortex core is characterized by a continuous growth and gradual degeneration of the region, unlike the supersonic core condition wherein a steady recirculation zone is achieved. The possibility of using a localized steady and pulsed periodic energy deposition on the vortex axis for stimulating the breakdown is demonstrated for various interaction regimes. It is shown that the formation of a subsonic wake downstream of an energy source lying on the vortex axis contributes to a more significant growth of the dimensions of the recirculation zone compared to the case when the vortex core remains supersonic. The possibility of achieving the effects similar to the steady case is demonstrated by the effect of a pulsed periodic energy source on the flow under consideration for corresponding equivalence parameters.

"INVESTIGATION OF WIND TURBINE WAKES OVER COMPLEX TERRAIN BASED ON ACTUATOR DISK METHOD"

AIAA Paper 2017-4073, June 2017, Denver, CO.

As wind energy in flat terrain have been exploited, sites in complex terrain is becoming more attractive. However, the topographic effect makes the installation in complex confront great difficulty. One of the problems is the wind farm layout optimizations as a lack of accurate, computational tractable wake model. In order to found a suitable model considering the topographic effect, the numerical investigation of wind turbine wakes over complex terrain is presented in this paper. The method is based on the actuator disk theory and is validated with the experimental data. The result indicates that the deficit at hub height is not monotonously decreasing as the wind turbine sited in front of the hill for gentle slope without flow separation, and the turning point is on the hilltop. The wake center height doesn't change obviously as wind turbine sited on the hilltop, while it has an evident change for other locations of wind turbine. For steep slope with flow separation, the wind turbine in front of the hill can decrease the separation region, while the turbine on the hilltop has no evident effect on the flow separated. It is likely because that the wake improves the turbulence intensity, which is good for the velocity recovery. The flow separation makes the wake characteristic different from that without separation, and there is need to study farther about the terrain with steep slopes.

Zheng, Y. and Ramaprian, B. R.

"AN EXPERIMENTAL STUDY OF WING TIP VORTEX IN THE NEAR WAKE OF A RECTANGULAR WING"

MME-TF-93-1, June 1993, Washington State University, Pullman, WA.

An experimental study of the tip vortex behind a NACA 0015 rectangular wing of aspect ratio 4 was carried out to understand the structure and evolution of the vortex in the near-wake region. The results of these experimental studies are presented in this report. These measurements were made nonintrusively using three-component laser-Doppler velocimetry (LDV). The experiments were carried out at a Reynolds number of about 180,000 in a low-speed wind tunnel. Two cases were studied, namely, (i) stationary wing and (ii) wing oscillating in pitch sinusoidally about its quarter-chord axis. The flow properties measured were the three components of the instantaneous velocity. These data were processed to obtain time-mean and phase-locked flow properties such as velocity, vorticity and turbulence. The data were obtained at several locations at 0.15 - 3.0 chord lengths downstream from the trailing edge. The typical distributions of mean velocity, vorticity, circulation, and turbulent intensity in the near wake are presented and discussed for the stationary wing. In the case of the oscillating wing, the phase-locked velocity, vorticity and turbulence data show details of the evolution of the unsteady tip vortex downstream from the trailing edge. The results also show that the flow is strongly non-quasi-steady at the oscillation frequency studied. The results are fully archived on tape and are available to any interested reader. These can be used as database in the development of wake models for the finite wing, and in studies of three-dimensional wing aerodynamics.

Zheng, Z. C.

"A CONSISTENT BOUNDARY CONDITION FOR VORTICITY-STREAMFUNCTION SIMULATIONS OF WALL-BOUNDED VORTEX FLOWS"

In: Numerical Methods in Laminar and Turbulent Flow, Vol. 9, Pt. 1; Proceedings of the 9th International Conference, Atlanta, GA, Pineridge Press, 1995, pp. 179-190

This paper was motivated by an ongoing computational effort to model the aircraft wake vortex hazard near airports. Those flows can usually be approximated as a pair of 2D incompressible vortices interacting with an infinite solid wall. The present numerical model uses a vorticity-streamfunction formulation to simulate the 2D problem. Since vorticity generation near the wall alters the evolution of the secondary and tertiary vortices directly, accurate modeling of the wall region is critical. A local relationship between vorticity and streamfunction for a wall boundary condition has been established from a new point of view by specifying the streamfunction at the boundary grid lifted away from the solid wall. The new method has utilized Taylor series expansions near the wall boundary. Although the resulting expressions are only first order accurate, the critical importance of physical and mathematical consistency has been achieved. Numerical test cases are discussed in the paper.

Zheng, Z. C.

"THE INFLUENCE OF REYNOLDS NUMBER AND ATMOSPHERIC EFFECTS ON AIRCRAFT WAKE VORTICES NEAR THE GROUND"

Ph.D. Thesis, 1993, Old Dominion University, Norfolk, VA

Aircraft wakes represent potential hazards which can control aircraft spacing and thus limit airport capacity. Wake vortex trajectories and strengths are altered radically by interactions with the ground plane and by atmospheric conditions. This work has been concerned with developing more accurate numerical predictions. A two-dimensional, unsteady numerical-theoretical study is presented which has included viscous effects, the influence of stratification, crosswind and turbulence on vortex behavior near the ground plane, using a vorticity-streamfunction formulation. A two-parameter perturbation procedure has been developed which uses analytic solutions for the initial flow field to accommodate the ground effect region in the numerical simulation. Using an order of magnitude analysis, it was possible to justify the Boussinesq approximations for turbulent wake vortex predictions, including ground effects and atmospheric stratification. It has been shown that the eddy-viscosity turbulence models were not effective in predicting wake vortex flows and a Reynolds stress transport model was implemented. The numerical solutions to the Navier-Stokes equations have been compared with experimental results for the laminar, unstratified cases and good agreement has been obtained. The computational simulations show that the vortex rebound near the ground plane is caused by ground boundary-layer separation. High stratification levels can confine the motion of the vortex system and alleviate the primary vortex strength. Vortex turbulence influences vortex trajectories more strongly than it influences the rate of change in vortex strength. Weak crosswinds cause the upstream primary vortex to rebound less strongly than the downstream vortex. Finally, suggestions are made for future research.

Zheng, Z. C.

"FAR-FIELD ACOUSTIC PRESSURE FROM A SYSTEM OF DISCRETE VORTICES WITH TIME-VARYING CIRCULATION"

AIAA Paper No. 2005-3005, Monterey, CA, May 2005

Primary fluid dynamic sources of sound are from vortices. In problems such as aircraft high-lift noise and wake-vortex sound, vortex methods have been selected as modeling tools for the fluid dynamic processes. In order to use the results from vortex methods for sound generation predictions, it is necessary to relate the near-field vorticity to the far-field acoustic parameters. A theoretical development following an asymptotic expansion method is presented that results in a relation between the vortex impulse and the far-field sound. The formula, which includes the effect of time-varying vortices, can be considered as a two-dimensional representation of Powell's and Mohring's equations. An example of a pair of decaying, counter-rotating vortices is used to apply the formula to calculate the far-field sound of the vortex system.

Zheng, Z. C.

