Closely Spaced Parallel Runway configurations are capacity limited for departures due to the requirement to apply wake vortex separation standards from traffic departing on the adjacent parallel runway. To mitigate the effects of this constraint, a concept focusing on wind dependent departure operations has been developed known as the Wake Turbulence Mitigation for Departures (WTMD). This concept takes advantage of the fact that crosswinds of sufficient velocity blow wakes generated by aircraft departing from the downwind runway away from the upwind runway. Consequently, under certain conditions, wake separations on the upwind runway would not be required based on wakes generated by aircraft on the downwind runway as is currently the case. It follows that information requirements, and sources for this information, would need to be determined for airport traffic control tower (ATCT) supervisory personnel who would be charged with decisions regarding the use of the procedure. To determine the information requirements, data were collected from ATCT supervisors and controller-in-charge qualified individuals at Lambert-St. Louis International Airport (STL) and George Bush Houston Intercontinental Airport (IAH). STL and IAH were chosen as data collection sites based on the implementation of a WTMD prototype system, operating in shadow mode, at these locations. The 17 total subjects represented a broad-base of air traffic experience. Results indicated that the following information was required to support the conduct of WTMD operations: current and forecast weather information, current and forecast traffic demand, traffic flow restrictions, and WTMD System status information and alerting. Subjects further indicated that the requisite information is currently available in the tower cab except for the WTMD status and alerting. Subjects were given a demonstration of a display supporting the prototype systems and unanimously stated that the WTMD status information they felt important was represented. Overwhelmingly, subjects felt that approving, monitoring, and terminating the WTMD procedure could be integrated into their supervisory workload.

"INFORMATION REQUIREMENTS FOR SUPERVISORY AIR TRAFFIC CONTROLLERS IN SUPPORT OF A WAKE VORTEX DEPARTURE SYSTEM"

ICAS 2008, Anchorage, AK, Sept. 2008

Closely Spaced Parallel Runway configurations are capacity limited for departures due to the requirement to apply wake vortex separation standards from traffic departing on the adjacent parallel runway. To mitigate the effects of this constraint, a concept focusing on wind dependent departure operations has been developed, known as the Wake Turbulence Mitigation for Departures (WTMD). This concept takes advantage of the fact that crosswinds of sufficient velocity blow wakes generated by aircraft departing from the downwind runway away from the upwind runway. It follows that information requirements, and sources for this information, would need to be determined for airport traffic control tower (ATCT) supervisory personnel who would be charged with decisions regarding use of the procedure. Results indicated that the following information was required to support the conduct of WTMD operations: current and forecast weather information, current and forecast traffic demand, traffic flow restrictions, and WTMD System status information and alerting.

Lomax, H.

"LIFT DEVELOPED ON UNRESTRAINED RECTANGULAR WINGS ENTERING GUSTS AT SUBSONIC AND SUPERSONIC SPEEDS"

NACA Technical Note 2925, April 1953, Ames Aeronautical Laboratory, Moffett Field, CA.

The object of this report is to provide an estimate, based on theoretical calculations, of the forces induced on a wing that is flying at a constant forward speed and suddenly enters a vertical gust. The calculations illustrate the effects of Mach number (from 0 to 2) and aspect ratio (2 to infinity), and solutions are given by means of which the response to gusts having arbitrary distributions of velocity can be calculated. The effects of pitching and wing bending are neglected and only wings of rectangular plan form are considered. Specific results are presented for sharp-edged and triangular gusts and various wing-air density ratios.

Lomax, H. and Sluder, L.

"DOWNWASH IN THE VERTICAL AND HORIZONTAL PLANES OF SYMMETRY BEHIND A TRIANGULAR WING IN SUPERSONIC FLOW"

NACA Technical Note No. 1803, January 1949, Ames Aeronautical Lab., Moffett Field, CA.

A method developed in a previous report for finding the induced velocity field behind a supersonic wing with known load distribution is used to find the downwash behind a triangular wing with subsonic leading edges. Results are given for the chord plane in the extended vortex wake of the wing and for the vertical plane of symmetry up to about 20 percent of the wing span above the plane of the wing.

"IMPLICIT LARGE-EDDY SIMULATION OF A WINGTIP VORTEX"

AIAA Journal, Vol. 54, No. 2, February 2016, pp. 506-518.

In this article, recent developments in numerical methods for performing a large-eddy simulation of the formation and evolution of a wingtip vortex are presented. The development of these vortices in the near wake, in combination with the large Reynolds numbers present in these cases, makes these types of test cases particularly challenging to investigate numerically. First, an overview is given of the spectral vanishing viscosity/implicit large-eddy simulation solver that is used to perform the simulations, and techniques are highlighted that have been adopted to solve various numerical issues that arise when studying such cases. To demonstrate the method's viability, results are presented from numerical simulations of flow over a NACA 0012 profile wingtip at $Re = 1,200,000$ and they are compared against experimental data, which is to date the highest Reynolds number achieved for a large-eddy simulation that has been correlated with experiments for this test case. The model in this paper correlates favorably with experiment, both for the characteristic jetting in the primary vortex and pressure distribution on the wing surface. The proposed method is of general interest for the modeling of transitioning vortex-dominated flows over complex geometries.

"HIGH ASPECT RATIO WINGS - TIP VORTEX STRUCTURE AND ITS NUMERICAL IMPLICATIONS"

AIAA Paper No. 1996-1961, New Orleans, LA, June 1996

Some aspects related to the evaluation of the loads on high aspect ratio wings are analyzed. The complex structure of the flow typology close to the tip vortex is first studied by experiment. The formation of the tip vortex was found to take place by a complex mechanism. Subsequently, to verify the capability of different types of numerical codes to describe the effects of this type of flow, a comparison between numerical and experimental results is carried out considering the pressure distributions acting on sections close to the wing tip of an unswept and a forward-swept wing. Different non-viscous methods, typically used for the evaluation of lift distribution along the wing span, are shown to give rise to significant errors in the load evaluation close to the wing tip, due to the impossibility of adequately representing the tip flow typology. In particular, the lift close to the wing tip tends to be underestimated by a potential panel method and overestimated by an Euler code. Although these discrepancies are limited to a small zone close to the wing tip, they could produce non-negligible errors in the wing root bending moment.

Lombardi, G. and Skinner, P.

"WING-TIP VORTEX IN THE NEAR FIELD: AN EXPERIMENTAL STUDY"

J. of Aircraft, Vol. 42, No. 5, September-October 2005, pp. 1366-1368

An experimental study of the initial formation of the wing-tip vortex was conducted. The vorticity was directly measured using a vorticity probe, whose experimental uncertainties are smaller than those of other measurement probes. The measurements document, over a small streamwise distance, the formation of a double-core vortex structure that subsequently merges into a single vortex. The spanwise position of the primary vortex core varies as the square root of the streamwise distance; this is in good agreement with previous studies.

Lombardi, G., Talamelli, A. and Sjoberg, J.

"VORTICITY MEASUREMENTS IN THE NEAR-FIELD OF A WING TIP VORTEX"

ICAS Paper 98-3.2.2, Sept. 1998, Melbourne, Australia.

The initial phase of the roll-up of the wing tip vortex, emanating from high aspect ratio wings, is considered. An experimental investigation, based on hot-wire anemometry technique, is in progress; the measurement procedures used and some of the preliminary results are described. Tests are carried out on a tapered, no-swept wing model, with aspect ratio 5.7. The statistically averaged quantities of interest, viz. the three mean velocity components, the whole Reynolds stress tensor and the third order moments tensor, are measured, by combining different responses of the wires of single or X-wire probes positioned at different orientations in the measurement points. This procedure avoids the difficulties connected with the use and calibration of triple-wire probes and permits the use of

considerably smaller and less intrusive probe. A continuous complex wavelet transform technique is also used to assess some characteristics of the tip vortex wandering. Furthermore, to verify the results, a different measurement procedure, based on a pressure vorticity meter, has been used; it allows the time history of quantities related to the streamwise component of the vorticity to be obtained.

"THE BENEFITS OF REDUCED SEPARATION STANDARDS AT CHICAGO O'HARE INTERNATIONAL AIRPORT"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 29-1 - 29-14

In this paper, data collected for the Chicago Delay Task Force Study serve as the basis for an assessment of the operational benefits of reduced wake-vortex separation at Chicago O'Hare International Airport, using AIRSIM, an FAA approved airspace/airfield simulation model. Existing wake-vortex separation standards are simulated as the baseline scenario, while the aircraft separation research goals defined in the FAA Wake Vortex Research Program Plan are simulated as the test-case scenario. The operational benefits of reduced wake-vortex separation standards are defined as the difference in aircraft operational delays incurred under the test-case scenario relative to the performance of the baseline scenario. In addition, the effect on delay of changes in operating factors, such as fleet mix and meteorological conditions, is examined with respect to reduced separation standards. This assessment demonstrates the ability to reduce annual delays at O'Hare by more than 10,000 hours with reduced wake-vortex separation standards, reflecting a direct airline operating cost savings of \$20 million per year. In addition, the analysis suggests that the expected delay reduction increases: 1) as the percentage of 'Heavy' (i.e., 300,000 pounds or greater) aircraft increases; 2) as the level of ATC coordination decreases; and 3) as the level of demand approaches airport capacity.

"3D FILAMENT SIMULATIONS OF CROW-LIKE INSTABILITIES IN GROUND EFFECT"

AST4-CT-2005-012238, Universite Catholique de Louvain, Louvain-la-Neuve, Belgium, September 2006

The purpose of this work is to investigate two vortex systems in ground effect (IGE) using a vortex filament method. The method being inviscid, the scope of this study is however reduced: 2-D and 3-D (DNS and LES) results clearly show that a very important effect for wake vortices (WV) IGE is the viscous interaction with the ground through the creation of secondary vortices. We therefore restrict the study to the analysis of long wave (Crow-type) instabilities for WV IGE. After briefly describing the numerical method, we investigate two cases: (i) a configuration as close as possible to the one studied experimentally by CNRS-IRPHE (i.e., a thick vortex pair IGE with a forced long wave instability) and (ii) the case of aircraft like vortices IGE with a forced Crow instability (at different initial perturbation levels).

Long, K.

"INVESTIGATIONS OF SHIPBOARD ROTORCRAFT INTERACTIONAL AERODYNAMICS"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Since 1943, the US Navy has conducted Dynamic Interface (DI) shipboard flight tests to evaluate all aspects of shipboard rotorcraft compatibility, and to develop shipboard rotorcraft operating envelopes. The shipboard environment poses unique challenges to routine fleet operations and test operations alike. Since the mid-1990s, the US Navy has increasingly focused on developing improved analytic techniques that would facilitate more efficient and cost-effective shipboard rotorcraft flight test programs. This paper summarizes recent USN investigations, which include wind tunnel, CFD and other analytic efforts, conducted at NASA Ames Research Center, which are designed to investigate shipboard rotorcraft interactional aerodynamics, thereby allowing the USN to optimize and improve shipboard rotorcraft compatibility. The paper and accompanying brief summarize a variety of wind tunnel efforts, which were conducted to investigate and characterize the complicated flow fields that exist aboard various USN ship classes, for use in improving USN shipboard flight test programs. The efforts included investigations of the wake flow around simplified and complicated three-dimensional ship structures, with and without model rotorcraft (both conventional and tiltrotor) imposed into the flow. These investigations included a variety of quantitative and qualitative measurement techniques, including surface oil and wake smoke flow visualization, a seven-hole probe, hot wire anemometry, particle image velocimetry surface pressure taps, pressure sensitive paint, and shear-sensitive liquid crystals. The wind tunnel results are compared with calculations and with full-scale shipboard flight test data.

Long, L. N.

"RECENT ADVANCES IN COMPUTING AND VISUALIZATION RELEVANT TO AIRPORT CAPACITY"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

To keep the number of new airports and runways to a minimum, there is an urgent need to increase their efficiency while reducing the aircraft accident rate. This paper will describe several roles that computing and visualization can play in helping to meet future airport capacity issues. In particular, runway independent aircraft (primarily rotorcraft) promise to ease congestion by moving passengers through the airports without utilizing traditional runways. It will be essential to use computers to help design future rotorcraft that are quiet, efficient, cost effective, and reliable. In addition, computer visualization will be very valuable in future air traffic control systems. One of our research efforts attempts to create a general software system to integrate Virtual Reality with real-time numerical simulations for visualizing aircraft wakes near and around airports. Specifically, this work aims at creating a wake-vortex hazard avoidance system by realistically simulating an airport with real-time visualization of the predicted wake-vortices generated by the moving aircraft. The dangers (and unknowns) associated with aircraft flying through wake-vortices is a dominant limiting factor in airport throughput. If implemented, such a system has the potential to greatly increase the utilization of

airports while reducing the risks of possible accidents. Since the wake-vortex prediction for an entire fleet of aircraft taking-off and landing at a busy airport is a computationally intensive problem, a parallel solution is proposed.

Long, R. R.

"A VORTEX IN AN INFINITE VISCOUS FLUID"

J. Fluid Mech., Vol. 11, Part 4, December 1961, pp. 611-624

A solution is given for a viscous vortex in an infinite liquid. Similarity arguments lead to a reduction of the equations of motion to a set of ordinary differential equations. These are integrated numerically. A uniform feature is the constant circulation K outside the vortex core, which is also a viscous boundary layer. The circulation decreases monotonically towards the axis. The axial velocity profiles and the radial velocity profiles have several characteristic shapes, depending on the value of the non-dimensional momentum transfer M . The solution has a singular point on the axis of the vortex. The radius of the core increases linearly with distance along the axis from the singularity, and, at a given distance, is proportional to the coefficient of viscosity and inversely proportional to K .

Long, R. R.

"VORTEX MOTION IN A VISCOUS FLUID"

J. of Meteorology, Vol. 15, Issue 1, Feb. 1958, pp. 108-112

A discussion is given of a three-dimensional vortex in a viscous fluid. A theory is outlined that leads to a reduction of the steady-state Navier-Stokes equations of an incompressible fluid to three ordinary, nonlinear, differential equations. Although no numerical results are available, qualitative arguments based on these equations and on the form of their dependent and independent variables throw considerable light on the structure of the vortex. One important result is that the vertical velocity is of the same order of magnitude as the horizontal velocity.

"FLOWFIELD OF A WING EMBEDDED IN THE WAKE OF A BURSTED VORTEX"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 16-1 to 16-8

In the present paper the flowfield around a delta wing partially embedded in the wake of a burst vortex is numerically studied at $M\text{-}\theta=0.4$. The simulation is carried out solving the Euler equations on two structured grids of about 2.3 million points and 300000 points respectively. Due to the lack of experimental results, special emphasis is put on the analysis of the effect of grid fineness on the wake-flow. The present investigation indicates that the spiraling flow of a vortex continues after breakdown

with a swirl velocity comparable to that of a non-bursted vortex generated at lower angles of attack and hence interference effects coming from its wake persist long downstream.

Lopez, J. M.

"AXISYMMETRIC VORTEX BREAKDOWN, PART 1, CONFINED SWIRLING FLOW"

Journal of Fluid Mechanics, Vol. 221, 1990, pp. 533-552.

A comparison between the experimental visualization and numerical simulations of the occurrence of vortex breakdown in laminar swirling flows produced by a rotating end wall is presented. The experimental visualizations of Escudier were the first to detect the presence of multiple recirculation zones and the numerical model presented here, consisting of a numerical solution of the unsteady axisymmetric Navier-Stokes equations, faithfully reproduces these phenomena and all other observed characteristics of the flow. Further, the numerical calculations elucidate the onset of oscillatory flow, an aspect of the flow that was not clearly resolved by the flow visualization experiments. Part 2 of the paper examines the underlying physics of these vortex flows.

Lopez, J. M. and Perry, A. D.

"AXISYMMETRIC VORTEX BREAKDOWN, PART 3, ONSET OF PERIODIC FLOW AND CHAOTIC ADVECTION"

Journal of Fluid Mechanics, Vol. 234, 1992, pp. 449-471.

When the fluid inside a completely filled cylinder is set in motion by the rotation of one endwall, steady and unsteady axisymmetric vortex breakdown is possible. Nonlinear dynamical systems theory is used to describe the changing kinematics of the flow as the speed of the rotating endwall is increased. Two distinct modes of oscillation have been found in the unsteady regime and the chaotic advection caused by the oscillations has been investigated. The results of this study are used to describe the filling and emptying processes of the vortex breakdown bubbles observed in flow visualization experiments.

Lopez, J. M., Cui, Y. D., Marques, F. and Lim, T. T.

"QUENCHING OF VORTEX BREAKDOWN OSCILLATIONS VIA HARMONIC MODULATION"

J. Fluid Mech., Vol. 599, 2008, pp. 441-464

Vortex breakdown is a phenomenon inherent to many practical problems, such as leading-edge vortices on aircraft, atmospheric tornadoes, and flame-holders in combustion devices. The breakdown of these vortices is associated with the stagnation of the axial velocity on the vortex axis and the development of a near-axis recirculation zone. For large enough Reynolds number, the breakdown can be time-dependent. Here we present results from a combined experimental and numerical investigation of vortex breakdown in an enclosed cylinder in which low-amplitude modulations of the rotating end wall that sets up the vortex are used as an open-loop control. As expected, for very low amplitudes of the modulation, variation of the modulation frequency reveals typical resonance tongues

and frequency locking, so that the open-loop control allows us to drive the unsteady vortex breakdown to a prescribed periodicity within the resonance regions. For modulation amplitudes above a critical level that depends on the modulation frequency (but still very low), the result is a periodic state synchronous with the forcing frequency over an extensive range of forcing frequencies. Of particular interest is the spatial form of this forced periodic state: for modulation frequencies less than about twice the natural frequency of the unsteady breakdown, the oscillations of the near-axis recirculation zone are amplified, whereas for modulation frequencies larger than about twice the natural frequency the oscillations of the recirculation zone are quenched, and the near-axis flow is driven to the steady axisymmetric state.

"ACARS WIND MEASUREMENTS: AN INTERCOMPARISON WITH RADIOSONDE, CLOUD MOTION AND VAS THERMALLY DERIVED WINDS"

Journal of Atmospheric and Oceanic Technology, Vol. 1, 1984, pp. 131-137.

Statistical comparisons between winds measured by ACARS and winds obtained from radiosondes, geostationary satellite image cloud motions, and VAS are presented. Observations from three separate comparisons reveal over 60 percent of wind vector magnitude differences are within 9 m/s, and 70 percent of the directional differences are within 15 degrees. The comparisons indicate that the ACARS system provides an independent source of wind data that complements other sources of wind data for constructing composite wind field analyses.

Loth, J. L.

"WIND POWER LIMITATIONS ASSOCIATED WITH VORTICES"

AIAA Paper 1978-0278, January 1978, Huntsville, AL.

The total pressure dissipation inside vortices, due to viscous shear, has been analyzed. The reduced level of the total pressure flux, of the flow inside a vortex, has an adverse effect on all vortex ingesting wind machines. The Betz limit of wind turbines ingesting the vortex generated by an airfoil has been computed and is non-dimensionalized using the area of the vortex generator. The vacuum pumping ability of vortices is also limited. The Betz type limit for wind turbines exhausting into the core of a vortex has been computed for both wing tip and tornado tower type vortex generators. The energy required to eliminate a tornado has been computed.

"THE INTEGRATED SURFACE DATABASE: PARTNERSHIPS AND PROGRESS"

24th AMS Conference on Interactive Information Processing Systems for Meteorology, Oceanography, and Hydrology (IIPS), Paper 131387, Jan 2008, New Orleans, LA.

The National Oceanic and Atmospheric Administration (NOAA) National Climatic Data Center (NCDC) is responsible for the stewardship of global climatological data to support a variety of applications in the private, research, and public sectors. This includes the development of datasets to be used as input for a planned global climatological reanalysis. In support of these activities and to better streamline operations, NCDC implemented a plan to integrate surface climatological data into a common format and data model and process these data through one processing system that capitalizes on network-independent standardized quality control algorithms and procedures. Federal Climate Complex (FCC) partners (US Air Force and Navy) collaborated closely with NCDC in development of the global Integrated Surface Database (ISD), providing large volumes of data as input sources. Now, through additional partnerships, ISD is being further expanded and enhanced.