"THIN-TUBE VORTEX SIMULATIONS FOR SINUSOIDAL INSTABILITY IN A COUNTER-ROTATING VORTEX PAIR"

International J. for Numerical Methods in Fluids, Vol. 39, June 2002, pp. 301-324

A thin-tube vortex method is developed to investigate the intrinsic instability within a counter-rotating vortex pair system and the effects from the core size and the wavenumbers (or wavelengths). The numerical accuracy and the advantages of the scheme are theoretically estimated. A nearest-neighbor image method is employed in this three-dimensional vortex simulation. Agreement with Crow's instability analysis has been achieved numerically for the long-wave cases. A short-wave instability for the zeroth radial mode of bending instability has also been found using the thin-tube vortex simulations. Then, the combinations of long- and short-wave instability are investigated to elucidate the non-linear effects due to the interactions of two different modes. It is shown that instability is enhanced if both long- and short-wave instabilities occur simultaneously. Although the method used in the paper is not capable of including effects such as axial flow, vortex core deformation and other complicated viscous effects, it effectively predicts and clarifies the first-order factor that dominates the sinusoidal instability behaviour in a vortex pair.

Zheng, Z. C.

"THE EFFECTS OF ATMOSPHERIC TURBULENCE ON AIRCRAFT WAKE VORTICES NEAR THE GROUND"

AIAA Paper No. 1996-1954, New Orleans, LA, June 1996

A second-order-closure turbulence model has been used to study the effects of atmospheric turbulence on the behavior of aircraft wake vortices near the ground. The numerical simulations have been compared with flight measurement data and good agreement has been obtained. The results show that atmospheric turbulence levels have more significant influence on vortex decay histories than on its transport behavior. Although simple turbulence models are more practical for vortex hazard forecasts in terms of computational overhead, second-order closure models are shown to be the minimum level turbulence model to simulate properly the flow physics such as centrifugal effects near vortex cores and the phase shift between the shear strain and the turbulent shear stress.

Zheng, Z. C.

"BETZ INVARIANTS AND GENERALIZATION OF VORTICITY MOMENT INVARIANTS"

AIAA Journal, Vol. 39, No. 3, March 2001, pp. 431-437

The widely used Betz invariants can be categorized as invariants of vorticity moments or impulses in plane motion for mostly inviscid vortex flow. These invariants have served as a foundation of vortex roll-up process analysis as well as benchmarks to estimate numerical simulation errors for vortex flow. The analysis starts from a more general integral divergence relation in rational mechanics to extend the analysis for both inviscid and viscous vortex flow cases, with or without finite boundaries. Conditions for the existence of the Betz invariants and their extensions to include viscous effects are discussed. These extensions can be used as analytical means for theoretical modeling of complicated vortex systems, especially in flows with viscous effects and finite boundaries. The goal of this study is to clearly establish when the Betz invariants and the generalized vorticity moment invariants are applicable. The approach uses rigorous mathematical analysis, and the physical interpretations of the results are discussed. A trailing vortex pair is used as an example to illustrate the applications of the theoretical study.

Zheng, Z. C.

"INITIALIZATION AND SIMULATION OF THREE-DIMENSIONAL AIRCRAFT WAKE VORTICES"

AIAA Paper No. 1997-2264, Atlanta, GA, June 1997

This paper studies the effects of axial velocity profiles on vortex decay to properly initialize and simulate three-dimensional wake vortex flow. Analytical relationships are obtained based on a single vortex model and computational simulations are performed for a rather practical vortex wake, which show that the single vortex analytical relations can still be applicable at certain streamwise sections of three-dimensional wake vortices.

Zheng, Z. C.

"INFLUENCE OF ATMOSPHERIC TURBULENCE ON CROW-TYPE INSTABILITY OF A VORTEX IN GROUND EFFECT"

AIAA Paper 2013-2550, June 2013, San Diego, CA.

Crow instability of a pair of counter-rotating vortices in free space is extended to study the case of a single vortex interacting with its ground image when the vortex is in ground effect. The atmospheric turbulence condition triggers and enhances the instability and can potentially cause 'linking' of the vortex to the ground. An analytical model is employed to investigate the growth rate and standing-wave angle under different intensity and wave number of atmospheric turbulence.

Zheng, Z. C. and Ash, R. L.

"PREDICTION OF TURBULENT WAKE VORTEX MOTION NEAR THE GROUND"

Transitional and Turbulent Compressible Flows, edited by L. D. Kral and T. A. Zang, ASME Fluids Engineering Conference, Washington, DC., ASME, FED Vol. 151, 1993, pp. 195-207.

Various eddy viscosity turbulence models were compared with a Reynolds stress transport model for predicting the behavior of a two-dimensional vortex pair in ground effect. This study determined that the eddy viscosity models were not effective in predicting these flows and a Reynolds stress transport model was implemented. Subsequently, we have investigated the motion of a simulated aircraft wake vortex pair in ground effect at circulation-based Reynolds numbers of up to 75,000. Using an order or magnitude analysis, it was possible to justify the Boussinesq approximations for turbulent wake vortex predictions including ground effects and atmospheric stratification.

Zheng, Z. C. and Ash, R. L.

"VISCOUS EFFECTS ON A VORTEX WAKE IN GROUND EFFECT"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 31-1 - 31-30

Wake vortex trajectories and strengths are altered radically by interactions with the ground plane. Prediction of vortex strength and location is especially important in the vicinity of airports. Simple potential flow methods have been found to yield reasonable estimates of vortex descent rates in an otherwise quiescent ambient background, but those techniques cannot be adjusted for more realistic ambient conditions and they fail to provide satisfactory estimates of ground-coupled behavior. The authors have been involved in a systematic study concerned with including viscous effects in a wake-vortex system which is near the ground plane. The study has employed numerical solutions to the Navier-Stokes equations, as well as perturbation techniques to study ground coupling with a descending vortex pair. Results of a two-dimensional, unsteady numerical-theoretical study are presented in this paper. A time-based perturbation procedure has been developed which permits the use of analytical solutions to an inner and outer flow domain for the initial flowfield. Predictions have been compared with previously reported laminar experimental results. In addition, the influence of stratification and turbulence on vortex behavior near the ground plane has been studied.

Zheng, Z. C. and Ash, R. L.

"STUDY OF AIRCRAFT WAKE VORTEX BEHAVIOR NEAR THE GROUND"

AIAA Journal, Vol. 34, No. 3, March 1996, pp. 580-589

Aircraft wake vortices have been modeled using an unsteady, two-dimensional laminar (constant eddy viscosity) approximation of the Navier-Stokes equations, to study the influence of ground coupling, stratification, and crosswind on vortex system behavior and decay. Initialization and boundary conditions are developed and implemented systematically for a nonuniform grid representation of the semi-infinite domain containing a vortex pair. Subsequently, the physics of wake vortex interactions with the ground for different types of surface weather conditions are discussed.

Zheng, Z. C. and Baek, K.

"INVISCID INTERACTIONS BETWEEN WAKE VORTICES AND SHEAR LAYERS"

J. Aircraft, Vol. 36, No. 2, March-April 1999, pp. 477-480.

An inviscid vortex simulation showed that the shear-layer deformation causes the vortex descent history difference in the two vortices of a trailing vortex pair. Because of the interactions between the vortices from the shear layer and the vortex pair, the induced velocities on the vortex pair have been changed. Such changes produce different trajectories when the vortex pair is interacting with a concentrated shear layer below or above it. The results show that if a shear layer is put below the vortex pair containing shear vortices with the same sign as the left vortex, the right vortex descends less than the left vortex. When the same shear layer is set above the vortex pair, the right vortex descends more. The descent altitude difference increases with the shear-layer strength. The two vortices do not show altitude difference when they go through a constant, nondeformed shear layer.

Zheng, Z. C. and Baek, K.

"SHEAR-LAYER EFFECTS ON TRAILING VORTICES"

AIAA Paper No. 1998-0316, Reno, NV, January 1998

Crosswind shear can influence the trailing vortex trajectories significantly, according to both field measurement and numerical simulations. Point vortex models are used to study the fluid dynamic mechanism in the interactions between trailing vortex pair and shear layers. It has been shown that the shear-layer deformation causes the vortex descent history difference in the two vortices of the vortex pair. When a shear layer is below the vortex pair with the same sign as the left vortex, the right vortex descends less than the left vortex. When the same shear layer is above the vortex pair, the right vortex descends more. The descent altitudes of the two vortices are the same when they go through a constant, non-deformed shear layer. Those trends are in agreement with Navier-Stokes simulations.

Zheng, Z. C. and Baek, K.

"N-S SIMULATIONS OF CROW-TYPE INSTABILITIES IN VORTEX WAKE"

AIAA Paper No. 1999-0981, Reno, NV, January 1999

Three-dimensional Navier-Stokes simulations of the Crow instability of wake vortices are conducted using large-eddy simulations without background turbulence. Sinusoidal displacement has been specified as the initial perturbation for the vortex system. The results have shown that the minimum Crow instability wavelength is about one vortex spacing shorter than predicted by Crow's linear stability theory. The planar-standing-wave-angle value and the amplitude indifference behavior agree with Crow's analysis. Simulations with periodicity in the axial direction have indicated minor influence of axial flow on the Crow instability.

Zheng, Z. C. and Budlong, D. D.

"INTERACTIONS BETWEEN VORTICES AND SECONDARY VORTICAL STRUCTURES"

AIAA Paper No. 1999-3284, Norfolk, VA, June-July 1999

A vortex method is developed to investigate the intrinsic instability within the primary counter-rotating vortex pair system and the influence from the secondary structure such as vortex rings contouring the vortex pair. Agreement with Crow's instability analysis has been achieved numerically. Both steady and decayed disturbances from the ring structure have been simulated. The long-wave mode disturbances from the rings can develop differently from the long-wave sinusoidal disturbances in the vortex pair, while the short-wave mode disturbances stay neutrally stable.

Zheng, Z. C. and Hardin, J. C.

"IMPORTANCE OF ANTISYMMETRIC MODES OF THE CROW INSTABILITY"

AIAA Journal, Vol. 55, No. 7, July 2017, pp. 2123-2128.

The antisymmetric mode was neglected in the original Crow instability. In this study, a general-instability-analysis method was used to obtain the upper bounds of the instability growth rates, which are independent of the cutoff parameter in the self-induction integral. This result suggests that, not only do the antisymmetric modes exist, but also they are most amplified. These antisymmetric modes can occur in both the long- and short-wave modes. An example of the growth histories of the symmetric and antisymmetric modes for an aircraft wake is given. It is shown that the presence of the antisymmetric modes can cause the time of linking of the wake vortices to be shortened, which could lead to the reduction of the wake-vortex hazard to following aircraft.

Zheng, Z. C. and Li, W.

"FREQUENCY DEPENDENCE ON CORE DYNAMICS IN MULTIPLE VORTEX INTERACTIONS"

AIAA Paper No. 2007-3415, Rome, Italy, May 2006

In a vortex system with multiple vortices such as a complicated aircraft vortex wake, the sound emission frequency of the unsteady vortex core is subjected to change because of interactions between multiple vortices. The behavior of the influence, indicated by the ratio between the core size and the distance of the vortices, and the underlining vortex core dynamic mechanisms are investigated. A vortex particle method is used to simulate the vortex core dynamics in two-dimensional, inviscid and incompressible flow. The flow field, in the form of vorticity, is employed as the source in the far-field acoustic calculation using a vortex sound formula. Cases of co-rotating vortices and a multiple-vortex system composed of two counter-rotating vortex pairs are studied for applications to aircraft wake vortex sound. The study shows, without vortex merging, individual frequencies can be clearly identified that are due each to core rotation (self-induction) and co-rotating motion of a vortex center around the other (mutual induction). The ratio of the core size and the distance between vortices does not seem to significantly influence the frequency of vortex core rotation. With vortex merging, a single frequency due to the merged vortex core is generated.

Zheng, Z. C. and Li, W.

"DEPENDENCE OF RADIATED SOUND FREQUENCY ON VORTEX CORE DYNAMICS IN MULTIPLE INTERACTIONS"

The Aeronautical Journal, Vol. 113, No. 1142, April 2009, pp. 233-242.

With both theoretical analysis and measurement data, it has been identified previously that there exists a robust sound emission from a pair of counter-rotating aircraft wake vortices at the frequency of unsteady vortex core rotation. In a vortex system with multiple vortices, the sound emission frequency can be subjected to change because of interactions among the vortices. The behavior of the influence, indicated by the ratio between the core size and the distance of the vortices and the underlying vortex dynamic mechanisms, is investigated in this study. A vortex particle method is used to simulate the vortex core dynamics in two-dimensional, inviscid, and incompressible flow. The flow field, in the form of vorticity, is employed as the source in the far-field acoustic calculation using a vortex sound formula. Cases of co-rotating vortices and a multiple-vortex system composed of two counter-rotating vortex pairs are studied for applications to aircraft wake vortex sound. The study shows, without vortex merging, individual frequencies can be clearly identified that are due each to core rotation (self-induction) and co-rotating motion of a vortex center around the other (mutual induction). The ratio of the core size and the distance between vortices does not seem to significantly influence the frequency of vortex core rotation. With vortex merging, a single frequency due to the merged vortex core is generated.

"VALIDATION AND OPERATION OF A WAKE VORTEX/SHEAR INTERACTION MODEL"

J. Aircraft, Vol. 37, No. 6, November-December 2000, pp. 1073-1078

A vortex method model developed previously for studying the mechanism in vortex/shear-layer interactions has been validated with large-eddy turbulence simulations and field measurement data. A shear-detection algorithm used to incorporate meteorological wind data is developed. Operational issues are also explored. The shear-thickness effects and the wind measurement resolution requirement and its sensitivity to the prediction algorithm are discussed. The objective of this work is to develop a computational method that is both accurate enough for the intended purpose and rapid enough to be of use in an operational setting at airports.

Zheng, Z. C. and Wei, Z.

"EFFECTS OF SURFACE ROUGHNESS AND PATTERNS ON A SURFACE-APPROACHING PAIR OF AIRCRAFT WAKE VORTICES"

AIAA Paper 2013-0364, January 2013, Grapevine, TX.

Surface roughness can have significant effects on the behavior of a pair of wake vortices approaching to the surface. In this paper, the effects of surface roughness are investigated using numerical simulation. Different types of surface roughness are simulated for both solid, stationary rough surfaces and moving wave surfaces. It has been shown from the results that because of more complicated secondary vortices generated near these rough surfaces than near a smooth surface, wake vortex trajectories and strengths can be significantly altered.

Zheng, Z. C. and Xu, Y.

"A VISUALIZED WAKE HAZARD ASSESSMENT"

AIAA Paper No. 2008-467, Reno, NV, January 2008

In this study, the rolling moment coefficient induced by wake vortices is considered an appropriate measure of wake vortex hazard on an aircraft encountering the wake generated by another aircraft. The rolling moment coefficient is calculated based on the strip theory treating the wake vortex velocity field as the downwash. The computation has been validated against wind tunnel experiment data. Numerical simulation results are then used to study the effects that influence the wake-vortex roll hazard, including vortex core size, follower aircraft size, atmospheric turbulence, and wake contortion due to sinusoidal-wave instability. These effects are displayed visually with two-dimensional and three-dimensional field contours to provide a dynamic and intuitive vortex hazard assessment.