"FLIGHT-SIMULATOR STUDY OF AIRPLANE ENCOUNTERS WITH PERTURBED TRAILING VORTICES"

Journal of Aircraft, Vol. 42, No. 4, July-August 2005, pp. 924-931

This study provides a preliminary, but concrete, assessment of the potential benefits of causing the breakup of airplane trailing vortices via large-scale instability, resulting in vortex rings. The 737-300 flight simulator is used to model the autopiloted response of an airplane encountering the vortices at different stages in the breakup process. A series of encounters with straight vortices is used to establish a baseline response. For the early stages of the vortex breakup, the vortices are modeled as wavy vortex filaments. For the late stages of the vortex breakup, the vortices are modeled as vortex rings, whose shape is based on experimental observation. The primary results of the study are presented in a collection of contour plots for the maximum bank angle that occurs during an encounter. The bank angles are given as a function of the horizontal and vertical vortex-intercept angles. The results show a significant reduction in the maximum bank angle, experienced by the encountering airplane, because of the vortex breakup. The simulations show a continuous reduction in the level of

upset as the vortices become increasingly wavy and ultimately break up into rings. The most significant reductions (both in terms of the magnitudes of the upset and the likelihood of their occurrence) result from the formation of vortex rings. The results suggest that the controlled breakup of the vortices could be exploited to enable reduced airplane separations, based on a vortex-destruction concept in addition to vortex avoidance.

"UNRAVEL: A ROBUST MODULAR VELOCITY DEALIASING TECHNIQUE FOR DOPPLER RADAR"

Journal of Atmospheric and Oceanic Technology, Vol. 37, May 2020, pp. 741-758.

Unfold Radar Velocity (UNRAVEL) is an open-source modular Doppler velocity de-aliasing algorithm for weather radars. UNRAVEL is an algorithm that does not need external reference velocity data, making it easily applicable. The proposed algorithm includes 11 core modules and 2 de-aliasing strategies. UNRAVEL is an iterative algorithm. The goal is to build the de-aliasing results starting with the strictest possible continuity tests in azimuth and range and, after each step, relaxing the parameters to include more results from a progressively growing number of reference points. UNRAVEL also has modules that perform 3D continuity checks. Thanks to this modular design, the number of de-aliasing strategies can be expanded in order to optimize the de-aliasing results. While the first driver de-aliases Doppler velocity from each tilt independently from one another, the second driver also performs a three-dimensional continuity check of the velocity using successive elevations. The proposed de-aliasing algorithm is tested using severe weather data from an S-band Doppler radar that have been aliased to mimic aliased radial velocity patterns that would be observed by a C-band Doppler radar. Artificially aliasing S-band data permits creation of a reference to which the performance of various de-aliasing techniques can be compared. Comparisons show that UNRAVEL consistently outperforms other established de-aliasing algorithms for the test period selected in this work.

Lovell, D. A.

"MILITARY VORTICES"

RTO AVT Symposium on Advanced Flow Management, May 2001, Loen, Norway.

This paper briefly reviews the wide range of vortex flows encountered on military vehicles. Vortex flows are classified into those designed into a vehicle to improve performance, those which cannot be avoided and whose deleterious effects must be minimized, and those that were not expected to occur. Examples of vortex-flow effects on air and sea vehicles and in propulsion systems are cited to illustrate these categories. It is concluded that vortex flows are all-pervasive and can have major effects on the operation and performance of military vehicles. With the trend to increased diversity in shape for future vehicles it is deemed essential to continue to improve the knowledge and predictive capability for vortex flows.

Lowe, J. D.

"CALCULATION OF LIFT-CURVE SLOPE USING A WING TIP BIASED VORTEX DISTRIBUTION"

J. Aircraft, Vol. 25, No. 5, May 1988, pp. 472-473

A horseshoe vortex model based on wing tip biased cascades of vortices modifying a central vortex core has been used to calculate the lift-curve slope of a flat, untwisted rectangular wing. If the cascades are confined to the outer quarters of the wing, the lift-curve slope can be calculated to a reasonable degree of accuracy over a broad range of aspect ratios using seven vortex elements. At very high aspect ratios greater than 30, limiting the wing tip cascades to the outermost $1/AR$ fractions of the wing improves the accuracy of the calculations. This provides a method of calculating aerodynamic properties that is not computation intensive while at the same time attempting to model the more qualitative properties of the flow. Conventional horseshoe vortex methods based on extended lifting-line theory can be modified to model the rapid changes in flow properties near the wing tips by using nonuniform distributions of vorticity. One such technique is the so-called 'circle distribution method' whereby a semicircle, whose diameter is the quarter-chord line, is erected over the wing and equally spaced arcs are projected onto the quarter-chord line to form the bound vortex segments. As a result, the horseshoe vortices are more densely packed near the tips than in the center of the wing. However, the concept of the whole wing as a composite of many smaller wings is not changed from the uniform distribution method; only the distribution of vorticity has changed. The main difference between the wing tip biased method and other methods is in its perception of the wing as a simple horseshoe-shaped vortex structure that is explicitly modified by its tips.

Lowry, J. G. and Polhamus, E. C.

"A METHOD FOR PREDICTING LIFT INCREMENTS DUE TO FLAP DEFLECTION AT LOW ANGLES OF ATTACK IN INCOMPRESSIBLE FLOW"

NACA Technical Note 3911, January 1957, Langley Aeronautical Laboratory, Langley Field, VA.

A method is presented for estimating the lift due to flap deflection at low angles of attack in incompressible flow. In this method provision is made for the use of incremental section-lift data for estimating the effectiveness of high-lift flaps. The method is applicable to swept wings of any aspect ratio or taper ratio. The present method differs from other current methods mainly in its ease of application and its more general application. Also included is a simplified method of estimating the lift-curve slope throughout the subsonic speed range.

Lowson, M. V.

"VISUALIZATION MEASUREMENTS OF VORTEX FLOWS"

J. Aircraft, Vol. 28, No. 5, May 1991, pp. 320-327

Novel flow visualization experiments have been used on the separated vortex flow on a delta wing at low speed to give measurements of flow parameters for comparison with theory. Data on vortex core

position, vortex sheet shape, vortex strength, and local velocity magnitude and direction in the core have been determined. The results show surprising consistency with several features of established theoretical models for high Re flows and further justify the use of low Re experiments for vortex flows. The results also indicate areas where care should be taken in extrapolating results at low Re to flight cases.

Lu, T.

"ON THE DYNAMICS OF VORTEX FILAMENTS AND THEIR CORE STRUCTURE"

Journal of Shanghai University, Vol. 3, No. 2, June 1999, pp. 87-94.

We give a brief review of the asymptotic theory of slender vortex filaments with emphasis on (i) the choices of scaling and small parameters characterizing the physical problem, (ii) the key steps in the formulation of the theory and (iii) the assumptions and/or restrictions on the theory of Callegari and Ting (1978). We present highlights of an extension of the 1978 asymptotic theory: the analyses for core structures with axial variation. Making use of the physical insights gained from the analyses, we present a new derivation of the evolution equations for the core structure. The new one is simpler and straightforward and shows the physics clearly.

Lu, W., Zhao, Q. and Xu, G.

"ANALYSIS OF ROTOR WAKE STABILITY IN FORWARD FLIGHT ASSOCIATED WITH DISTORTION REVISE"

Acta Aeronautica et Astronautica Sinica, Vol. 33, No. 11, November 2012, pp. 1958-1966.

The state of the art in the analysis of rotor wake stability has its limitation that it will obtain impractically large divergence rate where the vortex filaments get too close. To eliminate this unreasonable interference in the analysis of rotor wake stability coming from highly distorted wakes in forward flight, a linearized method of wake stability analysis associated with wake distortion revision under a sinusoidal perturbation is presented. In this method, the wake vortex filaments are discretized into a series of vortex elements with a sinusoidal perturbation distributed on the nodes along the vortex filaments, where the self/mutually-induced velocity of wakes and the influence of blades is considered. A fake vortex core is novelly applied to revise this unreasonable interference in the analysis of rotor wake stability coming from highly distorted wakes. Taking the H-34 model rotor as a numerical example, the influence of wake drifting, size of vortex core and advance speed on rotor wake stability are calculated by this method and analyzed individually in forward flight. The results show that the fake vortex core can effectively revise the impractically large divergence rate where the vortex filaments are getting too close. Furthermore, in forward flight, the change of the size of vortex core or advance speed, etc., cannot change the inherent instability of rotor wakes, but it can slightly influence the instabilities under some conditions. [In Chinese.]

Lu, Z.

"MERGE OF A VORTEX-PAIR"

AIAA Paper No. 2004-2419, Portland, OR, June-July 2004

The unsteady merging process of two identical circular vortex cores is further studied using the diffusing-vortex method. A series of new results for vorticity field and instantaneous stream line patterns are presented. The accuracy of the numerical results is analyzed and examined in terms of the initial invariants and decay laws of vorticity distribution.

Lua, K. B., Lim, T. T., Yeo, K. S. and Oo, G. Y.

"A STUDY OF WAKE STRUCTURES OF A HEAVING TWO-DIMENSIONAL ELLIPTIC AIRFOIL USING DPIV TECHNIQUE"

AIAA Paper No. 2007-276, Reno, NV, January 2007

The formation of the wake structures of a two-dimensional (2D) elliptic airfoil executing a simple harmonic heaving motion is investigated using Digital Particle Image Velocimetry (DPIV) technique. This work is motivated partly by the lack of experimental data on a 2D heaving elliptic airfoil and partly by the anomaly between the numerical results of Lewing and Haz-Hariri [Lewin, G. C. and Haj-Hariri, H., 'Modelling thrust generation of a two-dimensional heaving airfoil in viscous flow, ' Journal of Fluid Mechanics, Vol. 492, 2003, pp. 339-362] and dye visualization results of Lai and Platzer [Lai, J. C. S and Platzer, M. F., 'Jet Characteristics of a Plunging Airfoil', AIAA Journal, Vol. 37, No. 12, 1999, pp. 1529-1537]. The former study found that both the leading-edge vortices (LEV) and the trailing edge vortices (TEV) contributed to the formation of the wake structures of a 2D heaving elliptic airfoil, whereas the latter study showed that only the TEV contributed to the wake structures of a heaving NACA 0012 airfoil. Possible reasons for the anomaly are provided.

Luber, W.

"WAKE PENETRATION EFFECTS ON DYNAMIC LOADS AND STRUCTURAL DESIGN OF MILITARY AND CIVIL AIRCRAFT"

Proceedings of the IMAC-XXVIII, Society for Experimental Mechanics, Feb. 2010, Jacksonville, FL, pp. 1381-1402.

The effects on the structural design of military and civil aircraft caused by dynamic loads resulting from the flight through high wake velocities which are generated by different types of aircraft have not been sufficiently investigated in the past. Military aircraft might experience this impact during formation or squadron flight or during combat maneuvers. Civil aircraft could be affected during start and cruise through wakes from other aircraft. Passing through the wake the safety of the aircraft might be critical by wrong guidance, uncontrolled movements or by induced dynamic loads which might cause failure of structure or structural fatigue. The design of aircraft structure accounting for wakes is not state of the art. The standard design includes dynamic loads from PSD gust analysis and buffet or tuned gust analysis, where the intensities of the gust velocities are defined by military or civil

specifications and buffet intensities are defined from wind tunnel test results. Predictions by analysis of wake velocity fields of different aircraft indicate however that the known maximum gust velocities are exceeded and the time history of the velocities experienced by the affected aircraft during penetration is different for example to the 1-cos gust in the discrete analysis. Moreover, flight test results of the dynamic aircraft response during wake penetration produced evidence for its criticality in several flight regimes. This contribution concentrates on military aircraft and demonstrates several examples of predicted critical wake fields and results from calculated dynamic response during different kind of penetration. Also examples from flight dynamic responses are discussed.

"VORTEX BREAKDOWN: A REVIEW"

Progress in Energy and Combustion Science, Vol. 27, 2001, pp. 431-481.

This paper reviews the studies undertaken on vortex breakdown over the past 45 years. The paper is structured such that the area is considered in three sections -- experimental, numerical and finally theoretical, and provides a 'guide' to the literature and where necessary directs the reader to more in depth reviews in the specific areas.

Luckner, R.

"MODELING AND SIMULATION OF WAKE VORTEX ENCOUNTERS: STATE-OF-THE-ART AND CHALLENGES"

AIAA Paper No. 2012-4633, August 2012, Minneapolis, Minnesota.

Wake vortices are one of the major constraints on separations between aircraft pairs, as wake vortex encounters (WVEs) can be harmful to other aircraft during any phase of flight. The vortex flow field disturbs the encountering aircraft. This affects pilot's workload, comfort and safety of passengers and crewmembers and it has an impact on structural loads. Pilot workload refers to the effort for compensation of perturbations in aircraft's attitude and flight path. The level of tolerable disturbances and acceptable aircraft response depends on the flight phase. Modeling and simulation of WVEs is an important prerequisite for investigations of this phenomenon in fast-time or in piloted real-time flight simulations. This paper describes how the effects of wake-vortex-induced velocities on aircraft flight dynamics can be modeled and how such models are applied. The model requirements for different applications are discussed e.g. for WVE simulations in real-time, piloted simulator tests or for flight simulator training (real-time models), for risk assessments with fast-time Monte Carlo simulations in the rule making process (fast-time models). An overview on the state-of-the-art of WVE modeling is given, i.e. quality, constraints and maturity of models are discussed and directions for future research are given.

Luckner, R.

"VORTEX ENCOUNTER SEVERITY ASSESSMENT (VESA)"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

Airbus has prepared a methodology to assess the severity of a wake vortex encounter, WVE. This methodology is called Vortex Encounter Severity Assessment (VESA). VESA makes it possible to compare aircraft reactions and the effects of vortex encounters behind various aircraft (for example behind all aircraft in the HEAVY class). VESA is proposed as a tool to support air traffic service providers and national aviation safety regulators, which need assurance of the adequacy of the separation standards, if modifications of the current system are proposed. A potential application is to assess if the operational safety of other airplanes is maintained after introduction of the A380. The presentation describes the methodology.

"PILOT MODELS FOR SIMULATION OF WAKE VORTEX ENCOUNTERS IN CRUISE"

AIAA Paper No. 2010-7683, Toronto, Canada, August 2010.

This paper describes the development of pilot models for simulation of wake vortex encounters in cruise, which could be used for risk assessments for example using the Airbus encounter risk assessment methodology VESA (Vortex Encounter Severity Assessment). Following a brief literature overview, potential encounter scenarios, and worse-case encounter scenarios for cruise are derived for current air traffic separation standards including Reduced Vertical Separation Minima (RVSM). The preparation, conduct, and analysis of a piloted simulation study of cruise flight wake encounters in an Airbus A330 Full Flight Simulator are explained, the simulator results are evaluated and discussed, and pilot models are proposed for Autopilot and Auto Throttle disengagement and for severity classification.

"HAZARD CRITERIA FOR WAKE VORTEX ENCOUNTERS DURING APPROACH"

Aerospace Science and Technology, Vol. 8, 2004, pp. 673-687

Airbus has prepared a methodology to assess the severity of a Wake Vortex Encounter, WVE. This methodology is called Vortex Encounter Severity Assessment (VESA). VESA makes it possible to compare the effect of wake vortices generated by various aircraft on an aircraft that encounters such a vortex. Important elements of VESA are the hazard criteria that rate aircraft reactions during WVEs. They are used to compare WVEs in batch simulations. This paper describes how piloted flight simulations for WVE investigations during landing approach were prepared and how the hazard criteria were developed. This work was part of the European S-WAKE program.

Luckner, R., Hohne, G. and Fuhrmann, M.

"HAZARD CRITERIA FOR WAKE VORTEX ENCOUNTERS DURING APPROACH"

DLR Congress 2003, November 2003, Munchen, Germany.

"NUMERICAL STUDY OF THE EFFECT OF SPOILER CONFIGURATION ON WAKE VORTEX ALLEVIATION"

Journal of Aerospace Engineering, Vol. 28, No. 3, 2015, pp. 04014077-1 -- 04014077-26.

A numerical investigation was undertaken to evaluate the capabilities of a differential spoiler setting (DSS) in modifying the spanwise wing load and reducing the hazard of wake vortices imposed on a following aircraft. Numerical simulations were carried out on a scaled, half-model aircraft under a high lift configuration (HCL) condition for two outboard loading cases and two inboard loading cases in addition to the baseline configuration case. The study has covered the near-wake field and the extended near-wake field regions. The results are presented in terms of velocity contours, vorticity contours, tangential velocity, circulation, and streamlines at several measurement sections downstream, namely, at $x/b = 0.345$, $x/b = 0.444$, $x/b = 0.658$, $x/b = 1.794$, and $x/b = 4.484$ measured from the wing-tip trailing edge. Comparison between numerical simulations and experimental results has shown good agreement in terms of lift coefficients for all cases and acceptable agreement in terms of maximum cross-flow velocity, maximum normalized total circulation, and maximum-induced rolling moment. However, in some cases the agreement is not good. Evaluation of the results has shown promising outcomes for the inboard loading cases compared with the outboard loading cases, which agree with the experimental results. The interaction between spoilers' wake and the outboard flap tip vortex of the inboard loading cases reduces the magnitude of the tangential velocity and circulation of the wing tip vortex, delays vortex merging to a farther distance downstream, and thus, minimizes the induced rolling moment imposed on the following aircraft. Therefore, DSS can be considered a promising technique in wake vortex alleviation that can be used commercially in the future. The only limitation of this study is the need for more sophisticated computational resources to benefit from using finer mesh, which can minimize the difference between numerical and experimental results. This should therefore enable extending the study of wake vortices to the very far-wake field or up to a distance where the following aircraft is usually located.

Ludweig, H.

"ERGANZUNG ZU DER ARBEIT: 'STABILITAT DER STROMUNG IN EINEM ZYLINDRISCHEN RINGRAUM'"

Z. Flugwiss., Vol. 11, No. 9, 1961, pp. 359-361.

In a former report the frictionless, helical flow in a cylindrical annulus has been investigated for stability with reference to the occurrence of helical vortices, in analog to the well-known Taylor annular vortices, and a corresponding stability criterion has been given. In this report the author shows that helical disturbance vortices of a more general kind might as well occur in case of such flows, these disturbance vortices somewhat further limiting the formerly indicated region of stability. A stability criterion being modified correspondingly is given.

Ludwig, H.

"VORTEX BREAKDOWN"

DLR-FB-70-40, September 1970, Deutsche Forschungs- und Versuchsanstalt für Luft- und Raumfahrt, Göttingen, West Germany

Vortex breakdown, an abrupt change in the velocity distribution of a vortex, is often observed under quite different conditions. The various theories for the explanation of the phenomenon are discussed. It is concluded that various physical phenomena may cause a vortex breakdown, so that it is not possible to explain all observed breakdown processes by one theory only.

Ludwig, H.

"AN EXPLANATION OF AN INSTABILITY IN FREE VORTEX CORES OCCURRING ABOVE DELTA WINGS"

Z. Flugwiss., Vol. 10, No. 6, June 1962, pp. 242-249

By rolling up the surfaces of discontinuity originating from the leading edge of delta wings, free vortex cores are formed above the wing. In case of greater angles of incidence, the flow in these vortex cores shows an instability which abruptly produces strong turbulence. An explanation is given of this instability being a 'frictionless instability' of the vortex core flow by increasing helical interference vortices. [In German.]

Ludwig, H.

"INTERPRETATION OF VORTEX BREAKDOWNS WITH THE AID OF THE THEORY OF STABILITY OF FLOWS WITH HELICAL STREAMLINES"

Z. Flugwiss., Vol. 13, No. 12, December 1965, pp. 437-442

The breakdown of the vortices over delta wings is interpreted as instability in the sense of the theory of stability of flows. The manner in which the breakdown progress ought to evolve is investigated in detail according to the theory and the results are compared with recent experimental investigations. [In German.]

"EFFECTS OF SPOILERS AND GEAR ON B-747 WAKE VORTEX VELOCITIES"

NASA TM X-73197, August 1976, NASA Ames Research Center, Moffett Field, CA

Vortex velocities were measured in the wakes of four configurations of a 0.61-m span model of a B-747 aircraft. The wakes were generated by towing the model underwater in a ship model basin. Tangential and axial velocity profiles were obtained with a scanning laser velocimeter as the wakes aged to 35 span lengths behind the model. A 45 deg deflection of two outboard flight spoilers with the model in the landing configuration resulted in a 36 percent reduction in wake maximum tangential velocity, altered velocity profiles, and erratic vortex trajectories. Deployment of the landing gear with the inboard flaps in the landing position and outboard flaps retracted had little effect on the flap vortices to 35 spans, but caused the wing tip vortices to have: (1) more diffuse velocity profiles; (2) a 27 percent reduction in maximum tangential velocity; and (3) a more rapid merger with the flap vortices.

Luers, J. K.

"A MODEL OF WIND SHEAR AND TURBULENCE IN THE SURFACE BOUNDARY LAYER"

NASA CR-2288, July 1973, University of Dayton, Dayton, OH.