Zheng, Z. C. and Xu, Y.

"BEHAVIORS OF VORTEX WAKE IN RANDOM ATMOSPHERIC TURBULENCE"

AIAA Paper 2009-0347, Jan. 2009, Orlando, FL

Atmospheric turbulence has significant influences on both the trajectories and the strengths of wake vortices. In this paper, a quasi-wavelet method is used to generate a random atmospheric turbulence

field based on the von Karman spectrum where atmospheric turbulence is represented by groups of random eddies. An inviscid wake vortex system in proximity to the ground is introduced in the generated turbulence background to study the effects of random turbulence on wake vortices. Wake trajectories with and without random turbulence are compared in the cases for non-decaying and decaying vortices.

"A STUDY OF THE INFLUENCE OF CROSS FLOW ON THE BEHAVIOR OF AIRCRAFT WAKE VORTICES NEAR THE GROUND"

Proceedings 19th ICAS Congress, Anaheim, CA, September 18-23, 1994, Vol. 2, pp. 1649-1659.

This paper studies the influence of cross wind on a vortex pair interacting with the ground. The study has been focused on exploring how various types of cross flow alter the trajectories and strengths of each vortex in different laminar ambient flows. The computation has employed the vorticity-streamfunction formulation of the Navier-Stokes equations. Then, the computational results are used to determine downwash velocities and induced rolling moment on hypothetical following aircraft, employing Prandtl's lifting line theory. This method provides alternative means to assess the wake vortex hazard.

Zheng, Z. C., Li, W., Wang, F. Y. and Wassaf, H.

"INFLUENCE OF VORTEX CORE ON WAKE VORTEX SOUND EMISSION"

Journal of Aircraft, Vol. 44, No. 4, July-August 2007, pp. 1369-1377

A consistent and persistent mechanism of sound emission from aircraft wake vortices has been identified. Both measurement data and theoretical results show that a dominant frequency of sound pressure matches the rotation frequency of a Kirchhoff vortex due to the self-induction inside the vortex core. Numerical simulations for more realistic wake vortex pairs with inviscid ground effects and shear flow are carried out using a vortex particle method. A far-field vortex sound formulation, based on asymptotic expansions, is developed and compared with formulae in the literature. The simulation results reveal that the frequency of the wake sound emission would remain essentially the same as the classical Kirchhoff vortex, even under the influences of an inviscid ground effect or a weak-shear cross wind. These results suggest that the mechanism identified should be robust.

Zheng, Z.-Q.

"INITIALIZATION AND COMPUTATION OF 3-D WAKE VORTICES"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206233, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 202-211

The following topics are included in the presentation: (1) Axial velocity effects on 3-D Vortices; (2) Initial 3-D computational simulation with axial flow; and (3) The Zonal computational method. Conclusions include: (1) Initial axial velocity profiles influence the 3-D vortex decay behavior; (2) Axial velocity deviation can change the effects of vortex core growth on total circulation, axial vorticity, and maximum tangential velocity; (3) Computational results agree with the trend predicted in the analytical study; and (4) The zonal method can be utilized to extend far downstream 3-D simulation.

"REAL-TIME SIMULATION OF LARGE AIRCRAFT FLYING THROUGH MICROBURST WIND FIELD"

Chinese Journal of Aeronautics, Vol. 22, 2009, pp. 459-466.

This article deals with real-time hi-fi simulation of large aircraft flying in turbulent wind in a simulator to study its takeoff and landing behavior in microburst wind shear. A parameterized three-dimensional (3D) microburst model is built up based on vortex ring and Rankine vortex principle. Complicated microburst wind fields are simulated by means of vortex ring declination and multi-vortex superposition. Based on the modeling data of Boeing B747-100, a dynamic model with wind shear effects considered is established and a general method to modify the aerodynamic model is proposed. A controller for longitudinal and lateral escapes is designed and verified in simulated microburst wind field. Results indicate that, with high extensibility, reasonability and effectiveness, the 3D microburst model with wind shear effects considered is fit to simulate real wind fields. Different escape schemes can be adopted to fly through a wind field from different locations. The model can be used for real-time flight simulation in a flight simulator.

"CONTROLLING THE NEAR VORTEX WAKE OF A SWEEPED HALF-WING BY MEANS OF MINI-FLAPS"

Fluid Dynamics, Vol. 43, No. 5, 2008, pp. 718-724.

The effect of mini-flaps on the flow pattern in the near vortex wake behind a model swept half-wing is investigated. The distributions of the time-average flow velocity were measured in a subsonic wind tunnel, in a section normal to the freestream velocity vector located at 3.8 wing half-spans from its trailing edge. When mini-flaps are mounted on both upper and lower wing surfaces, two vortices (tip and auxiliary) of the same sign are observable in the above-mentioned flow section; they are separated by an extended region of vorticity of the opposite sign. The model angle-of-attack effect on the intensities of the tip and auxiliary vortices is estimated.

Zhigulev, S. V., Kogan, M. N., Kuryachii, A. P., Litvinov, V. M. and Uspenskii, A. A.

"EFFECT OF MINI-FLAPS ON THE STRUCTURE OF THE NEAR WAKE BEHIND A MODEL HALF-WING"

Fluid Dynamics, Vol. 42, No. 2, 2007, pp. 212-220.

The effect of mini-flaps on the vortex structure of the near wake flow behind a model of a half-wing, rectangular in plan, is investigated. In a subsonic wind tunnel the time-average flow parameters are measured in several sections behind a model with flaps mounted on both upper and lower surfaces near the trailing edge. The wake flow parameters are compared with those for a model with no flaps. The considerable effect of the flaps on the flow structure in the viscous core of a tip vortex formed behind the model half-wing is established.

"BILU IMPLICIT MULTIBLOCK EULER/NAVIER-STOKES SIMULATION FOR ROTOR TIP VORTEX AND WAKE CONVECTION"

International Journal for Numerical Methods in Fluids, Vol. 55, 2007, pp. 509-536.

In this paper, A block incomplete lower-upper (BILU) decomposition method is incorporated with a multi-block three-dimensional Euler/Navier-Stokes solver for simulation of hovering rotor tip vortices and rotor wake convection. Results of both Euler and Navier-Stokes simulations are obtained and compared with experimental observations. The comparisons include surface pressure distributions and tip vortex trajectories. The comparisons suggest that resolution of the boundary layer is important for the accurate evaluation of the blade surface loading, but is less so for the correct prediction of the vortex trajectory. Numerical tests show that, using Courant-Friedrichs-Lewy (CFL) number of 10 or 30 with the developed BILU implicit scheme can be 6-7 times faster than an explicit scheme. The importance of solution acceleration schemes that increase the permitted time-step is illustrated by comparing the evolving wake structures at different stages of the calculation. In contrast to fixed wing simulations, the extent of the wake structures is shown to require resolution of large physical time. This observation explains the poor performance that is obtained when employing convergence acceleration strategies originally intended for solution of equilibrium problems, such as the multigrid methods.

Zhong, B., Shaw, S. T. and Qin, N.

"BILU IMPLICIT MULTIBLOCK EULER/NAVIER-STOKES SIMULATION FOR HELICOPTER ROTOR VORTICAL FLOW"

AIAA Paper No. 2005-0465, Reno, NV, January 2005

A Block Incomplete Lower-Upper (BILU) decomposition method is incorporated within a multi-block three dimensional Euler/Navier-Stokes solver for hovering rotor vortical flow simulation. The BILU method is used to solve the linear system arising at each step of the implicit time marching procedure. The inviscid flux is calculated using the Osher's approximate Riemann solver. Multi-block techniques are used to obtain a quality structured grid around the blade and in the near wake for better tip vortex and wake simulation. A modified MUSCL scheme is employed to alleviate the inaccuracy in the discretization. Numerical tests show that for fixed wing calculations the implicit scheme, using a CFL number of 30, can be 6-7 times faster compared to the time spent when using an explicit scheme. For rotating wing simulations numerical experiments demonstrate similar improvements. Compared to the

explicit scheme used for hovering rotor simulation, significant improvement in computational efficiency is achieved utilizing the BILU implicit scheme. The fidelity of the solutions is demonstrated by comparing results from Euler and Navier-Stokes solutions, including surface pressure distributions and vortex trajectories.

"EXTRACTING 3D VORTICES IN TURBULENT FLUID FLOW"

IEEE Transactions on Pattern Analysis and Machine Intelligence, Vol. 20, No. 2, February 1998, pp. 193-199

This paper presents a computational framework to extract salient patterns, called vortex structures, from 3D turbulent fluid flows. These structures can be characterized as regions of dominating rotational motion in the velocity fields and intensity concentrations in the corresponding vorticity fields. A pointwise linear representation is employed to approximate the kinematics of the flow field, and the fluid motion is classified according to motion analysis or topological patterns. The regions of vortex structures are identified as those dominated by rotational motion or those of focus-type singularity. The 2D vortices, as a special case of 3D vortices, are detected by searching for regions of vorticity concentrations.

"HIGH EFFICIENCY ALL FIBER COHERENT LIDAR FOR WIND MEASUREMENT"

19th Coherent Laser Radar Conference (CLRC), Paper P16, June 2018, Okinawa, Japan.

Recently a high efficiency all-fiber coherent lidar system at 1.55-micron wavelength is developed to achieve real-time measurements of wind fields. The system employs 80-micro J-pulse energy at 10 kHz pulse repetition rate. In addition, the system consists of a fiber-based optical transceiver unit, a 2-axis scanner, and a multicore digital signal processor (DSP) for real-time signal processing. The lidar with compact and waterproof architecture can provide mobility, reliability, and ease of field deployment for wind measurements. And the high receiver efficiency provides for measurement range of wind up to 5km. Continuous wind profiles of the planetary boundary layer are presented to demonstrate the robustness and stability of the system.

"INFLUENCE OF CROSSWIND SPEEDS ON AIRCRAFT WAKE VORTEX MOVEMENT"

ACTA Aeronautica et Astronautica Sinica, Vol. 30, No. 5, May 2009, pp. 773-779.

To enable the airdrome radar to detect and locate aircraft wake vortices in real time, a passive conservative model is proposed to simulate the wake vortices with reasonable assumptions about the flying environment. This model can depict reasonably well the movement evolution of water vapor and

other matter in wake vortices. This model takes into consideration the influence of crosswind speeds in the atmosphere on wake vortices, and is used to simulate the wake vortices in real time and find their distribution characteristics at different crosswind speeds and times. Analysis of the impact of crosswind speeds on aircraft wake vortices indicates that the most dangerous crosswind speed is between 1.0 and 3.0 m/s. This conclusion can be of theoretical value in the study of the impact of vortices on aircraft flying. [In Chinese.]

Zhou, H.

"ON THE MOTION OF SLENDER VORTEX FILAMENTS"

Physics of Fluids, Vol. 9, No. 4, April 1997, 970-981

Several approaches for slender vortex motion (the local induction equation, the Klein-Majda equation, and the Klein-Knio equation) are compared on a specific example of sideband instability of Kelvin waves on a vortex. Numerical experiments on this model problem indicate that all these equations yield qualitatively similar behavior, and this behavior is different from the behavior of a nonslender vortex with variable cross-section. It is found that the boundaries between stable, recurrent, and chaotic regimes in the parameter space of the model problem depend on the equation used. The boundaries of these domains in the parameter space for the Klein-Majda equation and for the Klein-Knio equation are closely related to the core size. When the core size is large enough, the Klein-Majda equation always exhibits stable solutions for our model problem. Various conclusions are drawn; in particular, the behavior of turbulent vortices cannot be captured by these approximations, and probably cannot be captured by any slender vortex model with constant vortex cross-section. Speculations about the differences between classical and superfluid hydrodynamics are also offered.

"SOUND GENERATION BY DIFFERENT VORTEX INTERACTIONS IN MIXING LAYERS"

AIAA Paper No. 2012-1173, January 2012, Nashville, Tennessee.

To understand the correlation between far-field sound and near-field vortex dynamics, in this paper, we numerically investigate the sound generation from different types of vortex interaction (e.g. vortex pairing, vortex tearing, triple/quadruple-vortex merging). Direct Numerical Simulation (DNS) of the compressible Navier-Stokes equations is carefully conducted for an accurate description of far-field sound radiation. By choosing different phase delays between the fundamental frequency and its sub-harmonics, the vortex interaction changes from perfect pairing to tearing. The sound generated by vortex tearing is much quieter than the one from vortex pairing at the same excitation level. However, the directivity of sound radiations keeps almost the same. When different combinations of forcing frequencies are chosen, there are more complex triple and quadruple vortex mergings. The sound intensity of such cases is stronger than the one of either vortex pairing or vortex tearing. With more frequencies being involved, multi-directivity appears in triple/quadruple-vortex merging cases.

"EFFECT OF INITIAL CONDITIONS ON VORTICES IN A TURBULENT NEAR WAKE"

AIAA Journal, Vol. 32, No. 6, June 1994, pp. 1207-1214.

The nature of turbulent vortices behind wake-generating bodies with similar dimensions depends on the initial conditions of porous or solid body wakes. Vortex strength, two-dimensional features, convection velocity topology and phase shift in the vortex shedding frequencies are different for the porous and solid body wakes. Solid body wake vortices contribute to Reynolds shear stress, and more to Reynolds normal stress than porous body wake vortices.

Zhou, Y., Zhang, H. J. and Whitelaw, J. H.

"WING-TIP VORTEX MEASUREMENT WITH PARTICLE IMAGE VELOCIMETRY"

AIAA Paper No. 2004-2433, Portland, OR, June-July 2004

Vortices shed from the tip of a rectangular half-span wing model (NACA 0012) have been investigated with flow visualization and a particle image velocimeter (PIV) at chord Reynolds number between $3.4 \times 10,000$ and $26.6 \times 10,000$, at distances from 0.2 to 5 chord lengths downstream and at angles of attack of 8 and 16 degrees. The tangential velocities, size and downstream evolution of the tip vortex were measured together with the growth in size and strength and of the formation length. The vortex core vorticity reached its maximum value at one and three chord lengths for angles of attack of 8 and 16 degrees. Perturbation of the tip vortex by blowing in the spanwise direction led to increased dispersion of the vortex and the otherwise stable vortex evolution or roll-up was disrupted. The extent to which the tip vortex was perturbed was sensitive to the velocity and position of the jet.

Zhu, R., Liu, J., Liu, Z. and Bao, F.