A model of wind and turbulence has been described for the surface boundary layer. The wind structure in the surface layer is a function of the surface parameters, stability, and height. The surface parameters considered are Z zero, the surface roughness length; u star, the surface friction velocity; and d , the zero plane displacement height. The stability parameter, Z/L , where L is the Monin-Obukov stability length, describes the thermal effect on the wind profile. The logarithmic wind profile is used to describe the mean wind field in the neutral boundary layer, and a logarithmic profile with a stability defect is used to describe the stable and unstable atmospheric conditions. For the very stable conditions, the logarithmic wind law does not hold. Under this condition, the layers of the atmosphere become disconnected and large-scale frontal motions are the predominant factor in defining the wind profile. Figures are presented which represent some typical wind profiles in the very stable condition. The Dryden spectral function was chosen to represent the statistical properties of turbulence. The parameters of the Dryden model, σ and L (scale length), are specified as functions of stability, height, and surface conditions for each component of turbulence. The interrelationship between the components of σ and L are constrained to satisfy a condition of local isotropy at large wave numbers.

Luffsey, W. S.

"AIRCRAFT WAKE TURBULENCE"

Safe Engineering, Vol. 3, November 1969, pp. 21-22

Review of the questions posed and tests called for by the problem of aircraft wake turbulence. Available information on wake characteristics is very limited. Tests conducted toward gaining the knowledge required are described. The test methods applied include hot-film anemometry from towers in whose proximity aircraft are flown and wake penetrations by aircraft instrumented with three-axis linear accelerometers, multichannel recording oscillograph, and motion picture cameras providing photo coverage of contrail outlined vortices. It is believed that data from planned testing should ultimately result in a meaningful and practical solution to the problem.

"SIMULATION OF LIDAR-BASED AIRCRAFT WAKE VORTEX DETECTION USING A BI-GAUSSIAN SPECTRAL MODEL"

IEEE International Geoscience and Remote Sensing Symposium (IGARSS 2007), July 2007, Barcelona, Spain

A new spectral model of the return signal from a LIDAR Doppler wake vortex detector is proposed. It has been experimentally discovered during ground-based and flight test campaigns but suffered a lack of theoretical evidence. Using high resolution fluid simulations of wake vortices, we highlight the physical meaning of this model. Comparisons with the traditional single Gaussian model show the superiority of this new approach is consistent with previous experimental results.

"ASYMPTOTIC BEHAVIOR OF THE FAR REGION OF TURBULENT WAKE VORTICES"

Journal of Applied Mechanics and Technical Physics, Vol. 40, No. 2, 1999, pp. 198-208.

An approximate mathematical model, formulation of the problem, and its approximate solution are proposed for the far region of a turbulent vortex wake past a moving body, where the departure of the horizontal velocity component from the uniform flow is slight. It is assumed that the single important parameter that defines the main flow characteristics in this region is the vortex momentum per unit length produced in the fluid by the lift equal to the weight of the moving body uncompensated by the buoyancy force. Thus, the flow is self-similar, and the self-similarity law determines the intensity, shape, and location of vortex lines as functions of the downstream distance with accuracy up to a constant factor, which cannot be determined theoretically and should be obtained by comparison of theory with experiment. A boundary-value problem is formulated to determine the flow structure of vortex lines (vorticity distribution). A solution of the problem is obtained numerically in the limit of 'vanishing turbulent viscosity.' The variation in the maximum velocity of a vortex line with distance, determined by self-similarity, is in agreement with available experimental data.

Lugt, H. J.

"VORTEX BREAKDOWN IN ATMOSPHERIC COLUMNAR VORTICES"

American Meteorology Society, Vol. 70, December 1989, pp. 1526-1537

Vortex breakdown occurs in tornadoes and waterspouts. This phenomenon may give information on the state and future behavior of those whirlwinds. Because of the rarity of recorded events, archival sources are consulted for qualitative descriptions from earlier times and compared with contemporary sources. Drawings and eyewitness reports from earlier times, rare photographs, movies, and observations from recent years indicate the occurrence of vortex breakdown in tornadoes and waterspouts near the ground, in the midsection of the funnel, and close to or inside the parent cloud. Since the contour of the whirlwind's funnel is delineated only by markers in the form of condensates, dust, or other debris, these markers may distort or obscure the evidence of vortex breakdown. This is a likely reason for the rare observation and identification of vortex breakdown which might be more common in whirlwinds than has been previously thought. According to the records examined, meteorologists deserve the honor for discovering and describing vortex breakdown long before the systematic investigation of recent years.

"THE APPLICATION OF A FIVE-HOLE PROBE WAKE-SURVEY TECHNIQUE TO THE STUDY OF SWEEPED WING ICING AERODYNAMICS"

AIAA Paper 2017-4374, June 2017, Denver, CO.

This paper describes a wake survey system used to improve the understanding of the underlying flowfield and aerodynamics of a swept wing with ice accretions. This system allows the rapid collection and analysis of large amounts of flowfield data by utilizing an array of five-hole probes on a precisely controlled traverse arm. Flowfield structure on the surface of the wing is acquired using an oil flow visualization technique and correlated to the associated wake survey. This method allows quantitative

calculations such as spanwise lift and drag to be compared with qualitative measurements and observations to enhance the understanding of the aerodynamics of wings containing ice accretions. Wind tunnel tests for a range of configurations are presented and analyzed in this paper. Results based on this wake survey method are compared with traditional measurement techniques such as force balance measurements to assess their accuracy.

Lund, F.

"SOUND-VORTEX INTERACTION IN INFINITE MEDIA"

Lecture Notes in Physics, Vol. 586, 2002, pp. 112-159

This lecture describes the interaction of sound and vorticity in infinite media. The scattering of sound by the vorticity is described. Recent results on ultrasound propagation through a disordered flow are given.

Lund, F. and Zabusky, N. J.

"A NEW APPROACH TO THE EFFECT OF SOUND ON VORTEX DYNAMICS"

Phys. Fluids, Vol. 30, No. 8, August 1987, pp. 2306-2307

Two questions are asked, and answered, concerning the dynamics of vortex filaments in a three-dimensional slightly compressible fluid with constant sound speed: What is the flow (including the sound) generated by a vortex in prescribed motion? What is the response of a test vortex to an external flow? The first question is answered by the convolution of a Green's function with a source localized at the filament; the second by a differential equation valid in the localized induction approximation. A variational principle encompassing both problems is also provided.

Lundquist, J. K. and Bariteau, L.

"DISSIPATION OF TURBULENCE IN THE WAKE OF A WIND TURBINE"

Boundary-Layer Meteorology, Vol. 154, 2015, pp. 229-241.

The wake of a wind turbine is characterized by increased turbulence and decreased wind speed. Turbines are generally deployed in large groups in wind farms, and so the behavior of an individual wake as it merges with other wakes and propagates downwind is critical in assessing wind-farm power production. This evolution depends on the rate of turbulence dissipation in the wind-turbine wake, which has not been previously quantified in field-scale measurements. In situ measurements of winds and turbulence dissipation from the wake region of a multi-MW turbine were collected using a tethered lifting system (TLS) carrying a payload of high-rate turbulence probes. Ambient flow measurements were provided from sonic anemometers on a meteorological tower located near the turbine. Good agreement between the tower measurements and the TLS measurements was established for a case without a wind-turbine wake. When an operating wind turbine is located

between the tower and the TLS so that the wake propagates to the TLS, the TLS measures dissipation rates one to two orders of magnitude higher in the wake than outside of the wake. These data, collected between two and three rotor diameters D downwind of the turbine, document the significant enhancement of turbulent kinetic energy dissipation rate within the wind-turbine wake. These wake measurements suggest that it may be useful to pursue modelling approaches that account for enhanced dissipation. Comparisons of wake and non-wake dissipation rates to mean wind speed, wind-speed variance, and turbulence intensity are presented to facilitate the inclusion of these measurements in wake modelling schemes.

Lundry, J. L.

"INITIAL DEVELOPMENT OF A WAKE TURBULENCE ASSESSMENT SYSTEM"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 183-193

The initial development of a computer software system for wake vortex technology is discussed. The system is intended for use in the preliminary design of new airplanes. Several overall objectives are listed, including the prediction of hazard as a function of geometry and flight conditions of the wake-producing and wake-penetrating airplanes, low cost of use, adaptability to new technology, and an explanation of currently known alleviation concepts. Essential elements of a Wake Turbulence Assessment System are listed, and an upper-level system design is presented. Candidate technology for system elements is discussed. Prototype code has been produced for the initial wake rollup and for the wake penetration. Initial results of these two modules are compared with experimental data, and are promising. The comparisons also show the importance of considering the low Reynolds number at which model studies of wake penetration are conducted.

Lunnon, B.

"TURBULENCE EVENTS INTERPRETED BY VORTEX ROLLS"

In *Aviation Turbulence*, edited by R. Sharman and T. Lane, Chapter 4, 2016, Springer International Publishing Switzerland, pp. 83-94.

The severity of an aircraft encounter with turbulence is usually quantified by reference to the aircraft normal acceleration. For an encounter between an idealized aircraft and an idealized vortex, the acceleration vector is equal to the cross product of half the vorticity vector with air velocity vector. More realistic expressions for the aircraft acceleration have been derived in the context of aircraft encounters with wake vortices, and, although the scale of wake vortices is smaller than that of naturally occurring vortices, the broad methodology is broadly applicable. This chapter looks both at these idealized cases and more practical issues. Many of the issues touched on are dealt with more comprehensively elsewhere. Two issues are addressed which are particular to the interpretation of turbulence using vortex constructs. Firstly, the feasibility of forecasting vortex characteristics is

addressed. Secondly, a method of representing the significant statistical properties of anisotropic turbulence is suggested.

Lunsford, C. R.

"A CONCEPT FOR PAIRING DEPARTURES FROM PARALLEL RUNWAYS FOR WAKE AVOIDANCE"

ICNS Conf., Bethesda, MD, May 2008

The Paired Departure concept increases the ability to use closely spaced parallel runways for departures by providing an alternate means of avoiding the wake turbulence created by departing Heavy and Boeing 757 aircraft. Wake research over the past thirty years has developed a better understanding of wake movement and decay near the ground. By considering the spacing between the parallel runways at an airport and by establishing a maximum allowable crosswind, a wake-free departure time window can be defined such that it is not possible for a wake to transport to the other runway within that time interval. For airports that can implement the Paired Departure concept, the time that wake-free departures can be enabled could potentially be doubled due to the additional crosswind conditions that can safely be accommodated using the Paired Departure time window. This paper describes the Paired Departure concept, discusses key implementation options and issues, and provides results of an initial analysis of feasibility and potential benefit.

"EXPLORATION OF TERMINAL PROCEDURES ENABLED BY NASA WAKEVAS TECHNOLOGIES"

NASA-CR-2004-213023, January 2004, Mitre Corporation, McLean, VA

The National Aeronautics and Space Administration (NASA) tasked The Mitre Corporation's Center for Advanced Aviation System Development (CAASD) to investigate potential air traffic control (ATC) procedures that could benefit from technology used or developed in NASA's Wake Vortex Advisory System (WakeVAS). The task also required developing an estimate of the potential benefits of the candidate procedures. The main thrust of the investigation was to evaluate opportunities for improved capacity and efficiency in airport arrival and departure operations. Other procedures that would provide safety enhancements were also considered. The purpose of this investigation was to provide input to the WakeVAS program office regarding the most promising areas of development for the program. A two-fold perspective was desired: First, identification of benefits from possible procedures enabled by both incremental components and the mature state of WakeVAS technology; second identification of procedures that could be expected to evolve from the current Federal Aviation Administration (FAA) procedures. The evolution of procedures should provide meaningful increments of benefit and a low risk implementation of the WakeVAS technologies.

Lunsford, C., Audenaerd, L., Cooper, W., Mundra, A., Tittsworth, J. and Cormier, T.

"THREE PHASES OF WAKE PROCEDURES: AN INTEGRATED CAPACITY BENEFIT STORY, 2nd Workshop WakeNet2-Europe"

The U.S. Federal Aviation Administration (FAA) and National Aeronautics and Space Administration (NASA) are cooperatively working toward developing and implementing ATC procedures and wake turbulence technology that will safely increase arrival and departure capacity at key airports. These improvements will be achieved in three major phases with each phase including additional weather prediction and wake avoidance aspects. MITRE/CAASD has been conducting assessments of capacity benefits of these proposals. In particular, it has been analyzing incremental benefits for the major evolutionary phases, as well as potential smaller steps within each phase. These analyses are intended to help determine trade-offs between potential benefits and overall technology requirements. The analyses also examine sensitivities to operationally meaningful parameters such as accuracies of weather forecast parameters. This presentation provides results regarding the relative capacity increases of incremental steps spanning the three phases of deployment. Both arrival and departure procedures are addressed. Benefits will be compared in terms of increases in peak hour arrival and departure capacity and their sensitivities to certain key prediction parameters.

Lunsford, C., Mundra, A., Audenaerd, L., Cheng, J., Devlin, C., Gross, A., Mayer, R., Sherry, J., Bryant, W., Johnson, E. and McKissick, B.

"WIND DEPENDENT CONCEPTS FOR WAKE AVOIDANCE: A COMPARATIVE ANALYSIS OF CAPACITY BENEFITS AND IMPLEMENTATION RISKS"

24th Digital Avionics Systems Conference, Vol. 1, 2005, pp. 3.A.4-1--3.A.4-16

The FAA and NASA are jointly embarking on a multi-phased research and development program to develop and implement wake vortex avoidance solutions that can safely reduce separations and improve capacity at airports in the NAS. Many options have been proposed by the wake turbulence community and it is necessary to focus research efforts on the most promising solutions. As part of its WakeVAS initiative, NASA has investigated the research difficulty and cost for candidate operational enhancements through a Conops Evaluation Team (CET). This team included participation by stakeholders from many research, system engineering, system development, pilot, and controller organizations. The operational enhancements that were evaluated included wind-dependent concepts for arrivals to Closely Spaced Parallel Runways (CSPRs), departures from CSPRs operated as a single runway, arrivals to single runways, and departures from single runways. To complement this work and help provide the information necessary for NASA to focus their research program toward the most promising concepts, MITRE/CAASD performed an analysis of the potential capacity benefit, opportunity for application, and implementation risk for each arrival and departure concept evaluated by the CET. This paper provides an overview of the direction in which NASA research will proceed and the analysis results that help support this decision.

Luo, J., Zhu, L. and Yan, G.

"NOVEL QUADROTOR FORWARD-FLIGHT MODEL BASED ON WAKE INTERFERENCE"

AIAA Journal, Vol. 53, No. 12, December 2015, pp. 3522-3533.

The traditional aerodynamic model of the quadrotor is almost entirely based on the modeling of a single rotor, ignoring the wake interference among the four rotors in close proximity. Because of the oversimplification of the aerodynamic model, the attitude control and trajectory tracking of the quadrotor is unsatisfactory in high-speed flight. To accurately and effectively control the attitude and trajectory of the quadrotor, this study proposes a quadrotor forward-flight mathematical model considering rotor wake mutual interference, which can be used in flight control. To validate the model, a series of computational-fluid-dynamics analyses were conducted. An integral quadrotor model and an isolated rotor were analyzed under the same conditions. The mathematical model and results of the computational-fluid-dynamics analyses results provided trends and demonstrated the suitability of the proposed model for high-speed forward flight.

Lush, P. A.

"THE PRESSURE AND VELOCITY FIELDS OF CONVECTED VORTICES"

Journal of Sound and Vibration, Vol. 27, No. 2, February 1973, pp. 266-270

The pressure and velocity fields of convected vortices are calculated for irrotational, incompressible, and inviscid flow and assuming the vortex strength and convection velocity are constant. The case of a single vortex filament and the case of two contrarotating line vortices of equal strength are considered.

Luton, A., Ragab, S. and Telionis, D.

"INTERACTION OF SPANWISE VORTICES WITH A BOUNDARY LAYER"

Physics of Fluids, Vol. 7, No. 11, November 1995, pp. 2757-2765.

The interaction of a spanwise vortex with a boundary layer has been numerically simulated using a fractional-step method. The incompressible Navier-Stokes equations are solved to accurately predict the strong viscous-inviscid interaction between a vortex either near or embedded within a boundary layer of comparable size. A strong vortex induces an eruption and the production of a secondary vortex. The secondary vortex causes the primary vortex to rebound, a response observed in many previous experiments and numerical simulations. However, weaker vortices as well do not follow the inviscid trajectory despite the absence of a secondary vortex. Rather than creating vorticity at the wall, a weaker vortex mainly redistributes the vorticity of the boundary layer, pulling it away from the wall. The redistributed vorticity alters the path of the vortex. In the laminar cases studied the decay of the vortex is not significantly altered by the boundary layer.

Luton, A., Ragab, S. and Telionis, D.

"INTERACTION OF SPANWISE VORTICES WITH A BOUNDARY LAYER"

AIAA Paper No. 1994-2377, Colorado Springs, CO, June 1994

The interaction of a spanwise vortex with a boundary layer has been numerically simulated using a fractional-step method. The incompressible Navier-Stokes equations are solved to accurately predict the strong viscous-inviscid interaction between a vortex either near or embedded within a boundary layer of comparable size. A strong vortex induces an eruption and the production of a secondary vortex. The secondary vortex causes the primary vortex to rebound, a response observed in many previous experiments and numerical simulations. However, weaker vortices as well do not follow the inviscid trajectory despite the absence of a secondary vortex. Rather than creating vorticity at the wall, a weaker vortex mainly redistributes the vorticity of the boundary layer, pulling it away from the wall. The redistributed vorticity alters the path of the vortex. In the laminar cases studied the decay of the vortex is not significantly altered by the boundary layer.

"THE THREE-DIMENSIONAL INTERACTION OF A VORTEX PAIR WITH A WALL"

Physics of Fluids, Vol. 9, No. 10, October 1997, pp. 2967-2980.

The interaction of vortices passing near a solid surface has been examined using direct numerical simulation. The configuration studied is a counter-rotating vortex pair approaching a wall in an otherwise quiescent fluid. The focus of these simulations is on the three-dimensional effects, of which little is known. To the authors' knowledge, this is the first three-dimensional simulation that lends support to the short-wavelength instability of the secondary vortex. It has been shown how this Crow-type instability leads to three dimensionality after the rebound of a vortex pair. The growth of the instability of the secondary vortex in the presence of the stronger primary vortex leads to the turning and intense stretching of the secondary vortex. As the instability grows the secondary vortex is bent, stretched, and wrapped around the stronger primary. During this process reconnection was observed between the two secondary vortices. Reconnection also begins between the primary and secondary vortices but the weaker secondary vortex dissipates before the primary, leaving reconnection incomplete. Evidence is presented for a new type of energy cascade based on the short-wavelength instability and the formation of continual smaller vortices at the wall. Ultimately the secondary vortex is destroyed by stretching and dissipation leaving the primary vortex with a permanently distorted shape but relatively unaffected strength compared to an isolated vortex.

"ESTIMATION OF PERSPECTIVE ERRORS IN 2D2C-PIV MEASUREMENTS FOR 3D CONCENTRATED VORTICES"

Experiments in Fluids, Vol. 59, 2018, pp. 101-1 to 101-14.

Two-dimensional planar PIV (2D2C) is still extensively employed in flow measurement owing to its availability and reliability, although more advanced PIVs have been developed. It has long been recognized that there exist perspective errors in velocity fields when employing the 2D2C PIV to

measure three-dimensional (3D) flows, the magnitude of which depends on out-of-plane velocity and geometric layouts of the PIV. For a variety of vortex flows, however, the results are commonly represented by vorticity fields, instead of velocity fields. The present study indicates that the perspective error in vorticity fields relies on gradients of the out-of-plane velocity along a measurement plane, instead of the out-of-plane velocity itself. More importantly, an estimation approach to the perspective error in 3D vortex measurements was proposed based on a theoretical vortex model and an analysis on physical characteristics of the vortices, in which the gradient of out-of-plane velocity is uniquely determined by the ratio of the maximum out-of-plane velocity to maximum swirling velocity of the vortex; meanwhile, the ratio has upper limits for naturally formed vortices. Therefore, if the ratio is imposed with the upper limits, the perspective error will only rely on the geometric layouts of PIV that are known in practical measurements. Using this approach, the upper limits of perspective errors of a concentrated vortex can be estimated for vorticity and other characteristic quantities of the vortex. In addition, the study indicates that the perspective errors in vortex location, vortex strength, and vortex radius can be all zero for axisymmetric vortices if they are calculated by proper methods. The dynamic mode decomposition on an oscillatory vortex indicates that the perspective errors of each DMD mode are also only dependent on the gradient of out-of-plane velocity if the modes are represented by vorticity.