"EXPERIMENT ON A NEW CONCEPT WING LAYOUT WITH ALLEVIATED WAKE VORTEX"

Acta Aeronautica et Astronautica Sinica, Vol. 38, No. 4, April 2017, pp. 120250-1 to 120250-9.

Aircraft wake vortex will be produced by the wing tip to have a negative impact on flight safety, when a large aircraft applies flap wing to take-off and landing under a large angle of attack. Based on the Rayleigh-Ludwig instability, a new concept flap layout is developed by adding a set of specially designed flaps. Water channel experiments reveal that the new concept flap layout can significantly promote the wingtip vortex dissipation. The wingtip vortex which is affected by flap vortex with disparate parameter combinations performs differently with respect to movement characteristics and energy. The experiments also provide references to wake vortex control, when the requirement for flight mechanics design is satisfied. Building four-vortex system reasonably by taking advantage of high lift devices will have a significant effect on alleviating the intensity of aircraft wake, and improve the efficiency of aircraft take-off and landing at the airport. [In Chinese.]

"VALIDATION OF AIRBORNE 1.5 MICRON ALL-FIBER COHERENT LIDAR MEASUREMENT OF WIND PROFILES"

19th Coherent Laser Radar Conference (CLRC), Paper Th13, June 2018, Okinawa, Japan.

A high pulse energy 1.5-micron all-fiber coherent Doppler lidar airborne engineering prototype is developed for wind profiles measurement. The lidar system is very compact with 300 micro-J single pulse energy output and 100 mm telescope diameter, which could work in wide temperature range. Wind profiles are measured every 16 seconds with 60m range resolution. The airborne wind profiles measurement experiments-based UAV platform was successfully implemented. The airborne lidar measured wind speeds were compared with the ground-based coherent wind lidar and the GPS balloon, and good agreements were validated with wind speed standard error of less than 1 m/s from 1700 m to 3700 m.

"DYNAMIC SOARING OF UNMANNED AERIAL VEHICLE WITHIN AIRLINER WAKE VORTEX IN CLIMB REGIME"

Journal of Aerospace Engineering, Vol. 231, No. 13, 2017, pp. 2479-2486.

The paper presents an analysis of an unmanned aerial vehicle gliding in an airliner wake vortex using the dynamic soaring principle. The goal of dynamic soaring is an improvement of flight performance of the unmanned aerial vehicle following an airliner. The paper extends previously published results of an airliner unmanned aerial vehicle climb regime flight formation analysis. Wake vortex model, the unmanned aerial vehicle basic parameters including drag polar and an airliner climb profile are taken from previous research. Dynamic soaring simulation within wake vortex is performed and evaluated. The presented results provide insight into energy balance and controllability of the unmanned aerial vehicle flying in an airliner wake vortex.

"AIRLINER-UAV FLIGHT FORMATION IN CLIMB REGIME"

International Journal of Aerospace and Mechanical Engineering, Vol. 9, No. 10, 2015, pp. 1786-1791.

Extreme formation is a theoretical concept of self-sustain flight when a big airliner is followed by a small UAV glider flying in the airliner wake vortex. The paper presents results of a climb analysis with the goal to lift the gliding UAV to airliners cruise altitude. Wake vortex models, the UAV drag polar and basic parameters and airliner's climb profile are introduced at first. Afterwards, flight performance of the UAV in a wake vortex is evaluated by analytical methods. Time history of optimal distance between an airliner and the UAV during a climb is determined. The results are encouraging. Therefore, available UAV drag margin for electricity generation is figured out for different vortex models.

"TURBULENT STRUCTURE OF A WINGTIP VORTEX IN THE NEAR FIELD"

AIAA Paper No. 1993-3011, Orlando, FL, July 1993

The turbulent rollup of a vortex generated by a rectangular wing has been investigated. Extensive mean and turbulence measurements of the flowfield on a wingtip and in the near field have been completed. Velocity fluctuation measurements show that the near-field core is not laminar. A large axial velocity excess was found to exist in the core of the vortex. A momentum balance in the near-field of the wingtip showed that the magnitude of the core Reynolds-stress gradient terms is the same order as the largest terms in the governing equations. Navier-Stokes computations of the identical configuration, including wind tunnel walls and using measured inflow and outflow boundary conditions, reproduced many of the features of the experiment. Inherent limitations of the Baldwin-Barth turbulence model combined with limited grid resolution caused the computed vortex core to be more diffuse than desired. The momentum balance also demonstrated that the level of numerically generated false diffusion in the vortex core is relatively high.

"INFLUENCE OF HELICOPTER ROTOR WAKE MODELING ON BLADE AIRLOAD PREDICTIONS"

International Journal of Engineering, Vol. 3, Issue 6, 2010, pp. 521-537.

In the present paper a computational investigation is made about the efficiency of recently developed mathematical models for specific aerodynamic phenomena of the complicated helicopter rotor flowfield. A developed computational procedure is used, based on a Lagrangian type, Vortex Element Method. The free vortical wake geometry and rotor airloads are computed. The efficiency of special models concerning vortex core structure, vorticity diffusion and vortex straining regarding rotor airloads prediction is tested. Investigations have also been performed to assess a realistic value for empirical factors included in vorticity diffusion models. The benefit of using multiple vortex line to simulate trailing wake vorticity behind blade span instead of isolated lines or vortex sheets, despite their computational cost, is demonstrated with the developed wake relaxation method. The computational results are compared with experimental data from wind tunnel tests, performed during joined European research programs.

"NUMERICAL INVESTIGATION OF BVI MODELING EFFECTS ON HELICOPTER ROTOR FREE WAKE SIMULATIONS"

24th International Congress of the Aeronautical Sciences, ICAS 2004, August 2004, Yokohama, Japan.

This paper presents the influences of numerical Blade Vortex Interactions (BVI) simulation on the computational results of rotor blade downwash distribution and airloading. This investigation is performed on the basis of a developed computational procedure utilizing Vortex Element Method for rotor free wake computations. By these means wake vortices are modeled by a series of discrete vortex elements and induced velocity on rotor disk is calculated for the distorted wake geometry, integrating Biot-Savart law in closed form over each one of them. Bound circulation variations and unsteady blade airloading because of the nonuniform induced downwash are computed utilizing a blade element like method. Wake roll up process, vortex core modeling, vorticity dissipation and elastic blade motion are some of the aerodynamic topics modeled with special care in the developed procedure. Using the computational flexibility of Vortex Element Method, BVI locations are captured and the phenomena are categorized as parallel, perpendicular, and oblique regarding their orientation relative to rotor blade. The corresponding intensity and locus for each category are calculated via a lifting surface methodology considering compressible blade flowfield. In addition, with the developed procedure the influence of each BVI phenomenon is isolated and its influence on blade downwash and airloads distribution is demonstrated. The computational results of BVIs location and strength distribution on rotor disk are compared with experimental data of blade airloading for several decent and level flight conditions. These data are derived from model-rotor wind tunnel tests, performed in the duration of joined European research programs.