"VOLUME VISUALIZATION OF AIRPLANE WAKE VORTICES"

In: Flow Visualization VII: Proceedings of the 7th International Symposium on Flow Visualization, Seattle, WA, September 1995, pp. 586-591

In this paper, we describe the use of volume rendering for visualizing unsteady 2D aircraft wake vortex computations. The problem we consider here includes crosswind effects. It involves a pair of wake vortices interacting with each other and, at the same time, with the ground. Ray-traced volume rendering is used to visualize the desirable vortex tube by first making a matte volume during the core tracing process. Volume rendering offers realistic visualization of the physical phenomena and allows us to see not only the core boundaries but also the core content.

"3D VISUALIZATION OF UNSTEADY 2D AIRPLANE WAKE VORTICES"

NASA Contractor Report 194931 (and ICASE Report 94-45), June 1994, Institute for Computer Applications in Science and Engineering, Hampton, VA.

Air flowing around the wing tips of an airplane forms horizontal tornado-like vortices that can be dangerous to following aircraft. The dynamics of such vortices, including ground and atmospheric effects, can be predicted by numerical simulation, allowing the safety and capacity of airports to be improved. In this paper, we introduce three-dimensional techniques for visualizing time-dependent, two-dimensional wake vortex computations, and the hazard strength of such vortices near the ground.

We describe a vortex core tracing algorithm and a local tiling method to visualize the vortex evolution. The tiling method converts time-dependent, two-dimensional vortex cores into three-dimensional vortex tubes. Finally, a novel approach calculates the induced rolling moment on the following airplane at each grid point within a region near the vortex tubes and thus allows three-dimensional visualization of the hazard strength of the vortices. We also suggest ways of combining multiple visualization methods to present more information simultaneously.

"COLLABORATIVE SEQUENCING AND SCHEDULING METHOD FOR ARRIVAL AND DEPARTURE TRAFFIC FLOW IN MULTI-AIRPORT TERMINAL AREA"

Acta Aeronautica et Astronautica Sinica, Vol. 38, No. 2, February 2017, pp. 320222-1 to 320222-13.

To cope with the increasing serious situation of flight conflict, airspace congestion and flight delay in the metropolis and metropolitan areas, the problem of arrival and departure traffic flow collaborative scheduling in multi-airport terminal area is studied. Considering the wake turbulence separation, runway operating separation, time window, airport capacity, and other constraints, the integrated traffic flow scheduling model for arrival and departure is built, in which the concept of flight satisfaction degree is introduced in the multi-dimensional-temporal perspective. Then an elitist non-dominated sorting generic algorithm (NSGA-II) is designed to search for Pareto optimal solutions of the proposed scheduling model in multi-airport terminal area. Simulation results show that the arrival and departure traffic flow scheduling in multi-airport terminal area is optimized using the proposed model which can also reduce the flight delay time, significantly increase the total satisfaction degree of flight, and ensure that the airspace resources in multi-airport terminal area are fairly and evenly used. Compared to the classic strategy of First-Come-First-Served, the integrated scheduling model has more significant effect

on the optimization of flights, and the proposed method can reduce the flight delay time to a certain extent. [In Chinese.]

"VORTEX STRUCTURE IN THE WAKE OF A WIND TURBINE ROTOR"

19th French Congress of Mechanics, August 2009, Marseille, France.

This paper describes the wind tunnel investigation of vortex wake flow downstream of a three-blade rotor of a horizontal-axis wind turbine. The phase-locked measurements are carried out by means of particle image velocimetry in several azimuth planes. To widen the explored area, the investigated velocity field is divided into several windows with some overlapping. An algorithm based on circulation calculation permits to find the vortex core centers and to extract velocity, vorticity and circulation with respect to these vortex centers. After the conditionally averaging, the net vortex induced velocity is extracted and the characteristics of the tip vortices trailing from consecutive blades are evaluated. The obtained results for the tangential velocity are analyzed and coefficients of Vatistas vortex model are evaluated. These coefficients are found to be different from the case of helicopter tip vortices. Finally, velocity field analysis shows how trailing vortex circulation, vortex core diameter and peak tangential velocity vary as a function of the vortex age.

"STRUCTURE OF ATMOSPHERIC TURBULENCE IN THE FRICTION LAYER BELOW 500 METERS"

NASA CR-2650, February 1976, Texas A&M University, College Station, TX.

Data consisting of measurements of wind direction and speed, vertical velocity, and temperature from several levels on the 444-m tower near Oklahoma City instrumented by the National Severe Storms Laboratory were analyzed to determine the nature of turbulence in the lowest 500 m of the friction layer. Turbulence quantities were calculated from the covariances between observed variables over periods ranging from 5 min to 1 hr. It was found that in some cases parameters such as mean wind speed, shearing stress, and vertical heat flux could be expressed by simple equations for periods of 15 min to 1 hr. Changes in these quantities with time are related to changes in vertical motion and stability. Power spectra were calculated for sequential 15-min, 30-min, and 1-hr periods for several levels on the tower. The effects of stability, wind speed, and surface roughness on the spectra of longitudinal and lateral velocity are examined, along with the effect of height on the spectrum of vertical velocity. The existence of an inertial subrange in the spectra of the horizontal velocity components also is evidenced. The region penetrated by the tower is shown to be composed of a lower region in which mechanical turbulence dominates and an upper region dominated by convective turbulence.

MacCready Jr., P. B.

"STANDARDIZATION OF GUSTINESS VALUES FROM AIRCRAFT"

Journal of Applied Meteorology, Vol. 3, August 1964, pp. 439-449.

A universal turbulence standardization technique is described which is based quantitatively on the atmospheric turbulence itself rather than on the effects it produces on an aircraft. It provides a single turbulence intensity number which may be measured continuously in flight in a variety of ways, and, with knowledge of the aircraft type and speed, can be linearly related to the rms value of vertical accelerations of the aircraft. The universal intensity number concept as applied here is an extension for aircraft use of the inertial subrange concept of atmospheric turbulence. In the inertial subrange all the statistical properties of turbulence of wavelengths less than a few hundred meters (the wavelength range which dominates gust loading for most aircraft) can be simply related to a single number. The intensity measurement also has value as a basic meteorological parameter, and has proven to be particularly useful in diffusion studies. The intensity scale is derived from various turbulence power spectrum studies. A larger background of data on turbulent distributions is also available because existing statistical discrete gust and continuous gust data can be fitted approximately to this standardization procedure, and meteorological studies have also given estimates of the distribution of this intensity number. The intensity number can be found from virtually any device moving through the air, as well as by some indirect meteorological means. A particular version of a universal turbulence indicator is described. The universal turbulence intensity rating provides a standard for communication about turbulence and for the collection of statistical turbulence information. It also provides a quantitative method of relating aircraft response and pilot 'feel' to the turbulence, so that the pilot can select or preselect the appropriate speed for specific missions.

"AN ASSESSMENT OF DOMINANT MECHANISMS IN VORTEX-WAKE DECAY"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 289-304

Predicting the transport and decay of the organized vortex system for various aircraft types, flight modes, and meteorological conditions requires clear identification of the various significant factors and mechanisms involved in the transport/decay process. Outside of the ground effect, the dominant factors include the circulation and core characteristics of the vortices, the turbulence in the wake and in the environment, and the thermal stability of the environment. The environmental factors are sometimes dominant; the vortex wakes from an airplane operating in two different meteorological regimes can differ by an order of magnitude in decay and by an order of magnitude in decent distance.

MacCready, Jr., P. B. and Bate, Jr., E. R.

"AIRCRAFT VORTEX-WAKE EFFECTS ON PARTICLE TRANSPORT, BREAKUP, AND COALESCENCE"

AV FR-301, January 1973, AeroVironment Inc., Pasadena, C.

The vortex sheet from an aircraft wing and the associated organized vortex pair in the aircraft's wake constitute a flow field with strong shears and accelerations which may have important consequences on the local microphysics of natural clouds and on certain cloud seeding techniques. Calculations are made of the trajectories of small (5-micron radius) droplets and large (50-micron radius) droplets released in the cores of two representative vortex situations (corresponding to a C-130 and a Piper Aztec). The small droplets only move out to a radius of 1m or so before their outflow speed is down to negligible value (assumed to be 20 cm/sec, comparable to the cloud turbulence). The large droplets are spun out about 5m for the C-130 and 1-1/2m for the Apache. The speed of the droplets relative to the air is everywhere too slow to cause droplet breakup.

"ASSESSMENT OF ATMOSPHERIC EFFECTS ON THE BEHAVIOR OF AIRCRAFT WAKE VORTICES"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 310-315

The transport and decay of an aircraft-generated vortex system depends on the characteristics of the generating aircraft, the proximity to the ground, and on atmospheric factors - the turbulence field, thermal stability, and mean wind shears throughout the region traversed by the vortex system. The number of variables involved, the statistical nature of the phenomena, and the difficulty of performing definitive field tests make the development of a comprehensive theory of vortex transport and decay an elusive goal, but significant strides have been made. This paper seeks to illuminate some of the main points, with more emphasis on dominant factors than on completeness or rigorosity.

"INFLIGHT VALIDATION OF VORTEX BEHAVIOR AND HAZARD MODELS IN THE VORTEX WAKES OF JET TRANSPORT AIRCRAFT"

AV-FR-502, January 1975, AeroVironment, Pasadena, CA

A plan is presented for an experimental program to validate three models - flow field, vehicle response, hazard region - which give (respectively) the vortex flow field as a function of generating aircraft characteristics and atmospheric characteristics; the response of an aircraft, with certain stability and control characteristics, to an encounter with the vortex system; and the limits of the hazard volume to be avoided by a specific aircraft.

Machado, C. R.

"AN ANALYSIS OF METEOROLOGICAL MEASUREMENTS USING A MINIATURE QUAD-ROTOR UNMANNED AERIAL SYSTEM"

MS Thesis, June 2015, Naval Postgraduate School, Monterey, CA.

Naval operational weather products, especially EM prediction, often fail to capture key meteorological features in the boundary layer due to the absence of high-resolution profile data. Quad-rotor small unmanned aerial systems (sUAS) with meteorological sensing capabilities may provide a solution for acquiring vertical profile data at sea. With the use of an RS92 radiosonde, InstantEye sUAS, and a calibrated sensing tower, we analyzed the effects a quad-rotor had on the accuracy of temperature and pressure profiles in the surface layer. In unstable atmospheres, temperature measurements made in the surface layer are as accurate as the manufacturer's claimed accuracy. In stable atmospheres, mixing occurs below 1.3 m, while above 2 m, sampled air comes from as much as 2 m aloft. The InstantEye's rotors contribute to the variation in temperature measurement, and this effect is strongest near the surface. The variations introduced by the prop-wash helped suppress natural variations from turbulent fluctuations, but are still present above the surface layer. The InstantEye also introduces a 0.12 hPa pressure bias while in flight due to rotor-induced lift.

"WAKE VORTICES - A PRIMER"

FAA Aviation Safety J., Vol. 3, No. 1, 1993, pp. 16-19

The FAA must balance safe separation with the need to operate an efficient air traffic control system. The FAA believes research and operational experience show current standards are safe, but with the capacity issue, wake vortex issues are in the forefront when it comes to considering closer separation standards.

Mack, G. R.

"WAKE VORTICES' EFFECT AND THE NEED FOR PROMPT ACTION - A U.S. VIEW"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 2-1 to 2-5

As we approach the next century, wake vortices have become one of the key limiting factors in airport capacity. Despite the significant effort expended on wake vortices over the years, several issues remain unresolved. The major issues that must be resolved before separation criteria can be refined are as follows: (1) defining the basis for wake turbulence separation; (2) determining the far-field characteristics of the wake; (3) understanding the influence of meteorological conditions on these characteristics; (4) evaluating the significance of the wake characteristics to safety of flight; and (5) developing the technology required to mitigate capacity constraints associated with wake turbulence. Regulatory agencies, airlines, manufacturers, the piloting and ATC communities, and research institutions must team together to ensure that the affected segments of the industry are engaged together, using their collective skills to achieve both the highest possible safety level and the most efficient operational procedures to meet travel demand.

Mack, L. M.

"THE COMPRESSIBLE VISCOUS HEAT-CONDUCTING VORTEX"

Journal of Fluid Mechanics, Vol. 8, 1960, pp. 284-292.

The plane, steady, laminar vortex flow of a viscous, heat-conducting perfect gas is treated. Simple relations are obtained for the flow quantities in the irrotational vortex, for arbitrary Prandtl numbers. When the Prandtl number is $1/2$, the irrotational vortex is also isentropic. When the temperature dependence of the viscosity coefficient is considered, the vortex flow is rotational. An exact solution for the rotational vortex is obtained which is suitable for numerical evaluation by successive approximations. Distributions of velocity, temperature, pressure, density, and stagnation temperature through the rotational vortex are given for a typical case.

Mackenzie, A. I.

"MEASURED CHANGES IN C-BAND RADAR REFLECTIVITY OF CLEAR AIR CAUSED BY AIRCRAFT WAKE VORTICES"

NASA TP-3671, November 1997, Langley Research Center, Hampton, VA

Wake vortices from a C-130 airplane were observed at the NASA Wallops Flight Facility with a ground-based, monostatic C-band radar and an antenna-mounted boresight video camera. The airplane wake was viewed from a distance of approximately 1 km, and radar scanning was adjusted to cross a pair of marker smoke trails generated by the C-130. For each airplane pass, changes in radar reflectivity were calculated by subtracting the signal magnitudes during an initial clutter scan from the signal magnitudes during vortex-plus-clutter scans. The results showed both increases and decreases in reflectivity on and near the smoke trails in a characteristic sinusoidal pattern of heightened reflectivity in the center and lessened reflectivity at the sides. Reflectivity changes in either direction varied from -131 to -102 dBm-1; the vortex-plus-clutter to noise ratio varied from 20 to 41 dB. The radar recordings lasted 2.5 min each; evidence of wake vortices was found for up to 2 min after the passage of the airplane. Ground and aircraft clutter were eliminated as possible sources of the disturbance by noting the occurrence of vortex signatures at different positions relative to the ground and the airplane. This work supports the feasibility of vortex detection by radar, and it is recommended that future radar detection be done with Doppler systems.

"USE OF A COMMERCIAL WIND SODAR FOR MEASURING WAKE VORTICES"

AIAA Paper No. 2006-2537, Cambridge, MA, May 2006

This paper describes the application of a commercial wind SODAR (SOmatic Detection and Ranging) to the measurement of aircraft wake vortices. Changes in data collection and processing were required to extract vortex location and circulation from the acoustic returns. Sample data are presented, and it is

demonstrated that SODARs represent valuable addition to the existing array of sensors for tracking and characterizing aircraft vortices in-ground effect.

"EXAMINATION OF THE APPLICABILITY OF NOAA MADIS AIRCRAFT BASED OBSERVATION DATASET FOR WAKE TURBULENCE RESEARCH"

AIAA Paper 2018-2866, June 2018, Atlanta, GA.

This paper summarizes an analysis conducted by the Volpe Center regarding aircraft-based observation (ABO) data from the National Oceanic and Atmospheric Administration (NOAA) MADIS (Meteorological Assimilation Data Ingest System). A series of validation or inter-comparison campaigns that include Eddy Dissipation Rate (EDR), Brunt-Vaisala Frequency (BVF), and Wind are made between NOAA MADIS datasets and ground based remote sensing measurements to establish confidence in and understanding of the ABO data for wake turbulence research application. The NOAA MADIS ABO data are then used to estimate the statistical distributions of the meteorological quantities that impact wake decay in the enroute environment, restricted to a subset of the current commercial flights over the continental United States (CONUS), and to preliminarily explore the likelihood of near best- and worst-case wake turbulence meteorological conditions. The possible implications for enroute wake decay are explored, and use of ABO crosswind data for wake mitigation is discussed.

"COMPARISON BETWEEN ARRIVAL AND DEPARTURE WAKE VORTEX STATISTICS NEAR THE GROUND"

1st CEAS European Air and Space Conference, Berlin, Germany, CEAS-2007-002, September 2007, pp. 1049-1054

In-Ground-Effect vortex measurements from arrival and departure aircraft have been made between 2003 and 2007 in a series of pulsed Lidar measurements in St. Louis, USA. These data collections support various objectives outlined in the joint FAA-NASA Wake Turbulence Research Management Plan. Wake turbulence data collection traditionally has been focused on arrival aircraft, leaving their departure counterpart less well understood. In response to the renewed interest internationally in studying vortices from departure aircraft, the present paper summarizes the initial results of comparing the vortex statistics near the ground between arrival and departure vortices generated from similar flight altitude to wingspan ratio and crosswind range. The present study also has the advantage that departure and arrival vortex data are collected from the same site, using the same sensor and the same processing technique, such that the relative characteristics can be revealed with simple statistical techniques and minimizing the potential biases from sensor, airport and processing related considerations. The study to date suggests that departure vortices have similar initial circulations compared to their arrival counterparts, and that the survival probabilities are likewise very similar. There also exists indication that the measured age for wake demise is correlated with environmental turbulence. The overall implication is that statistics compiled and models developed from historical

databases based on arrival vortices can be used at least as a first order estimate for examining departure wake mitigation concepts.

Macrorie, M. and Pauley, W. R.

"EXPERIMENTAL DEVELOPMENT OF SPANWISE VORTEX MODELS WITH STREAMWISE DECAY DUE TO WALL INTERACTION"

AIAA Paper No. 1992-2688, Arlington, VA, April 1992

Results of an experimental investigation of the interaction between convecting two-dimensional spanwise vortex structures and a flat plate are presented. The objective is to provide modeling of convected two-dimensional vortices developing in close interaction with a surface. Vortices of positive and negative circulation are studied at four generator heights above the test surface. The findings support that the strength of the vortices is not strongly affected by the interaction with the surface until the vortex core becomes fully embedded in the boundary layer. When a negative circulation vortex interacts closely with the surface it is quickly destroyed. The streamwise decay of vortices of both senses are studied for a single generator height at five streamwise stations. The results show that the core vorticity of dynamic stall vortices experience an initial decay rate of t^{-1} which is like that predicted for an Oseen vortex. The decay rate is not constant and increases with time. A simple analysis of end-wall effects is used to demonstrate that 3-dimensional effects should be small in this experiment and are not contributing substantially to the vortex decay.

Macrorie, M. and Pauley, W. R.

"EXPERIMENTAL INVESTIGATION OF CONVECTING VORTEX/BOUNDARY-LAYER INTERACTIONS"

AIAA Journal, Vol. 33, No. 8, August 1995, pp. 1383-1390

The interaction between propagating spanwise vortices and a turbulent boundary layer was studied experimentally. The results focus on the relationship between the passage of vortex structures and the response of the boundary layer in terms of ensemble-averaged unsteady mean velocity, wall shear, and turbulent stresses. Both positive and negative circulation vortices were studied at different heights above the test surface. The results indicate that the sign of the vortex influences the wall shear response as well as the height of the vortex above the surface. The negative circulation vortices were found to interact more closely with and penetrate deeper into the boundary layer than the positive sense vortices. A phase lag between the freestream disturbance caused by the vortex and the wall shear stress response is demonstrated. The relationship of the measured wall-shear stress to the pressure gradient and to a scaling velocity determined from the standard log-law fit for the overlap layer are discussed. The response of the boundary-layer turbulence is examined at key phases during the interaction.

Maddalena, L., Vergine, F. and Crisanti, M.

"VORTEX DYNAMICS STUDIES IN SUPERSONIC FLOW: MERGING OF CO-ROTATING STREAMWISE VORTICES"

Physics of Fluids, Vol. 26, 2014, pp. 046101-1 to 046101-17.

For air-breathing propulsion systems intended for flight at very high Mach numbers, combustion is carried out at supersonic velocities and the process is mixing limited. Substantial increase in mixing rates can be obtained by fuel injection strategies centered on generating selected modes of supersonic, streamwise vortex interactions. Despite the recognized importance, and potential of the role of streamwise vortices for supersonic mixing enhancement, only few fundamental studies on their dynamics and interactions have been conducted, leaving the field largely unexplored. A reduced order model that allows the dynamics of complex, interacting, supersonic vortical structures to be investigated, is presented in this work. The prediction of the evolution of mutually interacting streamwise vortices represents an enabling element for the initiation of an effective, systematic experimental study of selected cases of interest, and is an important step toward the design of new fuel injection strategies for supersonic combustors. The case presented in this work is centered on a merging process of co-rotating vortices, and the subsequent evolution of a system composed of two counter-rotating vortex pairs. This interaction was studied, initially, with the proposed model, and was chosen for the peculiarity of the resulting morphology of the vorticity field. These results were used to design an experimental investigation with the intent to target the same specific complex flow physics. The experiment revealed the same peculiar features encountered in the simulation.

"A PROGRAM TO ANALYZE AND MODEL TRAILING VORTICES ON AIRPORTS"

RN-69, October 1971, MIT Measurement Systems Laboratory, Cambridge, MA.

Three specific areas related to the wake turbulence hazard problem are studied. An examination of vortex formation, structure, and decay leads to appropriate mathematical models for use in simulation studies. The effects of atmospheric turbulence and meteorological conditions on the stability and persistence of vortices near the airports are assessed. Development and application of a three-degree-of-freedom computer simulation program provides an understanding of the hazard potential under a variety of encounter situations in which the aircraft, its approach to the vortex, and the vortex strength are varied. Vortex circulation is shown to be the paramount characteristic relating to the hazard potential.

Mager, A.

"SOLUTION ACROSS THE VORTEX BREAKDOWN"

ATR-71 (9999)-1, April 1971, Aerospace Corporation, Los Angeles, CA

The solutions of the quasi-cylindrical, momentum-integral equations for the incompressible, viscous core of a vortex embedded in constant-velocity, axial flow are obtained in a closed form. These

solutions are shown to be discontinuous when the axial flux of the axial momentum deficiency and the circumferential-to-axial velocity ratio at core boundary are larger than certain values. Since the axial gradients on both sides of the discontinuity are shown to be infinite and since the solutions are shown to disappear at one side of the discontinuity, and reappear on the other, vortex breakdown is assumed to occur in the region where the quasi-cylindrical approximation fails to describe the flow. Transition across the vortex breakdown is provided by the connection between the two separated parts of the solution having the same total axial flux of the axial momentum deficiency. The vortex breakdown is conceived as being equivalent to a sudden increase in the dissipation of the swirling motion. No additional constraints are required for the determination of the flow conditions on both sides of the vortex breakdown which indicate a steep increase of the static pressure axis, an enlargement of the core area, and usually, a reversal of the axial flow on the axis.

Mager, A.

"DISSIPATION AND BREAKDOWN OF A WING-TIP VORTEX"

J. Fluid Mech., Vol. 55, Part 4, October 1972, pp. 609-628

The solutions of the incompressible, quasi-cylindrical momentum-integral equations of describing the flow in the viscous core of a wing tip vortex are obtained in a closed form and are shown to have two distinct branches. The discontinuities of these solutions have infinite axial gradients and therefore, following Hall, are assumed to signal the inception of the vortex breakdown. Benjamin's finite transition, with its excess flow force dissipated, is shown to give results equivalent to a sudden cross-over, upstream of the discontinuity, from one branch solution to another. The critical point of such a cross-over is downstream from the cross-over, at the discontinuity. Sarpkaya's experimental data, and the nature of the solutions ahead of the discontinuity, suggest that the physical manifestation of the discontinuity is the spiral breakdown, whereas the cross-over seems to be related to the rapidly expanding and subsequently contracting axisymmetric bubble. This therefore implies that the beginning of the spiral breakdown is the all-important disturbance which triggers off not only the downstream asymmetric departure of the flow from its quasi-cylindrical form but also the formation of the upstream axisymmetric cross-over bubble. Solutions for the turbulent flow downstream from the spiral breakdown indicate that the wing-tip vortex breakdown can result in an appreciable reduction of the maximum circumferential velocity and should thus lessen the danger that trailing vortices present to following aircraft.

Magri, V. and Kalkhoran, I. M.

"NUMERICAL INVESTIGATION OF OBLIQUE SHOCK WAVE/VORTEX INTERACTION"

Computers and Fluids, Vol. 86, 2013, pp. 343-356.

The purpose of the present study was to investigate the interaction between stream-wise vortices with oblique shock fronts of various intensities. A three-dimensional, Navier-Stokes solution of the problem with an orthogonal grid incorporating a RANS approach with a k- ϵ turbulence model was used

to simulate earlier experimental studies of the problem. The accuracy of the computational study was examined by comparing the results to the previous experiments of oblique shock vortex interactions using three different shock wave intensities leading to weak, moderate and strong interactions as identified in our previous experimental investigations. Like the experimental findings, the weak and the moderate interactions did not result in vortex breakdown as the vortex was seen to deflect in the direction of the main flow downstream of the shock with lowered intensity. Computational simulation of the strong interaction case however, confirms presence of a supersonic vortex breakdown having many of the characteristics of subsonic vortex breakdown. The flow field generated by the strong interaction is characterized by the formation of a bulged forward shock structure followed by a rapid expansion of the vortex core, formation of a stagnation point on the vortex axis and appearance of a reversed flow region in a recirculation zone. The vortex was modeled by implementing the experimentally measured vortex properties at the inlet, namely total and static pressures, while constant total temperature was assumed to calculate the velocity, and components of the Mach number. Inlet values for turbulent kinetic energy and turbulent dissipation rate were calculated from assumed values of turbulent intensity.

"MEASUREMENTS OF THE NEAR WAKE OF A ROTOR IN FORWARD FLIGHT"

AIAA Paper No. 1998-0692, Reno, NV, January 1998

This paper describes initial measurements of the near wake of a 2-bladed teetering, untwisted, square-tipped rotor in forward flight. Issues of periodicity and repeatability of the core are studied using laser velocimetry and flow-visualization on the front of the rotor wake where cycle to cycle variations are expected. Core passage uncertainty from cycle to cycle is less than 1 degree of rotor azimuth. Velocity measurements on the advancing blade side show wake-like core-axial velocities higher than the core circumferential velocity for the first 180 degrees of vortex age. Both the axial and circumferential velocities approach 50% of blade tip speed. The inboard vortex sheet has substantial wake-like velocities and rolls up into a concentrated circulatory region of high wake-like axial velocity rotating opposite to the tip-vortex, within 30 degrees from the blade. The fully-developed values of the vortex core circulation, radius and axial velocity remain constant over 180 degrees of age as current measurements indicate. Measurement on the front, rear and retreating blade side of the rotor are in progress.

"STRUCTURE OF THE NEAR WAKE OF A ROTOR IN FORWARD FLIGHT AND ITS EFFECT ON SURFACE INTERACTIONS"

PhD Thesis, 1999, Georgia Institute of Technology, Atlanta, GA.

The near wake of a helicopter rotor has a significant role in the aerodynamics, structural dynamics and aeroacoustics of the helicopter. Experiments on a two-bladed rotor in axial flight demonstrate

excellent periodicity and reveal a vortex pairing phenomenon. A quantitative demonstration of periodicity is performed in the wake of a rotor in forward flight. Velocity measurements made at four azimuthal locations in the rotor wake in forward flight indicate strong wake-like axial velocities in the vortex core, comparable to the core circumferential velocity at all azimuthal stations and vortex ages. On the advancing blade side, the inboard wake rolls up into a discrete structure with vorticity close to 40 percent of the tip-vortex, but of opposite sign, and with wake-like axial velocity. Measurements near the blade tip indicate the presence of a strong spanwise flow during the vortex formation process. The evolution of core axial velocity suggests a periodic shedding pattern of rolled-up filaments at the blade tip. It is argued that the decay in core velocities is not related to turbulence in the vortex. The circulation contained in the tip-vortex is only about 40 percent of the peak bound circulation on the rotor blade, computed using the standard assumptions of blade-element theory. Empirical correlation of data from the literature over a wide range of test conditions confirms this finding. This indicates a need to rethink standard methods of blade-element analysis.

"CHARACTERIZATION OF THE NEAR WAKE OF A HELICOPTER ROTOR"

AIAA Paper No. 1998-2909, Albuquerque, NM, June 1998

Vortex characteristics in the near wake of a 2-bladed teetering rotor in steady forward flight are measured using a laser velocimeter. The vortex passage at a measurement point is seen to be repeatable to within 1 degree of rotor revolution. Velocity was measured in planes intersected by the rotor-blade tip at rotor azimuths of 0, 90, 180, 270 degrees. Variations in tip-vortex characteristics such as core radius, circulation and axial velocity were obtained as functions of rotor azimuth and vortex age. The core circulation and core-radius distributions conform to a simple harmonic function of the rotor azimuth. However, the core axial velocity has a fundamental and a 2-per rev variation with rotor azimuth. Empirical curve fits are described for these variations. The core axial velocity is of the order of the peak tangential velocity at all locations. It is higher than the tangential velocity over part of the advancing side of the rotor. The axial velocity is in all cases wake-like, being directed towards the blade of origin. Wake geometries obtained from the LDV data are also presented here.

Mahalingam, R. and Komerath, N.

"ROTOR TIP-VORTEX/AIRFRAME COLLISION FEATURES"

AIAA Paper No. 1996-2013, New Orleans, June 1996

We describe progress towards understanding the basic test case of the interaction between a vortex-dominated wake from a two-bladed rotor, and a solid cylinder surface. The substantial role of the core axial velocity, postulated from pressure data on the airframe, is confirmed by direct velocity measurements. Both the tip vortex core and the inboard vortex sheet, which have opposite signs of vorticity, have substantial wake-like velocities: further evidence that the axial velocity arises from the no-slip condition at the blade edges. Outside the vortex core, there are multiple thin regions of jet-like velocity, attributed to the induced effect of the rolling-up vortex sheets. During the collision, the axial velocity at the top of the airframe persists even after the flow has stagnated on the advancing blade side, further evidence of the blade-wake genesis of this flow. Suction peaks on the retreating blade side stay for a long duration. The levels of suction observed exceed those explainable by potential flow theory.

"FLOW VISUALIZATION OF LOW-SPEED PERPENDICULAR VORTEX-AIRFOIL INTERACTION"

AIAA Paper No. 1996-2387, June 1996, New Orleans, LA.

The interaction of a wing tip vortex with a downstream airfoil is visualized. The tip vortex from a straight wing was moved vertically in a wind tunnel. Laser sheet videography was used to document the quasi-steady interaction of the vortex with full-span airfoils in two test cases: a 21 percent thick symmetric airfoil, and a thin flat plate of 2.5 percent thickness, with rounded leading edge and sharp trailing edge. The strength of the vortex was computed from the measured velocity profile upstream. Vortex trajectories above and below both airfoils were measured. The vortex filament drifts spanwise above and below the airfoil as expected. During the downstream traverse, the vortex filament stays above the airfoil long after the generating wing has gone below the airfoil and then flips across the airfoil surface in a very short time. The vortex switching from the top to the bottom surface is initiated by the splitting of the primary vortex into two. During the upward traverse, the trajectory is exactly duplicated: there is no delay in switching from below to above, but there is a delay in vortex appearance after switching. Pressure gradient effects are observed in the thick airfoil interaction and near the leading and trailing edges for the flat plate. The trajectories continue to diverge behind the

trailing edge. In both experiments, the remaining vortex filaments downstream of the airfoil are too weak and far apart to recombine.

"LOW SPEED CANARD-TIP-VORTEX AIRFOIL INTERACTION"

SAE Paper No. 971469, April 1997, Wichita, KS.

This paper describes a series of ongoing experiments to capture the details of perpendicular vortex-airfoil interaction. Three test cases explored are: 1) a 21 percent thick symmetric airfoil at 1.1 deg angle of attack, 2) a thin flat plate of 2.5 percent thickness with rounded leading edge, sharp trailing edge and zero angle of attack and 3) a 12 percent thick symmetric airfoil at zero angle of attack. The tip vortex was generated by a NACA0016 wing at 5 deg AOA. The strength of the vortex was computed from the velocity profile measured upstream for the first two cases. Pressure measurements on the 21 percent airfoil were used to quantify the effect of the vortex as a function of its stand-off distance from the airfoil. Vortex trajectories over the airfoils were obtained from laser sheet videography. The vortex motion conforms to potential flow expectations except in regions of pressure gradient and during head-on interaction. When the generating wing is moved continuously across the airfoil there is a time lag between wing and vortex motion. The vortex switching from the top to the bottom surface is initiated by the splitting of the primary vortex into two and occurs in a short period of time. This is a source of unsteady effects on the interacting airfoil and a vortex jump parameter is defined for the switching process. Issues regarding symmetry in the motion above and below the airfoils are discussed.

"THREE-DIMENSIONAL VORTEX-SURFACE INTERACTIONS"

Seventh Asian Conference on Fluid Dynamics, December 1997, Madras, India.

Vortex-surface interactions of various orientations and relative scales occur in rotorcraft aerodynamics. Basic test cases at high Reynolds number involving cylinders, airfoils and flat plates are used to study the detailed collision processes. The surface pressure distribution is related to the 3-dimensional nature of the vortex-core dynamics, with the core axial velocity playing a crucial role. The phenomena during unsteady cylinder-vortex interaction are summarized. Rapid, oblique vortex-lifting surface interaction causes 3-D separation, alleviated by spanwise flow. Quasi-steady perpendicular vortex/airfoil interaction shows vortex splitting and secondary separation, but no recombination.

"VORTEX-SURFACE COLLISION: 3-D CORE FLOW EFFECTS"

AIAA Paper No. 1997-1785, Snowmass Village, CO, June 1997.

The interaction of a strong vortex with a curved surface is a basic problem in fluid mechanics, whose solution is crucial to predicting the flow around a rotorcraft. In past work, the initial stages of the interaction between a rotor tip-vortex and a cylindrical airframe were measured and computed using potential flow concepts followed by boundary layer calculations. This paper presents measurements of the lateral velocity component on the top of the airframe during the vortex interaction. These data are used in the prediction of airframe loading in a time frame far beyond that reported in previous work. The axial velocity in the core of the vortex is substantial and is directed back towards the rotor blade. The vortex core circulation scales with rotor rpm. We show here that the axial velocity plays a major role in the final stages of the collision process. Contours of lateral velocity correspond closely to contours of lateral vorticity from previous work. Core axial velocity during the collision is presented as a function of vortex age. The region of high axial velocity flattens and appears to break in two at the final stages of collision. In the computations, the tip-vortex is modeled as a family of helical vortices, whose strength and initial position are chosen based on experimentally measured core axial velocities. The analytical predictions are compared with experimentally measured vortex propagation and surface pressure.

Mahalingam, R., Wong, O. and Komerath, N.

"EXPERIMENTS ON THE ORIGIN OF TIP-VORTICES"

AIAA Paper No. 2000-0278, Reno, NV, January 2000

Measurements of the structure and evolution of the tip vortex from a rotor in low-speed forward flight are presented. On the advancing blade spanwise flow on the pressure side of the blade is comparable in magnitude to the inflow. Core circumferential velocity profiles show multiple features during formation. Trajectories and peak core velocities of the tip-vortex during its formation on top of the blade are presented. The peak core circumferential velocity is constant during vortex formation. Peak core axial velocity tends towards tip-speed near the blade tip. In the near wake, the variation in core axial velocity exhibits a periodic behavior. Circulation measurements from different rotary-wing tests are correlated with an empirical model that was developed to relate the tip-vortex circulation to the blade parameters. The trailed circulation is seen to be only about 40% of the bound circulation computed using the standard assumptions for calculation of blade loads.

Mahalov, A.

"TURBULENCE AND WAVES IN THE UPPER TROPOSPHERE AND LOWER STRATOSPHERE"

In *Aviation Turbulence*, edited by R. Sharman and T. Lane, Chapter 20, 2016, Springer International Publishing Switzerland, pp. 407-424.

The generation mechanisms and physical characteristics of jet stream turbulence, mountain, and inertia-gravity waves in the upper troposphere and lower stratosphere (UTLS) are investigated for real atmospheric conditions. To resolve multi-scale physical processes of wave breaking and laminated structures in the UTLS region, vertical nesting and adaptive vertical gridding have been developed and

applied in nested, high-resolution, coupled mesoscale-microscale simulations. The fully three-dimensional, moist, compressible Navier-Stokes equations are solved with a stretched, adaptive grid in the vertical and improved resolution in the UTLS region. For verification purposes, real-case simulations are conducted for the Terrain-Induced Rotor Experiment (T-REX) campaign of measurements and selected cases from pilot reports (PIREPs). Comparisons with observational datasets highlight significant benefits of nested computational techniques that consider the shear-stratified turbulence physics of the UTLS. Localized sharp shear layers characterized by stiff gradients of potential temperature and strong alternating vertical velocity patches are resolved in the tropopause region within the embedded microscale nest. We describe fully three-dimensional multi-scale dynamics of laminated structures and nonlinear processes in turbulent layers observed in the UTLS region. Depending on atmospheric conditions, the gravity waves might be trapped at the altitude of the jet stream and break or propagate into higher altitudes acquiring characteristics of inertia-gravity waves. Three-dimensional instabilities in nonparallel shear-stratified flows such as those induced by mountain and polarized inertia-gravity waves in UTLA are characterized by a polarized Richardson number.

Mahesh, K.

"THE INTERACTION OF JETS WITH CROSSFLOW"

Annual Review of Fluid Mechanics, Vol. 45, 2013, pp. 379-407.

It is common for jets of fluid to interact with crossflow. This article reviews our understanding of the physical behavior of this important class of flow in the incompressible and compressible regimes. Experiments have significantly increased in sophistication over the past few decades, and recent experiments provide data on turbulence quantities and scalar mixing. Quantitative data at high speeds are less common, and visualization still forms an important component in estimating penetration and mixing. Simulations have progressed from the Reynolds-averaged methodology to large-eddy and hybrid methodologies. There is a general consensus on the qualitative structure of the flow at low speeds; however, the flow structure at low-velocity ratios (jet speed/crossflow speed) might be fundamentally different from the common notion of shear-layer vortices, counter-rotating vortex pairs, wakes, and horseshoe vortices. Fluid in the near field is strongly accelerated, which affects the jet trajectory, entrainment, and mixing behavior. At low speeds, mixing depends more on Reynolds number than the jet trajectory or spatial extent does. Turbulence kinetic energy budgets are discussed that reveal the considerable nonequilibrium nature of the flow and the consequent challenges posed to time-averaged prediction methodologies. The parameter space at high speeds is large, and even experimentally derived correlations for trajectories show significant scatter. Coherent motions in high-speed jets are seen to entrain large amounts of crossflow fluid but do not mix effectively in the near field.

Mahesh, K.

"A MODEL FOR THE ONSET OF VORTEX BREAKDOWN"

Center for Turbulence Research Annual Research Briefs, 1996, pp. 143-149

A large body of information exists on the breakdown of incompressible streamwise vortices. Less is known about vortex breakdown at high speeds. An interesting example of supersonic vortex breakdown is the breakdown induced by the interaction of vortices with shock waves. The flow in supersonic engine inlets and over high-speed delta wings constitute technologically important examples of this phenomenon, which is termed 'shock-induced vortex breakdown'. In this report, we propose a model to predict the onset of shock-induced vortex breakdown. The proposed model has no adjustable constants, and is compared to both experiment and computation. The model is then extended to consider two other problems: the breakdown of a free compressible vortex, and free incompressible vortex breakdown. The same breakdown criterion is used in all three problems to predict the onset of breakdown. Finally, a new breakdown map is proposed that allows the simultaneous comparison of data from flows ranging from incompressible breakdown to breakdown induced by a shock wave.

Mahesh, K.

"A MODEL FOR THE ONSET OF BREAKDOWN IN AN AXISYMMETRIC COMPRESSIBLE VORTEX"

Physics of Fluids, Vol. 8, No. 12, December 1996, pp. 3338-3345

A simple inviscid model to predict the onset of breakdown in an axisymmetric vortex is proposed. Three problems are considered: the shock-induced breakdown of a compressible vortex, the breakdown of a free compressible vortex, and the breakdown of a free incompressible vortex. The same physical reasoning is used in all three problems to predict the onset of breakdown. It is hypothesized that breakdown is the result of the competing effects of adverse pressure rise and streamwise momentum flux at the vortex centerline. Breakdown is assumed to occur if the pressure rise exceeds the axial momentum flux. A formula with no adjustable constants is derived for the critical swirl number in all three problems. The dependence of the critical swirl number on parameters such as upstream Mach number, excess/deficit in centerline axial velocity, and shock oblique angle is explored. The predictions for the onset of shock-induced breakdown and free incompressible breakdown are compared to experiment and computation, and good agreement is observed. Finally, a new breakdown map is proposed. It is suggested that the adverse pressure rise at the vortex axis be plotted against the axial momentum flux to determine the onset of breakdown. The proposed map allows the simultaneous comparison of data from flows ranging from incompressible breakdown to breakdown induced by a shock wave.

Maines, B. and Arndt, R. E. A.

"THE CASE OF THE SINGING VORTEX"

Journal of Fluids Engineering, Vol. 119, June 1997, pp. 271-276.

A relatively high amplitude, discrete tone is radiated from fully developed tip vortex cavitation under certain conditions. The phenomenon of the 'singing vortex' was first reported by Higuchi et al. (1989).