"SIZE REQUIREMENTS IMPOSED UPON THE PARTICLES USED FOR VISUALIZING AIRCRAFT VORTEX WAKES"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 146-150

Computational study has been carried out of the motion of small particles within a vortex aimed at working out the requirements to be imposed upon the size of particles used to visualize aircraft wakes. The motion of the particles of various size in Lamb's vortex was considered with accounting for the air turbulence effect on vortex sheet attenuation. The particles of 5-10 microns in diameter were obtained to be used for visualization purposes. [In Russian]

"VORTEX ROLLUP OVER AND BEHIND WINGS RELATED TO NONLINEAR AERODYNAMIC CHARACTERISTICS"

J. Aircraft, Vol. 15, No. 4, April 1978, pp. 193-194

The present paper describes the investigation of the rolling up of vortices over and behind wings of rectangular and delta planforms. The present method can also be used to evaluate the loading of these wings. The method is based on the representation of the vortex distribution over the planform by a vortex lattice system incorporating in this calculation the influence of the vortices shed from these cells

into the flowfield. The evaluation of the diameter of the vortices far downstream of the wing, the spanwise position of the center of this vortex, and the appearance of the secondary vortices, which are some of the results obtained in this investigation, all are in reasonable agreement with available experimental results.

Zouaoui, Z., Szkatula, L. and Grant, R. J.

"COMPUTATIONAL ANALYSIS OF WAKE VORTICES GENERATED BY NOTCHED WINGS"

Journal of Aircraft, Vol. 44, No. 2, March-April 2007, pp. 487-500

The motivation behind the present investigations is the alleviation of vortex wake hazard. The present paper contains a 3-D computational analysis of the trailing wake vortices generated by notched (rectangular) wings, at a chord-based Reynolds number of $5.34 \times 10,000$. Various wing configurations were tested to determine the quantitative and qualitative effects of wing geometries on vortex dynamics. Two sets of computations were conducted up to 80 chord lengths downstream from the tip region. The first set used the conventional and notched-wing geometries for correlation of experimental and computed results. The second set of simulations concentrated on the development and testing of new wing designs. Wing geometries combined multiple tip (triangular/ogee) forms with the original notch design. The nature of vortices was classified in terms of their location, strength, and trajectories. Flow data were analyzed within these categories, at different crossflow planes behind the trailing edge. The first set of computational solutions demonstrated that the notched geometry significantly influenced the vortex location and strength of the wake system. The numerical results also confirmed that the tip and flap vortices generated by a notched wing remain distinct and unmerged, unlike those associated with the conventional wing. Finally, computed data demonstrated that the two-equation renormalization group turbulence model, combined with an appropriate treatment of the near-wall region can predict accurately steady and turbulent flows past wings. Very good agreement was obtained between the experimental and numerical results. Numerical simulations were performed for the second set of wing geometries to evaluate the effectiveness of wing modifications on the wake properties. Current results are promising: for all the cases considered, the wakes of the notched-triangular/ogee wings show maximum vorticity magnitudes that are substantially lower than those generated by the original notched wing. Numerical data clearly indicate that such geometrical combinations significantly reduce the wake strength and affect the merging process of the present vortex system.

"EXPERIMENTAL INVESTIGATION OF INTERACTING WING-TIP VORTEX PAIRS"

VPI-AOE-191, June 1992, Virginia Polytechnic Inst. and State Univ., Blacksburg, VA

The interaction of trailing vortex pairs shed from the tips of two rectangular wings have been studied through helium bubble flow visualizations and extensive hot wire velocity measurements made between 10 and 30 chord lengths downstream. The wings were placed tip to tip at equal and opposite

angles of attack, generating pairs of co-rotating and counter rotating vortices. Meaningful hot wire measurements could be made because the vortices were found to be insensitive to probe interference and experienced very small wandering motions. The co-rotating pairs were observed to rotate around each other and merge. Upstream of the merging location, the vortices have approximately elliptical cores. These are surrounded by the two wing wakes which join around the two cores.

"AN ASYMPTOTIC SOLUTION TO THE PROBLEM OF THE STRUCTURE OF A VORTEX PLAIT WITH CONSTANT CIRCULATION"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 129-136

In the framework of an ideal fluid model, an asymptotic solution to the problem is constructed, which describes the constant-circulation vortex sheet structure in a domain far downstream from the site of its generation. [In Russian.]

Zubtsov, A. V.

"ON THE CIRCULATION 'DISSIPATION' IN THE VORTEX WAKE"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 121-124

The paper addresses the reason for unsteady circulation in the far vortex wake. Drop of circulation in the vortex wake with the distance from an aircraft is shown to be associated with the redistribution of vorticity vector flux in the three-dimensional flow region. Main physical factors influencing the variation of the vortex wake circulation are fluid viscosity, Reynolds stresses in the wake, and atmospheric turbulence.

Zudov, V. N.

"INTERACTION OF A STREAMWISE VORTEX WITH THE NORMAL SHOCK"

J. of Applied Mechanics and Technical Physics, Vol. 52, No. 5, 2011, pp. 734-743.

Interaction of a supersonic streamwise vortex with the normal shock is considered. Two interaction modes (weak and strong interaction) are identified. It is demonstrated numerically that strong interaction can lead to vortex breakdown.

Zudov, V. N. and Pimonov, E. A.

"INTERACTION OF A STREAMWISE VORTEX WITH AN OBLIQUE SHOCK WAVE"

J. Applied Mechanics and Technical Physics, Vol. 44, No. 4, 2003, pp. 461-470

Interaction of a supersonic streamwise vortex with an oblique shock wave is considered. A mathematical model of the streamwise vortex is constructed. Three interaction regimes (weak, moderate, and strong) are found. It is shown numerically that vortex breakdown is possible in the case of strong interaction. The influence of the governing parameters on the interaction type is studied. It is shown that the main effect on the interaction type is exerted by the streamwise velocity and angle of the wedge forming the shock wave. The effect of splitting of the primary vortex on the shock wave in the case of moderate and strong interaction regimes is found.

Zudov, V. N., Shevchenko, A. and Tretyakov, P. K.

"THE INTERACTION OF STREAMWISE VORTEX WITH A SHOCK WAVE"

20th International Congress on Instrumentation in Aerospace Simulation Facilities (ICIASF), Aug. 2003, pp. 258-267.

Experimental investigation of a longitudinal vortex/normal shock interaction is conducted at Mach numbers of 3, 4 and 6. The fields of total pressures in the core of a longitudinal vortex and its neighborhood are obtained. The optical visualization of flow structure in an interaction region is executed. The strongly unsteady character of interaction process is detected. The numerical modeling of the streamwise vortex interaction with the oblique and normal shock wave was solved using three-dimension unsteady Euler and Navier-Stokes equations. Results of an experimental study of the region of interaction of a plane shock wave arising in the flow around a wedge and an axisymmetric shock wave formed by counterflow injection with a jet wake formed by co-current injection of gases (H₂, air, Ar). Three interaction modes are distinguished, depending on the gas-jet parameters: strong interaction with a subsonic velocity in the wake, moderate interaction with the formation of a subsonic flow region bounded by the shock wave whose shape is close to conical, and neutral interaction where the dynamic pressure in the jet is sufficient to overcome the pressure difference on the shock wave.

Zuhal, L. and Gharib, M.

"NEAR FIELD DYNAMICS OF WING TIP VORTICES"

AIAA Paper No. 2001-2710, Anaheim, CA, June 2001.

An experimental investigation has been conducted to study the formation and near-field dynamics of a wing tip vortex. Stereoscopic PIV (SPIV), which allows instantaneous measurements of all three components of velocity within a planar slice, was used to measure velocity fields behind the wing. The present study has found that the wing sheds multiple vortices of opposite signs. Farther downstream, the vortices, with opposite sense of rotation, break up into smaller vortices which satellite around the tip vortex. At least one relatively strong satellite vortex appears in some of the instantaneous fields. The study found that the interaction of the tip vortex and satellite vortices give rise to the unsteady motion of the wing tip vortex.