This study more closely examines the singing phenomenon by varying the hydrofoil cross-section, scale, angle of attack, water quality, and cavitation number in two different facilities. Noise data were collected for each condition with visual documentation using both still photography and high-speed video to explain the mechanism of vortex singing. The theory of Kelvin (1880) provides a framework for correlating all the data obtained.

"AN INVESTIGATION OF COUNTERROTATING TIP VORTEX INTERACTION"

NASA CR-185135, October 1989, GE Aircraft Engines, Cincinnati, OH.

A tip vortex interaction model originally developed for compressors has been extended and adapted for use with counterrotating open rotors. Comparison of available acoustic data with predictions made with and without the tip vortex model included illustrate the importance of this interaction effect. This report documents the analytical modeling, a limited experimental verification, and certain key parametric studies pertaining to the tip vortex as a noise source mechanism for the unsteady loading noise of counterrotating propellers.

"BOWLES-TATNALL WAKE VORTEX ENCOUNTER HAZARD METRIC"

NASA TM-220285, June 01 2019, NASA Langley Research Center, Hampton, VA.

Wake vortex spacing standards constrict the terminal area throughput and impose severe constraints on the overall capacity and efficiency of the National Airspace System. For more than two decades starting in the early 1990s, the National Aeronautics and Space Administration conducted extensive research on characterizing the formation and evolution of aircraft wakes. This multidisciplinary work included comprehensive field experiments (Pruis et al. 2016), flight tests (Vicroy et al. 1998), and wind tunnel tests (Rossow 1994; Chow et al. 1997). Parametric studies using large eddy simulations (Proctor 1998; Proctor et al. 2006) were conducted to develop fast-time models for the prediction of wake transport and decay (Ahmad et al. 2016). Substantial effort was spent on the formulation of acceptable vortex hazard metrics (Tatnall 1995; Hinton and Tatnall 1997). Several wake encounter severity metrics have been suggested in the past, which include the wake circulation strength, vortex-induced rolling moment coefficient (Clv), bank angle, and the roll control ratio (Tatnall 1995; Hinton and Tatnall 1997; Van der Geest 2012). The vortex-induced rolling moment coefficient introduced by Bowles and Tatnall (Tatnall 1995; Gloudemans et al. 2016) has been used extensively for risk and safety analysis of newly proposed air traffic management concepts and procedures. The original method of Bowles and Tatnall assumed a constant wing loading (the wing lift-curve slope, CL_α is constant), which resulted in an overestimation of the vortex induced rolling moment coefficient. Bowles (2014) suggested a correction to the original method that provides more accurate values of Clv and which is also consistent with the underlying physics of the problem. The overestimation of Clv in

the original method can be corrected by assuming an elliptical lift distribution. Figure 1.1 illustrates the correction in Clv achieved by the modified method.

"SENSITIVITY OF HELICOPTER BLADE-VORTEX-INTERACTION NOISE AND VIBRATION TO INTERACTION PARAMETERS"

Journal of Aircraft, Vol. 42, No. 3, May-June 2005, pp. 685-697

An externally imposed vortex is allowed to interact with a rotor, and the effect of variations in individual key blade-vortex-interaction (BVI) parameters on BVI noise and BVI-induced vibratory hub loading is numerically evaluated. The interaction parameters considered are as follows: 1) vortex strength, 2) vortex core radius, 3) blade-vortex miss-distance, 4) angle of interaction in the blade-shaft plane, 5) angle of interaction in the rotor disk plane (parallel vs oblique interactions), 6) spanwise location of the interaction, 7) spanwise length of the interaction, and 8) blade lift at the time of interaction. The results indicate that an increase in miss distance and interaction angle in the blade-shaft plane and a decrease in the interacting vortex strength are most influential in reducing BVI noise and BVI-induced vibratory hub loading, BVI noise and vibratory hub loading were found to be more sensitive to changes in blade-shaft plane interaction angles than disk plane interaction angles, suggesting that introduction of a modest amount of anhedral/dihedral might be more advantageous than introducing comparable amounts of sweep in the outboard regions of the blade. It is also suggested that vibration reductions obtained for the minimum vibration schedule in the HART test result from an increased interaction angle between the blade and vortex in the blade-shaft plane and have little to do with reduced miss distances.

Maltby, T. L.

"A GENERAL DISCUSSION OF THE DISTURBANCES IN THE WAKE AREA OF A JET AIRCRAFT AND THE EFFECTS OF A SHOCK WAVE INTERCEPTING A SMALL AIRCRAFT"

General Structural Report No. 241, July 1955, Beech Aircraft Corp., Wichita, KS

The purpose of the report is twofold: to investigate the disturbances in the wake area of a jet aircraft that affects the controllability and air loads on a small aircraft entering this region, and to investigate the effect on small aircraft of shock waves generated by supersonic aircraft. The wake area is divided into three areas: the jet engine wake, trailing vortices off the wing tips of the jet aircraft, and residual turbulence.

"A CFD APPROACH TOWARDS MODELING BLADE/VORTEX IMPINGEMENT EFFECTS AND BUFFETING OVER AIRFOILS"

ICAS-2002-2.5.1, Toronto, Canada, September 2002

Unsteady flows resulting from airfoil-vortex interaction (AVI) and a shockwave-boundary-layer-interaction (SBLI) are studied numerically using the Reynolds averaged Navier-Stokes equations. For the AVI problem, two NACA0012 airfoils are used in tandem. The lead airfoil is used to generate a vortex and the aft one to intercept the vortex and undergoes the AVI process. The interaction of the vortex with the aft airfoil has notable effects upon its aerodynamic characteristics. For the SBLI problem, separated unsteady flows past an 18% thick circular-arc-airfoil and the BGK No. 1 airfoil are studied. The results demonstrated that the unsteady behavior of the flow is sensitive to the turbulence models.

Mandella, M. and Bershader, D.

"QUANTITATIVE STUDY OF THE COMPRESSIBLE VORTEX: GENERATION, STRUCTURE AND INTERACTION WITH AIRFOILS"

AIAA Paper 1987-0328, January 1987, Reno, NV.

Detailed density mappings of shock-generated two-dimensional compressible vortex flow fields have been obtained by the method of pulsed holographic interferometry. The technique of repeated experiments, with sequential advance of time delays for firing the laser light source, provided a time history which included vortex production by an inclined 'generating' airfoil, convection in a quasi-uniform external flow and, finally, interaction with a 'target' airfoil. The measurements included radial density profiles through a single free vortex, supplemented in one case by an independent determination of the radial pressure profile. From these results, an empirical model of the compressible vortex has been developed which includes an extended physical description of its structure. Additionally, experimental results for the earlier transient flow field associated with both leading-edge and trailing-edge vortex generation and development show striking agreement in many details with that obtained by a fluid dynamic computational scheme. Interaction with the downstream target airfoil is characterized by production of a secondary oppositely-rotating vortex which is particularly prominent when the impact is head-on or nearly so. Since the vortex static pressures typically decrease rapidly by a factor of three or more at the center, it is clear that the airfoil interaction produces a substantial transient disturbance to both the lift and drag behavior.

"COMPARISON OF 3D TURBULENCE MEASUREMENTS USING THREE STARING WIND LIDARS AND A SONIC ANEMOMETER"

Riso-R-1660(EN), October 2008, Riso National Laboratory for Sustainable Energy, Roskilde, Denmark.

The goal is to compare lidar volume averaged wind measurement with point measurement reference sensors and to demonstrate the feasibility of performing 3D turbulence measurements with lidars. For that purpose three pulsed lidars were used in staring mode, placed so that their beams crossed close to a 3D sonic anemometer mounted at 80 m above the ground. The results show generally very good correlation between the lidar and the sonic times series, except that the variance of the velocity measured by the lidar is attenuated due to spatial filtering. The amount of attenuation can however be predicted theoretically.

Manneville, S., Maurel, A., Bottausci, F. and Petitjeans, P.

"ACOUSTIC CHARACTERIZATION OF A STRETCHED VORTEX IN AN INFINITE MEDIUM"

Lecture Notes in Physics, Vol. 555, 2000, pp. 231-240

A new experimental device is presented, that allows it to isolate and control a stretched vortex in an 'infinite' medium. Acoustic measurements based on the ultrasound-flow interaction yield the main vortex characteristics (position, circulation, core size). This global and non-invasive method also allows a dynamical tracking of the vortex. Experimental results on the mean vortex characteristics as a function of the control parameters are presented, together with some examples of transitory regimes.

Manneville, S., Maurel, A., Roux, P. and Fink, M.

"CHARACTERIZATION OF A LARGE VORTEX USING ACOUSTIC TIME-REVERSAL MIRRORS"

Eur. Physics J. B, Vol. 9, 1999, pp. 545-549

We report new results on the ultrasonic characterization of a fluid flow using an acoustic time-reversal mirror (TRM). The structure of a large vortex generated by a rotating disk in a hollow cylinder is investigated both inside and below the cylinder. For mean-flow characterization, the TRM is shown to be a powerful vorticity detector. Experimental time-of-flight data are successfully compared to a numerical simulation of the flow and the orthoradial velocity is reconstructed using simple geometrical acoustics. Real-time measurements allow us to extract the precession motion of the vortex, providing direct, non-intrusive, and dynamical information on the flow.

Manneville, S., Sandrin, L. and Fink, M.

"INVESTIGATING A STRETCHED VORTEX WITH ULTRAFAST TWO-DIMENSIONAL ULTRASONIC SPECKLE VELOCIMETRY"

Physics of Fluids, Vol. 33, No. 6, June 2001, pp. 1683-1690

Ultrasonic speckle velocimetry (USV) was recently introduced as a new ultrafast tool for measuring fluid velocities in two dimensions by analyzing the speckle signal backscattered from particles moving with the flow. An experimental study of a stationary stretched vortex is presented, which demonstrates the efficiency of ultrafast 2D USV in terms of quantitative assessment of vortical flows. The full velocity field is recovered and compared to the Burgers model for two different fluids: water and milk. The dependence of the vortex characteristics on the main control parameter is investigated.

Mansfield, J. R., Knio, O. M. and Meneveau, C.

"DYNAMIC LES OF COLLIDING VORTEX RINGS USING A 3D VORTEX METHOD"

Journal of Computational Physics, Vol. 152, 1999, pp. 305-345

A Lagrangian particle method is used to simulate the collision of coaxial vortex rings in three dimensions. The scheme combines a 3D, adaptive, viscous, vortex element method with a dynamic eddy viscosity model of the sub-filter scale stresses. The vortex method is based on discretization of the vorticity field into Lagrangian vortex elements and transport of the elements along particle trajectories. The computations incorporate a mesh redistribution algorithm which creates new elements in regions of high strain and locally redistributes the vorticity field into a smaller number of elements when particles tend to cluster. It is shown that the Lagrangian LES scheme captures several experimentally observed features of the ring collisions, including turbulent breakdown into small-scale structures and the generation of small-scale radially propagating vortex rings.

"FLIGHT INVESTIGATION OF THE RESPONSE OF A HELICOPTER TO THE TRAILING VORTEX OF A FIXED-WING AIRCRAFT"

3rd Atmospheric Flight Mechanics Conf., AIAA, Arlington, TX, June 1976

A flight investigation was conducted to quantitatively determine the response of a medium-weight helicopter to the trailing-vortex system of a fixed-wing aircraft. Flight tests and analytical tools were both utilized in the investigation. The flight tests involved an extensively instrumented UH-1H helicopter and a C-54 aircraft. Penetrations of the vortex system by the UH-1H were made at the following nominal conditions: the C-54 flew at 5500 feet altitude at a nominal gross weight of 58,000 pounds and an indicated airspeed of 115 knots in a cruise configuration. The UH-1H, nominally 7200 pounds gross weight, flew at 60 knots indicated airspeed during the penetrations at separation distances of 6.64 nautical miles to 0.42 nautical miles between aircraft. In general, the data analyzed for the above tests indicated that no unsafe penetration occurred. Further, penetrating vehicle attitude

changes and structural loads were nominal. In addition, the response of the helicopter did not change appreciably with decreased separation distance.

Mantay, W. R., Holbrook, G. T., Campbell, R. L., and Tomaine, R. L.

"HELICOPTER RESPONSE TO AN AIRPLANE'S TRAILING VORTEX"

J. Aircraft, Vol. 14, No. 4, April 1977, pp. 357-363

A flight investigation was conducted to determine quantitatively the response of a medium-weight helicopter to the trailing-vortex system of a fixed-wing aircraft. Both flight tests and analytical tools were utilized in the investigation. The flight tests involved an extensively instrumented UH-1H helicopter and a C-54 aircraft. Penetrations of the vortex system by the UH-1H were made at the following nominal conditions: the C-54 flew at 5500-ft altitude at a nominal gross weight of 58,000 lb and an indicated airspeed of 115 knots in a cruise configuration; the UH-1H, nominally 7200-lb gross weight, flew at 60-knots indicated airspeed during the penetration at separation distances of 6.64 nautical miles to 0.42 nautical mile between aircraft. In general, the data analyzed for these tests indicated that no unsafe penetration occurred. Further, penetrating vehicle attitude changes and structural loads were nominal. In addition, the response of the helicopter did not change appreciably with decreased separation distance.

"SOME RESULTS OF THE TESTING OF A FULL-SCALE OGEE-TIP ROTOR"

Journal of Aircraft, Vol. 16, No. 3, March 1979, pp. 215-221.

Full-scale tests were utilized to investigate the effect of the Ogee tip on helicopter rotor acoustics, performance, and loads. Two facilities were used for this study: the Langley whirl tower and a UH-1H helicopter. The test matrix for hover on the whirl tower involved thrust values from 0 to 44,480 N (10,000 lb) at several tip Mach numbers for both standard and Ogee rotors. The full-scale testing on the UH-1H encompassed the major portion of the flight envelope for that aircraft. Both near-field acoustic measurements as well as far-field flyover data were obtained for both the Ogee and standard rotors. Data analysis of the whirl-tower test shows that the Ogee tip does significantly diffuse the tip vortex while providing some improvement in hover performance at moderate thrust coefficients. Flight testing of both rotors indicates that the strong impulsive noise signature of the standard rotor can be reduced with the Ogee rotor. Forward flight performance was significantly improved with the Ogee configuration for moderate lift coefficients. Further, rotor control loads and vibrations were reduced through use of this advanced tip rotor.

"SOME RESULTS OF THE TESTING OF FULL SCALE OGEE TIP HELICOPTER ROTOR; ACOUSTICS, LOADS AND PERFORMANCE"

AIAA Paper No. 1977-1340, October 1977, Atlanta, GA.

Full-scale tests were utilized to investigate the effect of the Ogee tip on helicopter rotor acoustics, performance, and loads. Two facilities were used for this study: the Langley whirl tower and a UH-1H helicopter. The test matrix for hover on the whirl tower involved thrust values from 0 to 44,480 N (10,000 lb) at several tip Mach numbers for both standard and Ogee rotors. The full-scale testing on the UH-1H encompassed the major portion of the flight envelope for that aircraft. Both near-field acoustic measurements as well as far-field flyover data were obtained for both the Ogee and standard rotors. Data analysis of the whirl-tower test shows that the Ogee tip does significantly diffuse the tip vortex while providing some improvement in hover performance. Flight testing of both rotors indicates that the strong impulsive noise signature of the standard rotor can be reduced with the Ogee rotor. Forward flight performance was significantly improved with the Ogee configuration for a large number of flight conditions. Further, rotor control loads and vibrations were reduced through use of this advanced tip rotor.

"INDUCED DRAG OF WINGS IN GROUND EFFECT"

The Aeronautical Journal, Vol. 120, No. 1234, December 2016, pp. 1867-1890.

This paper provides a set of closed form solutions for the lift and drag of wings flying in ground effect both with and without end plates. The developed theories are based on observations of several independent sources of controlled model tests over ground planes and over water and on previous theories prepared by researchers from the original work by Prandtl and Wieselsberger to the present day. The theories developed cover wings of varying aspect ratio, thickness to chord ratios and angle of attack. The results for wings with end plates include the effect of ground (or surface) clearance height, end plate depth and air gap depths beneath the wings or end plates. Good agreement is found between the developed theory and test.

"IN-FLIGHT OFF-SURFACE FLOW VISUALIZATION USING INFRARED IMAGING"

SAE Paper 91-1006, April 1991, Wichita, KS.

A flight test investigation was conducted to evaluate an infrared (IR) imaging technique to visualize off-surface flow phenomena. A single-engine, general-aviation airplane was equipped with an IR imaging system that viewed the region around the left wingtip. Vortical flow at the wingtip was seeded

with sulfur hexafluoride, a gas with strong infrared absorbing and emitting characteristics. Different terrain and sky backgrounds were evaluated for their effect on IR images of vortical flow. The best IR images were obtained with a clear sky background. The results of the investigation indicate that IR flow visualization compliments existing smoke generator methods for off-surface flow visualization.

Manuel, G. S., Daryabeigi, K., Obara, C. J. and Alderfer, D. W.

"OFF-SURFACE INFRARED FLOW VISUALIZATION"

US Patent 5,200,621, April 1993.

A method for visualizing off-surface flows consists of releasing a gas with infrared absorbing and emitting characteristics into a fluid flow and imaging the flow with an infrared imaging system. This method allows for visualization of off-surface fluid flow in-flight.

"CONTINUOUS SPECTRA OF THE BATCHELOR VORTEX"

Journal of Fluid Mechanics, Vol. 681, 2011, pp. 1-23.

The spectra of the Batchelor vortex are obtained by discretizing its linearized evolution operator using a modified Chebyshev polynomial approximation at a Reynolds number of 1000 and zero azimuthal wavenumber. Three types of eigenmodes are identified from the spectra: discrete modes, potential modes and free-stream modes. The discrete modes have been extensively documented but the last two modes have received little attention. A convergence study of the spectra and pseudospectra supports the classification that discrete modes correspond to discrete spectra while the other two modes correspond to continuous spectra. Free-stream modes have finite amplitude in the far field whilst potential modes decay to zero in the far field. The free-stream modes are therefore a limiting form of the potential modes when the radial decay rate of velocity components reduces to zero. The radial form of the free-stream modes with axial and radial wavenumbers is investigated and the penetration of the free-stream mode into the vortex core highlights the possibility of interaction between the potential region and the vortex core. A wavepacket pseudo mode study confirms the existence of continuous spectra and predicts the locations and radial wavenumbers of the eigenmodes. The pseudo modes corresponding to the potential modes are observed to be in the form of one or two wavepackets while the free-stream modes are not observed to be in the form of wavepackets.

"NON-NORMAL DYNAMICS OF TIME-EVOLVING CO-ROTATING VORTEX PAIRS"

Journal of Fluid Mechanics, Vol. 701, 2012, pp. 430-459.

Transient energy growth of disturbances to co-rotating pairs of vortices with axial core flows is investigated in an analysis where vortex core expansion and vortex merging are included by adopting a

time-evolving base flow. The dynamics of pairs are compared with those of individual vortices to highlight the effect of vortex interaction. Three typical vortex pair cases are studied, with the pairs comprised respectively of individually inviscid unstable vortices at the streamwise wavenumber that maximizes the individual instabilities, viscously unstable vortices also at the streamwise wavenumber maximizing the individual instabilities and asymptotically stable vortices at streamwise wavenumber zero. For the inviscidly unstable case, the optimal perturbation takes the form of a superposition of two individual helical unstable modes and the optimal energy growth is like that predicted for an individual inviscid unstable vortex, while where the individual vortices are viscously unstable, the optimal disturbances within each core have similar spatial distributions to the individually stable case. For both cases, time horizons considered are much lower than those required for the merger of the undisturbed vortices. However, for the asymptotically stable case, large linear transient energy growth of optimal perturbations occurs for time horizons corresponding to vortex merging. Linear transient disturbance energy growth exhibited by pairs in this stable case is two to three orders of magnitude larger than that for a corresponding individual vortex. The superposition of the perturbation and the base flow shows that the perturbation has a displacement effect on the vortices in the base flow. Direct numerical simulations of stable pairs seeded by optimal initial perturbations have been carried out and acceleration/delay of vortex merging associated with a dual vortex meandering and vortex breakup related to axially periodic acceleration and delay of vortex merging are observed. For axially invariant cases, the sign of perturbation has an effect, as well as magnitude; the sign dependence relates to whether the perturbation adds to or subtracts from the swirl of the base flow. For a two-dimensional perturbation that adds to the swirl of the base flow, seeding with the linear optimal disturbance at a relative energy level 0.0001 induces the pair to move towards each other and approximately halves the time required for merger. Direct numerical simulation shows that the optimal three-dimensional perturbation can induce the vortex system to break up before merging occurs, since the two-dimensional nature of vortex merging is broken by the development of axially periodic perturbations.

Marais, C.

"PARTICIPATION OF METEO-FRANCE IN WAKE VORTICES STUDIES"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 127-128

To reduce aircraft separation standards defined by ICAO, the French STNA (Service Technique de la Navigation Aérienne) has developed different wake vortices studies. Two studies have been realized by Météo-France. Their goal is to optimize the operations on airports with single or two parallel runways, regarding meteorological conditions and more precisely in case of crosswind. In the first study, a classification of crosswind in terms of wake vortex risk is established using the VORTEX model, developed by CERFACS. This model allows real-time evaluation of hazards associated with the wake vortices (position and strength). The hazard duration is computed; it corresponds to the time the two vortices stay inside the safety corridor. The second study analyzes the evolution of wake vortices at small scale in 2D. This model is initialized with varying academic wind and potential temperatures, based initially on those of the Idaho Falls experiment.

Marchioro, C.

"ON THE INVISCID LIMIT FOR A FLUID WITH A CONCENTRATED VORTICITY"

Comm. in Math. Phys., Vol. 196, 1998, pp. 53-65

We study the time evolution of a viscous incompressible fluid in $\mathbb{R}^2$ when the initial vorticity is sharply concentrated in N regions of diameter ϵ . We prove that in the zero viscosity limit it converges as ϵ vanishes to the inviscid fluid and to the point vortex system.

Marchman, III, J. F.

"WAKE TURBULENCE AND ITS ELIMINATION"

SAE Paper No. 730294, Wichita, KS, 1973

The results of a detailed wind tunnel study of the structure of the trailing vortex to distances of 30 chord lengths downstream of the wing are reported. Five different means of reducing the dangerous high-swirl velocities in a vortex are described and their effects on the wake are illustrated. The effects of these possible vortex 'fixes' on the wing itself as well as the possibility of using these or other devices to accelerate the dissipation of wake turbulence are discussed.

Marchman, III, J. F. and Marshall, J. R.

"VORTEX AGE AS A WAKE TURBULENCE SCALING PARAMETER"

AIAA Paper No. 1974-0036, Washington, DC, 1974

Tests were conducted in the Virginia Tech Stability Wind Tunnel to determine the significance of vortex age as a scaling parameter in wake turbulence development and dissipation. Vortex structure was measured over a range of three angles of attack, three free-stream speeds, and seven downstream positions from 2 to 30 chord lengths using an NACA 0012 wing and a five-hole yaw head probe. The resulting data indicates that vortex age is not a self-sufficient scaling parameter but a free-stream velocity influence also exists at higher angles of attack which cannot be explained in terms of Re or M .

"EFFECT OF SEVERAL WING TIP MODIFICATIONS ON A TRAILING VORTEX"

J. Aircraft, Vol. 9, No. 9, September 1972, pp. 684-686

Several different wing-tip modifications were used to alter the characteristics of an airfoil trailing vortex. Preliminary photographs were taken using a tuft-grid to visually determine the effects of the

various tip configurations. Detailed mean flow measurements were then made at ten and thirty chord lengths downstream of the wing. As a first approximation, the static pressure was assumed to be constant. The results show a definite decrease in the tangential velocity of the vortex and a spreading out of the core for all modifications tested.

"WHITCOMB WINGLET APPLICATIONS TO GENERAL AVIATION AIRCRAFT"

AIAA Paper No. 1978-1478, Los Angeles, CA, August 1978

A study was conducted to examine several of the aspects of Whitcomb winglet applications to low speed, general aviation aircraft. Both supercritical and laminar flow airfoil section winglets were tested on straight and tapered symmetrical wings. Aerodynamic parameters were measured for a wide range of wing angles of attack and for several winglet angles. Tests were run to determine the low-speed effect of the wing on the winglet and of the winglets on the wing. Towing tank and wind tunnel tests were run to examine the trailing vortices from the wing-winglets combinations. The tests showed that winglets are effective at low speeds, however a tapered wing planform results in a reduction of the winglet effectiveness. Symmetrical winglets were shown to be effective at low speed. Tests also indicated that a proper choice of winglet angle can reduce the strength of the wing wake turbulence.

"DYNAMICS OF HEAVY PARTICLES IN A BURGERS VORTEX"

Physics of Fluids, Vol. 7, No. 2, February 1995, pp. 400-410.

This paper presents a linear stability analysis as well as some numerical results for the motion of heavy particles in the flow field of a Burgers vortex, under the combined effects of particle inertia, Stokes drag, and gravity. By rendering the particle motion equations dimensionless, the particle Stokes number, a Froude number, and a vortex Reynolds number are obtained as the governing three parameters. In the absence of gravity, the vortex center represents a stable equilibrium point for particles up to a critical value of the Stokes number, as the inward drag overcomes the destabilizing centrifugal force on the particle. Particles exceeding the critical Stokes number value asymptotically approach closed circular orbits. Under the influence of gravity, one or three equilibrium points appear away from the vortex center. Both their locations and their stability characteristics are derived analytically. These stability characteristics can furthermore be related to the nature of the critical points in a related directional force field. These findings are expected to be applicable to the coupling between the small-scale turbulent flow structures and the motion of suspended particles.

Marcus, D. L. and Berger, S. A.

"THE INTERACTION BETWEEN A COUNTER-ROTATING VORTEX PAIR IN VERTICAL ASCENT AND A FREE SURFACE"

Phys. Fluids A, Vol. 1, No. 12, December 1989, pp. 1988-2000

The inviscid, two-dimensional interaction between a pair of counter-rotating line vortices and a free surface has been studied. A solution to the linearized, small-disturbance problem has been thoroughly explored. For the nonlinear problem numerical calculations were carried out for Froude numbers representing a range of very weak to very strong vortices. Strong vortices are little affected by the presence of the surface, rising to form a bubblelike disturbance; weaker vortices follow paths like vortices approaching a plane boundary. The experimentally observed scarring phenomena - surface depressions whose axes are perpendicular to the flow plane - are seen in the numerical results.

Margaris, P. and Gursul, I.

"EFFECT OF STEADY BLOWING ON WING TIP FLOWFIELD"

AIAA Paper No. 2004-2619, Portland, OR, June-July 2004

An experimental investigation was conducted to study the effect of steady blowing near the wing tip, as a means of control of the trailing vortex. Velocity measurements were taken, using a PIV system, around the tip and in the near wake of a rectangular wing, which was equipped with several blowing slots. The results show that the effect of blowing is very sensitive to the blowing configuration. The location and strength of the vortices generated by the jet and their interaction with the tip vortex may lead to a diffused trailing vortex or an even more coherent one. Spanwise blowing generally leads to a diffused trailing vortex, unless it is applied very close to the suction surface of the wing, for which a much stronger vortex is generated. Blowing in the vertical direction produces multiple co-rotating vortices with increasing blowing coefficient. Diffused or stronger vortices are generated, depending on the direction of the vertical blowing. Finally, the instantaneous data derived from the PIV measurements show differences with the time-averaged measurements and reveal several differing phenomena in the flowfield.

Margaris, P. and Gursul, I.

"VORTEX TOPOLOGY OF WING TIP BLOWING"

Aerospace Science and Technology, Vol. 14, 2010, pp. 143-160.

An extensive parametric study was conducted to examine the effect of continuous blowing from high aspect ratio jets on the tip vortex in the near wake. It was found that the high aspect ratio jet produces a pair of counter-rotating vortices of unequal strength; their interaction with the tip vortex leads to single or multiple-vortex wakes. The flow topology of the wake depends on several parameters such as the blowing configuration, the blowing coefficient, and the wing incidence. Vertical and spanwise blowing were examined, from different vertical and longitudinal positions. In most cases, blowing from near the pressure surface led to diffused vortices in the near wake with blowing from near the suction surface producing the opposite effect. The tip shape was also varied; the round tip showed the ability to promote the Coanda effect, thus modifying the vortex interaction. The wing incidence was found to affect not only the tip vortex, but also the jet-generated vortices.

Margaris, P. and Gursul, I.

"WING TIP VORTEX CONTROL USING SYNTHETIC JETS"

Aeronautical Journal, October 2006, pp. 673-681

An experimental investigation was conducted to study the effect of synthetic jet (oscillatory, zero net mass flow jet) blowing near the wing tip, as a means of diffusing the trailing vortex. Velocity measurements were taken, using a Particle Image Velocimetry system, around the tip and in the near wake of a rectangular wing, which was equipped with several blowing slots. The effect of the synthetic jet was compared to that of a continuous jet blowing from the same configurations. The results show that the use of synthetic jet blowing is generally beneficial in diffusing the trailing vortex and comparable to the use of continuous jet. The effect was more pronounced for the highest blowing coefficient used. The driving frequency of the jet did not generally prove to be a significant parameter. Finally, the instantaneous and the phase-locked velocity measurements helped explain the different mechanisms employed by the continuous and synthetic jets in diffusing the trailing vortex.

Margaris, P. and Gursul, I.

"VORTEX TOPOLOGY OF WING TIP BLOWING"

AIAA Paper No. 2007-1122, Reno, NV, January 2007

An experimental investigation was conducted to study the effect of continuous blowing from high aspect ratio jets near the tip-on-tip vortex in the near wake. This study followed a previous study and focused on the effect of two new parameters: the shape of the tip and the longitudinal position of the blowing slot. Velocity measurements were taken, using a PIV system, around the tip and in the near wake of a rectangular wing, which was equipped with several blowing slots. The effect was compared to that of the previous study. The results showed that the tip shape is an important parameter, influencing the formation and characteristics of the tip vortex and thus leading to different flowfields in the near wake. Depending on the blowing configuration, a round tip can lead to a more diffused trailing vortex or to multiple coherent vortices, stronger than those produced by a square tip. The round tip also promotes the Coanda effect, which influences the structure of the vortex. The longitudinal position of the blowing slot is also an important parameter. It does not change the general topology of the near wake but when the blowing slot is located further downstream it retains more of its velocity leading to higher crossflow velocities in the near wake.

Margaris, P., Marles, D. and Gursul, I.

"EXPERIMENTS ON INTERACTION OF A JET WITH A TRAILING VORTEX"

AIAA Paper No. 2007-1123, Reno, NV, January 2007

A parametric study was performed to evaluate the effect of a cold jet on a single trailing vortex. Flow visualization and Particle Image Velocimetry (PIV) measurements were conducted in wind and water tunnels. The main parameters examined were the ratio of jet strength to vortex strength, the initial distance between the jet and the vortex, the jet inclination angle, the Reynolds number, and the downstream distance from the trailing edge. It was shown that the jet turbulence is wrapped around the vortex and ingested into it with increasing streamwise distance. This turbulence ingestion takes place faster with decreasing jet-to-vortex distance and increasing jet strength. Both time-averaged and instantaneous flow fields showed that the effect of the jet on the vortex can be quite significant. The trailing vortex became diffused with its rotational velocity and vorticity levels reduced. The mechanism with which the jet interacts with the vortex is a combination of vortices shed by the jet and the turbulence. No noticeable differences were found within the Reynolds number range tested. The effect of jet on vortex is delayed when the jet is blowing at an angle to the free stream and away from the vortex such as during take-off. The results suggest that the engine jets might have favorable effects on wing vortices, in particular on flap-edge vortices.

Margaris, P., Marles, D. and Gursul, I.

"EXPERIMENTS ON JET/VORTEX INTERACTION"

Electrorheological Fluids, Vol. 44, No. 2, Feb. 2008, pp. 261-278

An experimental study was performed to conduct a parametric study of the effect of a cold jet on a single vortex. Flow visualization and Particle Image Velocimetry (PIV) measurements were conducted in wind and water tunnels. The main parameters that were examined were the ratio of jet strength to vortex strength, the initial distance between the jet and the vortex, the jet inclination angle, the Reynolds number, and the downstream distance from the trailing edge. It was shown that the jet turbulence is wrapped around the vortex and ingested into it with increasing streamwise distance. This turbulence ingestion takes place faster with decreasing jet-to-vortex distance and increasing jet strength. Both time-averaged and instantaneous flow fields showed that the effect of the jet on the vortex can be quite significant. The trailing vortex got diffused with its rotational velocity and vorticity levels reduced. Some signs of decay were also found (small reduction in total circulation and cross-flow kinetic energy) for small jet to vortex distance and high jet strength. The mechanism with which the jet interacts with the vortex is a combination of vortices shed by the jet and the turbulence. No noticeable differences were found within the Reynolds number range tested. The effect of jet on vortex is delayed when the jet is blowing at an angle to the free stream and away from the vortex such as during take-off. The results suggest that the engine jets might have favorable effects on wing vortices, in particular on flap-edge vortices.

Margaris, P., Marles, D. and Gursul, I.

"EXPERIMENTS ON JET/VORTEX INTERACTION"

Experiments in Fluids, Vol. 44, 2008, pp. 261-278

An experimental study was performed to evaluate the effect of a cold jet on a single trailing vortex. Flow visualization and particle image velocimetry (PIV) measurements were conducted in wind and water tunnels. The main parameters were the ratio of jet-to-vortex strength, the jet-to-vortex distance, the jet inclination angle, and the Reynolds number. It was shown that the jet turbulence is wrapped around the vortex and ingested into it. This takes place faster with decreasing jet-to-vortex distance and increasing jet strength. Both time-averaged and instantaneous flow fields showed that the trailing vortex became diffused with its rotational velocity and vorticity levels reduced when the jet is located close to the vortex. The mechanism with which the jet interacts with the vortex is a combination of vortices shed by the jet and the turbulence. No noticeable differences were found within the Reynolds number range tested. The effect of jet on the vortex is delayed when the jet is blowing at an angle to the free stream and away from the vortex such as during take-off.

"THE COMPLETE FIRST ORDER EXPANSION OF A SLENDER VORTEX RING"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany, pp. 45-53.

Equations for the axisymmetric part of the velocity field and for the equation of motion of a non circular slender vortex ring are given at first order. This is the correction to the known leading order given by Callegari and Ting.

Margerit, D. and Brancher, J.-P.

"ASYMPTOTIC EXPANSIONS OF THE BIOT-SAVART LAW FOR A SLENDER VORTEX WITH CORE VARIATION"

J. Engineering Mathematics, Vol. 40, 2001, pp. 297-313

The Method of Matched Asymptotic Expansion of Singular Integrals is used to expand the Biot-Savart law in terms of different parameters. This method is first used to find, in terms of the small distance r to a line vortex, the first orders of the known expansion of the potential flow induced by this line vortex. This method is also used to easily compare two equations of motion of a slender vortex filament: the one obtained in an ad-hoc way by a cut-off line-integral technique and the other derived from the Navier-Stokes equations by Callegari and Ting. Finally, this method is used to give the inner expansion of the flow induced by a slender vortex in terms of its slenderness. This is the first inner expansion up to order one in terms of ϵ of the Biot-Savart law for a slender vortex. An application of this inner expansion is then given to find the induced velocity of a family of non-circular vortex rings with axisymmetric axial-core variation.

Margerit, D., Brancher, P. and Giovannini, A.

"IMPLEMENTATION AND VALIDATION OF A SLENDER VORTEX FILAMENT CODE: ITS APPLICATION TO THE STUDY OF A FOUR-VORTEX WAKE MODEL"

International J. for Numerical Methods in Fluids, Vol. 44, January 2004, pp. 175-196

A computational code EZ-vortex is developed for the motion of slender vortex filaments of closed or open shape. The integro-differential equations governing the motion of the vortex centerlines are either the Callegari and Ting equations, which are the leading order solution of a matched asymptotic analysis, or equivalent forms of these equations. They include large axial velocity and nonsimilar profiles in the vortical cores. The fluid may be viscous or inviscid. This code is validated both against known solutions of these equations and results from linear stability analyses. The linear and non-linear stages of a perturbed two-vortex wake and of a four-vortex wake model are then computed.

"IDENTIFICATION AND QUANTIFICATION OF VORTICAL STRUCTURES IN WIND TURBINE WAKES FOR OPERATIONAL WAKE MODELING"

The Science of Making Torque from Wind (TORQUE 2016), published in IOP Journal of Physics: Conference Series Vol. 753, 2016, pp. 032050-1 to 032050-11.

The present paper describes a method to quantify the vortical structure characteristics from simulation results of the flow past a wind turbine with the aim to develop an accurate, physics-based operational wake model. The wake centerline is first identified. Then, the flow characteristics are extracted by fitting a vorticity-based wake skeleton onto the velocity deficit profiles defined around the centerline and measured at several downstream distances from the rotor. The simulation results were obtained using a hybrid Vortex Particle-Mesh approach combined with an immersed Lifting Line technique to account for the blades. The characterization of the identified vortex wake structure lays a basis for the development of an operational wake model based on strong physical grounds.

"OUT OF THE VORTEX"

New Scientist, Vol. 167, No. 2248, 22 July 2000, p. 4

A pair of engineers from Boeing have patented a way of stifling deadly vortices. As well as making flying safer, it promises to ease congestion at busy airports by reducing the gap between planes as they land.

Marks, T. and Gollnick, V.

"INFLUENCE OF AIRCRAFT TYPE AND ORDER ON FUEL SAVINGS GAINED BY TWO-AIRCRAFT FORMATIONS"

ICAS-2016-0592, September 2016, Daejeon, Korea.

The work presented in this paper investigates the influence of aircraft pairing and order on the fuel savings gained by two-aircraft formations. It will be analyzed if in terms of formation efficiency as well as with respect to the maximum fuel savings favorable aircraft pairings exist. To achieve this goal, a detailed trajectory analysis including an aerodynamic model to calculate the aerodynamic benefits of the formation is performed for a predefined set of formation geometries and formation pairings thus creating a formation flight database that can be used for the evaluation. It will be shown by statistical analysis, that differences in formation flight performance exist depending on pairing and order. In addition to the full initial set of samples a subset of the formation geometries representing missions over the North Atlantic will be evaluated. It will be shown, that differences compared to the full set of samples exist. As the weight of the leader is a strong driver for the formation efficiency it will be analyzed, if the take-off weights of the formation members allow an estimation of the achievable benefits. Furthermore, it will be shown, how the database can be used to create surrogate models for a specific formation pairing and how these models can be utilized to evaluate specific formation geometries.

Marles, D. and Gursul, I.

"EFFECT OF A JET ON VORTEX MERGING"

AIAA Paper 2007-4364, June 2007, Miami, FL.

Experiments were conducted to understand the effect of an axial jet on the merging process of a simulated flap-edge and wing-tip co-rotating vortex pair in the near wake. Cross-flow velocity measurements and flow visualization were performed for three realistic jet positions on both equal and unequal strength like-signed vortices for a range of momentum coefficients. The main finding was that the initial jet position has a vastly contrasting effect on the merging process. If the jet turbulence interacts rapidly with only one of the vortices, severe diffusion of that vortex occurs which ultimately wraps around and becomes consumed by the unaffected vortex structure. The jet causes a reduction in the vortex spacing and an increase in the rotation angle, hence merging is promoted. If the jet turbulence does not interact directly with either vortex, but instead interferes with the mechanism in the outer-recirculation region that advects vorticity to a larger radius, then merging can be retarded. In this case, an increase in vortex spacing and reduction in rotation angle was observed. Increasing the momentum coefficient, hence introducing more turbulence into the flow, has a greater effect on the merging process.

Marles, D. and Gursul, I.

"EFFECT OF AN AXIAL JET ON VORTEX MERGING"

Physics of Fluids, Vol. 20, 2008, pp. 047101-1 - 047101-16.

Experiments were conducted to understand the effect of an axial jet on the merging process of a simulated flap-edge and wing-tip co-rotating vortex pair in the near wake. Cross-flow velocity measurements and flow visualization were performed for three realistic jet positions on both equal and

unequal strength like-signed vortices for a range of momentum coefficients. The main finding was that the initial jet position has a vastly contrasting effect on the merging process. If the jet turbulence interacts rapidly with only one of the vortices, severe diffusion of that vortex occurs which ultimately wraps around and becomes consumed by the unaffected vortex structure. The jet causes a reduction in the vortex spacing and an increase in the rotation angle, hence merging is promoted. If the jet turbulence does not interact directly with either vortex, but instead interferes with the mechanism in the outer-recirculation region that advects vorticity to a larger radius, then merging can be retarded. In this case, an increase in vortex spacing and reduction in rotation angle was observed. Increasing the momentum coefficient, hence introducing more turbulence into the flow, has a greater effect on the merging process.