"ANALYSIS OF WAKE VORTEX SPACING REDUCTION TECHNOLOGY"

Proceedings of the International Conference on Service Robotics Technologies (ICSRT 2018), March 2018, Chengdu, China, pp. 57-61.

There are two main purposes for our research on wake vortex: one is to improve operation safety; the other is to reduce the wake spacing and ensure the runway capacity and operation efficiency under the premise of ensuring safety. By comparing and analyzing the technology of wake spacing reduction, we have studied aerial classification technology, synchronous offset approach technology, high glide slope approach technology, wake vortex warning system, aircraft wake vortex interval system and so on. Research shows that by proposing advanced concepts or improving the ATM program, namely the wake interval reduction technology, we can avoid the influence of the wake generated by the front aircraft, ensure the operation safety and increase the airport capacity by 3.7% - 25%. The key technology of the wake interval reduction technology is the wake vortex prediction model and the safety analysis of the wake encounter. However, the higher the accuracy of the model is, the more complex the computation is. The research on wake detection technology will be the future development direction.

Zurheide, F. and Schroder, W.

"NUMERICAL ANALYSIS OF WING VORTICES"

New Results in Numerical and Experimental Fluid Mechanics VI, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 96, 2008, pp. 17-25.

The temporal development of generic vortex systems based on Lamb-Oseen vortices is computed by large-eddy simulations. For a two-vortex system the growth of short-wave co-operative elliptical and long-wave Crow instabilities leads to a pronounced decay of its vorticity distribution. The four-vortex system possesses a smaller decay rate than the two-vortex system.

Zurheide, F. T., Huppertz, G., Fares, E., Meinke, M. and Schroder, W.

"INTERACTION OF WING-TIP VORTICES AND JETS IN THE EXTENDED WAKE"

Flow Modulation and Fluid-Structure Interaction, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 109, 2010, pp. 105-135.

The interaction of wing-tip vortices and jets in the extended wake is experimentally and numerically investigated. The measurements focus on the unsteady wake of a swept-wing half-model equipped with an engine jet and on the analysis of meandering vortex. The aircraft engine is modeled by a cold jet driven by pressurized air. To investigate the influence of the location of the engine jet on the vortex wake, it is mounted in two different positions under the wing model. The spatial development of a vortex wake behind a wing is simulated up to the extended near field. The measurements are used as

inflow distribution for a large-eddy simulation of the wake region. To better capture the motion of the wake vortices a method for hexahedral block structured adaptive mesh refinement with vertex-centered fluxes is introduced. The numerical simulations of the wake can predict trajectories and instabilities of the vortex core. The closer the engine is located near the root of the wing, the smaller is the deflection of the vortex and the fewer wave modes of the vortex are excited. The meandering motion of the vortex core is triggered by the engine jet.

Zurheide, F. T., Meinke, M. and Schroder, W.

"MEANDERING OF WING-TIP VORTICES INTERACTING WITH A COLD JET IN THE EXTENDED WAKE"

High Performance Computing on Vector Systems, Springer Berlin Heidelberg, 2009, pp. 223-242.

The spatial development of a vortex wake behind a half wing is simulated up to the extended near field. Results from wind tunnel measurements are used as inflow boundary conditions for an LES of the wake region. An aircraft engine is modeled in the experimental setup, where a cold jet is driven by pressurized air. The engine is mounted in two different positions under the wing model to investigate the influence of the location of the engine jet on the vortex wake. The numerical simulations of the wake can predict trajectories and instabilities of the vortex core. A position of the engine towards the root of the wing creates a smaller deflection of the vortex and excites fewer wave modes of the vortex.

Zurheide, F. T., Meinke, M. and Schroder, W.

"WING-TIP VORTEX / JET INTERACTION IN THE EXTENDED NEAR FIELD"

High Performance Computing in Science and Engineering, Part 5, 2009, pp. 269-283.

The vortex wake behind a half wing is spatially simulated up to the extended near field. Instabilities of the wing tip vortex are analyzed. Results from wind tunnel measurements are used as inflow boundary conditions for an LES of the wake region. An aircraft engine is modeled in the experimental setup, where the jet is driven by pressurized air. The engine was mounted in two different positions under the wing model to investigate the influence of the location of the engine jet on the vortex wake. The numerical simulations of the wake were able to predict trajectories and instabilities of the vortex core. A position of the engine towards the root of the wing created a smaller deflection of the vortex.

Zvonova, J. S.

"SIMULATION OF THE VORTEX WAKE EVOLUTION BEHIND THE AIRCRAFT IN THE FRAMEWORK OF A BOUNDARY-VALUE PROBLEM FOR THE EULER EQUATIONS"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 176-182.

One of the most important factors limiting airport capacity is vortex wakes behind the aircraft during landing operations. Because of this, research into vortex wakes with the aim of their alleviation

becomes especially urgent. In the present work, the problem of the evolution of the far wake behind an aircraft and assessment of its lifespan is considered based on the Euler equations. The problem is solved without restrictions usually used in asymptotic theories. A method has been developed, that allows one to analyze the development of vortex filaments with the structure varying during their motion, which is impossible to do by asymptotic methods using the 'frozen' vortex structure hypothesis.

Zwack, P. and Tardif, R.

"USING THE COBEL COLUMN MODEL IN SUPPORT OF A WAKE VORTEX ADVISORY SYSTEM"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 125-126

Column (height-time) models represent an accurate and economical approach to the problem of analyzing the atmospheric structure and providing very short-range forecasts over specific sites. This presentation will focus on the COBEL column model for providing meteorological analysis and forecasts for airports. With funding from NASA and the FAA, COBEL is being adapted to provide accurate current and very short-term predictions of the atmosphere's vertical structure over the terminal area. The most recent development has been the implementation of a real-time version of COBEL during the Dallas-Fort Worth field measurement program. In this deployment, COBEL uses horizontal forcing (temperature and humidity advection, meso-scale vertical motions) and assimilates in-situ and remotely sensed measurements to provide an up-to-date vertical structure of the atmosphere.

Zwieback, E. L.

"TRAILING VORTICES OF JET TRANSPORT AIRCRAFT DURING TAKEOFF AND LANDING"

FAA-RD-64-3, January 1964, Douglas Aircraft, Long Beach, CA

The effect of ground plane and ambient winds on movement and strength decay was investigated. The results are compared with a modified potential flow theory. The position of the trailing vortices near the ground is extremely sensitive to low level ambient winds and vertical gradients of the wind. The measured positions of the trailing vortices indicate probable correlation with the potential flow theory with noted exceptions to the assumptions used. Measured vortex velocity decay rates are comparable to a modified theoretical free vortex viscous decay. Distinct vortex velocity fields were observed near the ground using a smoke generator technique for periods up to 65 seconds after aircraft passage. No differences in the trailing vortex system of two rolled-up vortices were observed for both the takeoff and landing configurations of the DC-8 aircraft.

Zwieback, E. L.

"TRAILING VORTICES OF JET TRANSPORT AIRCRAFT DURING TAKEOFF AND LANDING"

J. Aircraft, Vol. 1, No. 5, September-October 1964, pp. 308-310

A test program with a DC-8 determined that wing trailing vortex positions were extremely sensitive to low-level wind conditions, including vertical velocity gradients, and that the existing theories can predict the approximate behavior of the vortices near the ground. It is concluded from the test results that the location of trailing vortices near the ground cannot be accurately predicted based on routine wind data furnished by the control towers.