"EFFECT OF AN AXIAL JET ON AIRCRAFT WAKE VORTICES"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

The effects of an axial jet on trailing vortices were investigated experimentally. To simulate various configurations of aircraft wake vortices, experiments were performed with single vortices, co-rotating vortex pairs, and counter-rotating vortex pairs generated by rectangular wings. Flow visualization and PIV measurements were conducted in wind and water tunnels. For a single trailing vortex, the main parameters were the ratio of jet-to-vortex distance, the jet inclination angle, and the Reynolds number. It was shown that the jet turbulence is wrapped around the vortex and ingested into it. This takes place faster with decreasing jet-to-vortex distance and increasing jet strength. Both time-averaged and instantaneous flow fields showed that the trailing vortex became diffused with its rotational velocity and vorticity levels reduced when the jet was located close to the vortex. The mechanism with which the jet interacts with the vortex is a combination of vortices shed by the jet and the turbulence. No noticeable differences were found within the Reynolds number range tested. The effect of jet on the vortex is delayed when the jet is blowing at an angle to the free stream and away from the vortex such as during take-off. For a co-rotating vortex pair, which simulates flap-edge and wing-tip vortices in the near wake, cross-flow velocity measurements and flow visualization were performed. These experiments included three realistic jet positions on both equal and unequal strength like-signed vortices for a range of momentum coefficients. The main finding was that the initial jet position has a vastly contrasting effect on the merging process. If the jet turbulence interacts rapidly with only one of the vortices, severe diffusion of that vortex occurs which ultimately wraps around and becomes consumed by the unaffected vortex structure. The jet causes a reduction in the vortex spacing and an increase in the rotation angle, hence merging is promoted. If the jet turbulence does not interact directly with either vortex, but instead interferes with the mechanism in the outer-recirculation region that advects vorticity to a larger radius, then merging is retarded. In this case, an increase in vortex spacing and reduction in rotation angle was observed. Increasing the momentum coefficient, hence introducing more turbulence into the flow, has a greater effect on the merging process.

"MASS MOMENT OF INERTIA ESTIMATION METHODS -- MANNED AIRCRAFT"

21st National Conference, Society of Aeronautical Weight Engineers, May 1962, Seattle, WA.

The purpose of this paper is to furnish the engineer with a method for rapidly and accurately estimating the moment of inertia of manned aircraft during the advanced design period. Such inertias are needed so that dynamic load and stability characteristics of the aircraft may be evaluated. To evolve a method which would not be limited to any particular type of aircraft, empirical data were gathered from many types of combat and transport aircraft and combined with the results of a mass distribution parametric study. By this method, the moment of inertia for a complete aircraft can be computed with a total expended time of about three man-hours. The prerequisite data needed are a group weight and balance statement, a three-view drawing, and some knowledge of the design characteristics of the airplane. As with all procedures and methods based on empirical data, extrapolations by this method are limited to aircraft within the present state of the art. As advancements in the state of the art occur which significantly affect aircraft weight distribution, the method should be altered accordingly.

Marsh, D. P.

"MASS MOMENT OF INERTIA ESTIMATION METHODS - MANNED AIRCRAFT"

Society of Allied Weight Engineers, Inc., 21st National Conference, May 1962, Seattle, WA.

This paper was presented at the Twenty-first Annual National Conference of the Society of Aeronautical Weight Engineers at Seattle, Washington, May 14-17, 1962. The purpose of this paper is to furnish the engineer with a method for rapidly and accurately estimating the moment of inertia of manned aircraft during the advanced design period. Such inertias are needed so that dynamic load and stability characteristics of the aircraft may be evaluated.

"VORTEX AGE AS A WAKE TURBULENCE SCALING PARAMETER"

NASA CR-132312 (VPI-AERO-006), August 1973, Virginia Polytechnic Institute and State University, Blacksburg, VA.

A program of research was conducted in the Virginia Tech Stability Wind Tunnel to determine the significance of vortex age as a scaling parameter in wake turbulence development and dissipation. Tests were conducted at three angles of attack, three free stream speeds, and seven downstream positions from 2 to 30 chord lengths using an NACA 0012 wing and a five hole yawhead pitot probe. The end surface of the wing tip was flat. Speeds were selected to give a predetermined range of vortex ages. The complete velocity structure of the vortex was measured at each station and speed. The resulting plots of maximum tangential velocity and vortex core diameter versus downstream distance and vortex age indicate that vortex age is not a self-sufficient scaling parameter. In addition to the expected effect

of lift coefficient there is also a definite free stream speed influence at high wing angles of attack. The exact cause and nature of this effect is not fully understood, but it does not appear to be explainable in terms of Mach number or Reynolds number; however, the influence of tip edge shape on spanwise flow separation appears to be an important factor.

"PARTICLE DISPERSION IN A TURBULENT VORTEX CORE"

Physics of Fluids, Vol. 17, No. 2, Feb. 2005, pp. 025104-1 to 025104-15

A study is performed using direct numerical simulation to examine the effect of turbulence on particle dispersion in a columnar vortex. A procedure is used to generate initial conditions in which turbulence external to the vortex has the wrapped, nearly azimuthal form characteristic of turbulence around a large-scale vortex structure. This approach enables control of the initial values of the external turbulence intensity and length scale for a given vortex size and strength. The effect of turbulence on dispersion of particles by the vortex flow is examined for a wide range of different values of the initial turbulence intensity. Cases both with zero mean axial flow and unstable vortices with nonzero mean axial flow are examined. The state of the external turbulence is determined by a balance between dissipation, stretching, and vorticity reorientation and stripping from the large-scale vortex core. We examine cases with peak initial turbulence kinetic energy differing by a ratio of up to 400, and for all cases we observe that the external turbulence has a dramatic effect on the particle dispersion. The results of the study have implications for large-eddy simulation of particulate flows for which the particle concentration in the region surrounding the coherent vortex structures will not be accurately predicted if the effect of smaller-scale turbulence surrounding these structures on particle dispersion is not resolved or appropriately modeled.

Marshall, J. S.

"THE FLOW INDUCED BY PERIODIC VORTEX RINGS WRAPPED AROUND A COLUMNAR VORTEX CORE"

J. Fluid Mech., Vol. 345, 1997, pp. 1-30

A study has been performed of the interaction of periodic vortex rings with a central columnar vortex, both for the case of identical vortex rings and the case of rings of alternating sign. Numerical calculations, both based on an adaptation of the Lundgren-Ashurst (1989) model for the columnar vortex dynamics and by numerical solution of the axisymmetric Navier-Stokes and Euler equations in the vorticity-velocity formulation using a viscous vorticity collocation method, are used to investigate the response of the columnar vortex to the ring-induced velocity field. In all cases, waves of variable core radius are observed to build up on the columnar vortex core due to the periodic axial straining and compression exerted by the vortex rings. For sufficiently weak vortex rings, the forcing by the rings serves primarily to set an initial value for the axial velocity, after which the columnar vortex waves oscillate approximately as free-standing waves. For the case of identical rings, the columnar vortex waves exhibit a slow upstream propagation due to the nonlinear forcing. The cores of the vortex rings

can also become unstable due to the straining flow induced by the other vortex rings when the ring spacing is sufficiently small. This instability causes the ring vorticity to spread out into a sheath surrounding the columnar vortex. For the case of rings of alternating sign, the wave in core radius of the columnar vortex becomes progressively narrower with time as rings of opposite sign approach each other. Strong vortex rings cause the waves on the columnar vortex to grow until they form a sharp cusp at the crest, after which an abrupt ejection of vorticity from the columnar vortex is observed.

"CROSS-STREAM VORTICITY FIELD INDUCED BY STREAMWISE VORTICES IN UNBOUNDED AND WALL-BOUNDED SHEAR FLOWS"

Theoretical and Computational Fluid Dynamics, Vol. 16, 2003, pp. 231-247.

This computational study examines the unsteady cross-stream vorticity structures that form when one or more streamwise vortices are immersed in homogeneous and boundary-layer shear flows. A quasi-two-dimensional limit is considered in which the velocity and vorticity fields, while still possessing three nonzero components, have vanishing gradient in the streamwise direction. This idealization is suitable to applications such as streamwise vortices that occur along a ship hull or airplane fuselage and it can be used as an idealized representation of the quasi-streamwise vortices in the near-wall region of a turbulent boundary layer. In this quasi-two-dimensional idealization, the streamwise velocity has no effect on the cross-stream velocity associated with the vortex. However, the vortex acts to modify the cross-stream vorticity component, resulting in regions of the flow with strong deviations in streamwise velocity. This paper examines the complex structures that form as the cross-stream vorticity field is wrapped up by the vortex and the effect of these structures on the streamwise velocity field, first for vortices immersed in homogeneous shear flow and then for vortices immersed in a boundary layer along a flat wall.

Marshall, J. S.

"BUCKLING OF A COLUMNAR VORTEX"

Physics of Fluids A, Vol. 4, No. 12, December 1992, pp. 2620-2627.

The instability of a columnar vortex under axial compression is studied analytically. Prediction of the change with time of an initial perturbation in the form of a small-amplitude helical wave on the vortex core is reduced to solution of a system of two linear, second-order ordinary differential equations. For small rates of compression, a closed-form asymptotic solution of these equations is obtained using a two-variable expansion in time. The results indicate that a vortex under compression may bend (or 'buckle') or it may remain columnar with an increase in core radius. The choice of which of these possible outcomes will occur is found to depend on the value of a single dimensionless parameter given by the product of the wave number k of the helical perturbation and the radius r of the vortex core. Where kr is greater than a critical value, found to be approximately 1.77, the perturbation amplitude will decrease with axial compression and no 'buckling' will occur. When kr is less than this critical value,

the perturbation amplitude will increase as the vortex axis is compressed and 'buckling' will be observed.

"VORTEX CUTTING BY A BLADE, PART I: GENERAL THEORY AND A SIMPLE SOLUTION"

AIAA Journal, Vol. 32, No. 6, June 1994, pp. 1145-1150.

A simplified theory for long-wave motion of vortex filaments with variable core radius is given, for small values of the ratio $e = \max(a/L)$ of core radius a to axial length scale L , which offers a number of advantages for numerical computations of the vortex response. An analytical solution of this theory is then obtained for the axial flow within a straight vortex filament following cutting of the vortex by a flat blade at an angle of attack α . The mathematical structure of the solution is like the classic problem of impulsive piston motion in a shock tube, and analogies of shocks and expansion waves propagating on the vortex away from the blade are predicted. A simple expression for the vortex force on the blade is derived, which is found to be mainly dependent on the ratio of the vortex core radii on opposing sides of the blade.

Marshall, J. S.

"MODELS OF SECONDARY VORTICITY EVOLUTION DURING NORMAL VORTEX-CYLINDER INTERACTION"

AIAA Journal, Vol. 40, No. 1, January 2002, pp. 170-172

A generic experimental setup was used to study the secondary vorticity produced during vortex-body interaction. The study is believed to have implications on a broad class of problems involving vortices interacting with helicopter rotor, or marine propeller blades and control surfaces. Analytical models are presented for aspects of the flow observed during normal interaction of a columnar vortex and a circular cylinder, including onset of outward ejection of secondary vorticity from the cylinder boundary layer and variation of the strength of the ensuing vortex loop as a function of time and position along the loop.

Marshall, J. S.

"EFFECT OF PARTICLE COLLISIONS ON THE EXPULSION OF HEAVY PARTICLES FROM A VORTEX CORE"

Physics of Fluids, Vol. 18, 2006, pp. 113301-1-113301-12

A computational study has been performed on the effect of particle collisions as heavy particles are expelled from a vortex core. In the absence of collisions, particles collect in a band surrounding the vortex core, where the maximum particle concentration within this band increases indefinitely as the band of particles propagates radially outward. Particle collisions act to regulate the increase in concentration within this band by the enhanced spreading of the particles that occurs through the action of shear-induced migration. The presence of axial flow within the vortex core introduces a drift

of the particles within the core toward the low-shear region at the core center, thus resisting the outward particle drift caused by centrifugal force. With increasing axial flow rates, the particles are retained in the vortex core for longer time periods. The role of various parameters on the particle expulsion is evaluated, including particle diameter, restitution coefficient, and initial concentration. The study also examines the effect of collisions on cases with two distinct particle sizes, in which the different outward expulsion rates act to separate particles of different size.

Marshall, J. S.

"RESPONSE OF A COLUMNAR VORTEX TO A WRAPPED VORTEX LOOP"

ESAIM Proceedings, Vol. 7, 1999, pp. 280-291.

A computational and experimental study of the interaction between an initially columnar vortex and a wrapped vortex loop was performed, which focused on the columnar vortex response to the vortex loop. This problem is motivated by applications involving three-dimensional vortex interaction with a solid body, where the secondary vorticity shed from the body rolls up into a series of loop-like structures that are advected away from the body by the primary vortex. As a secondary vortex loop wraps around a columnar vortex, it becomes entrained into the vortex core due to the self-induced velocity of the loop. The columnar vortex response as a secondary vortex loop moves close to and impacts upon its lateral core surface includes a combination of bending waves, waves of variable core area, and core shape deformation. If a vortex loop is sufficiently strong, its interaction with the columnar vortex is also accompanied by ejection of vorticity from the columnar vortex, sometimes leading to development of a traveling vortex breakdown.

Marshall, J. S. and Chen, H.

"STABILITY OF A COUNTER-ROTATING VORTEX PAIR IMMERSSED IN CROSS-STREAM SHEAR FLOW"

AIAA Journal, Vol. 35, No. 2, February 1997, pp. 295-305

The three-dimensional stability and nonlinear evolution of a single vortex and a pair of vortices of opposite strength immersed in a weak cross-stream shear flow are examined. The shear flow rate is assumed to be sufficiently small compared to the average core vorticity that the vortex cross sections are nearly circular and the effect of stretching of the background shear flow is negligible, while being sufficiently large compared to the vortex mutual interaction frequency to significantly influence the stability of the vortex pair. The effect of shear flow on the long- and short-wave instabilities are studied using a combination of linear theory and numerical simulations for nonlinear disturbances. The presence of cross-stream shear is found to introduce a coupling between the symmetric and antisymmetric perturbation modes of the vortex pair, which leads to the development of three distinctly different types of long-wave vortex instabilities. One type of instability is dominated by the interaction of the vortex self-induced velocity with the shear flow. The second type of instability is dominated by interaction of the vortices with each other. In the third type of instability, both the shear flow and the mutual interaction of the vortices are important. The nonlinear evolution of the vortex

pair is qualitatively different for each of these three cases. For short-wave perturbations, the presence of cross-stream shear is found to increase the growth rate and wave-number range of the unstable perturbations, provided that the shearing rate is sufficiently large.

Marshall, J. S. and Chen, H.

"STABILITY OF A COUNTER-ROTATING VORTEX PAIR IMMERSSED IN CROSS-STREAM SHEAR FLOW"

AIAA Journal, Vol. 35, No. 2, February 1997, pp. 295-305

Three-dimensional stability and nonlinear evolution of a single vortex and a pair of vortices of opposite strength immersed in a weak cross-stream shear flow are examined. The shear flow rate S is assumed to be sufficiently small compared to the average core vorticity that the vortex cross sections are nearly circular and the effect of stretching of the background shear flow is negligible, while being sufficiently large compared to the vortex mutual interaction frequency to significantly influence the stability of the vortex pair. The effect of shear flow on the long- and short-wave instabilities are studied using a combination of linear theory and numerical simulations for nonlinear disturbances. The presence of cross-stream shear is found to introduce a coupling between the symmetric and antisymmetric perturbation modes of the vortex pair, which leads to the development of three distinctly different types of long-wave vortex instabilities. One type of instability is dominated by the interaction of the vortex self-induced velocity with the shear flow. The second type of instability is dominated by interaction of the vortices with each other. In the third type of instability, both the shear flow and the mutual interaction of the vortices are important. The nonlinear evolution of the vortex pair is qualitatively different for each of these three cases. For short-wave perturbations, the presence of cross-stream shear is found to increase the growth rate and wave-number range of the unstable perturbations, provided that the shearing rate is sufficiently large.

"SIMULATION OF SECONDARY VORTICITY EJECTION AND EVOLUTION DURING THREE-DIMENSIONAL VORTEX-CYLINDER INTERACTION"

2000 ASME Fluids Engineering Division Summer Meeting, June 2000

Results of direct numerical computations are reported for the problem of three-dimensional interaction between a circular cylinder and a vortex with axis oriented nominally orthogonal to the cylinder axis. The computations employ a new type of tetrahedral vorticity element (TVE) method which solves the vorticity transport and Biot-Savart equations using a tetrahedral mesh fit to a set of Lagrangian computational points. The computations examine the secondary vorticity field shed from the cylinder and its evolution in the presence of the primary vortex. Cases with background free-stream velocity oriented in different directions are considered. Computational results are found to be consistent with previous experimental flow visualization results.

"A LAGRANGIAN VORTICITY COLLOCATION METHOD FOR VISCOUS, AXISYMMETRIC FLOWS WITH AND WITHOUT SWIRL"

Journal of Computational Physics, Vol. 138, 1997, pp. 302-33.

This paper presents a new Lagrangian vorticity collocation method for viscous, axisymmetric fluid flows with or without swirl. The velocity calculation is performed using a representation of the vorticity field in terms of Gaussian vortex rings for off-center points and Gaussian vortex blobs along the axis of symmetry. A matrix equation for the element 'amplitudes' is obtained via a collocation approach, by fitting the vorticity representation to the known vorticity values at the control points, prior to each velocity evaluation. This matrix equation is solved using an iterative procedure, which both speeds the calculation and filters out 'noise' in the element amplitudes. Viscous diffusion is accomplished with use of a diffusion velocity method, in which control points are moved with the sum of the local fluid velocity and an additional 'diffusion velocity' that accounts for the effect of viscosity on the spread of vorticity support. Derivatives are obtained by locally fitting a polynomial function to control points about a given control point via a least-square formulation and then differentiating the polynomial. This method is found to maintain high accuracy even for very irregularly spaced control points. The method introduced for viscous diffusion in the paper can also be used for three-dimensional vortex methods in general.

"A METHOD FOR DETERMINING THE VELOCITY INDUCED BY HIGHLY ANISOTROPIC VORTICITY BLOBS"

Journal of Computational Physics, Vol. 126, 1996, pp. 286-298

Resolution of boundary layer flows at moderate or high Reynolds numbers with the vortex blob method requires a great many isotropic elements. In this paper, an approximate method for determination of the induced velocity from highly anisotropic vorticity blobs is presented, and issues related to use of anisotropic elements in calculations with vortex blob algorithms for high Reynolds number near-wall flows are examined. The method presented here can be used to determine the induced velocity from smooth blob functions of arbitrary form, provided that the vorticity length scale associated with the blob is much less in one direction than in orthogonal directions. The ratio of these length scales is called the blob aspect ratio, and is used as a small parameter to construct an asymptotic approximation to the induced velocity field. This method is applied in the present paper to derive induced velocity expressions for anisotropic Gaussian blob functions in both two and three dimensions. It is argued, using test calculations for a Blasius boundary layer, that although direct calculation of the induced velocity requires about an order of magnitude more CPU time for anisotropic Gaussian elements than for isotropic elements, this difference is more than made up for by a reduction of several orders of magnitude in the number of elements needed to resolve boundary layer flows at moderate to high Reynolds numbers. It is also found that the standard vortex blob representation leads to errors in the calculation of wall slip velocity and wall shear stress due to smoothing of the discontinuity between

the real and image vorticity fields at the wall, but that these errors can be avoided by placing doublet-type elements along the wall.

Marshall, J. S. and Grant, J. R.

"EVOLUTION AND BREAKUP OF VORTEX RINGS IN STRAINING AND SHEARING FLOWS"

Journal of Fluid Mechanics, Vol. 273, 1994, pp. 285-312.

A study of the effect of external straining and shearing flows on the evolution and form of breakup of vortex rings has been performed. Two orientations each of straining and shearing flows are considered. A theoretical analysis of the ring motion for small strain and shear rates is performed, and it is found that for shearing and straining flows in the plane of the ring, the ring may oscillate periodically. For a straining flow with compression normal to the initial plane of the ring, the linear theory predicts that the ring radius will expand with time. For shearing flow normal to the initial plane of the ring, the linear theory predicts tilting of the ring in the direction of the shear flow rotation. Numerical calculations are performed with both single vortex filaments and with a three-dimensional discrete vortex element method. The numerical calculations confirm the predictions of the linear theory for values of stress and strain rates below a certain critical value (which depends on the ratio of initial ring to core radii), whereas for strain and shear rates above this value the ring becomes very elongated with time and eventually pinches off. Three distinct regimes of long-time behavior of the ring have been identified. Regime selection depends on initial ring geometry and orientation and on values of strain and shear rates. These regimes include (i) periodic oscillations with no pinching off, (ii) pinching off at the ring center, and (iii) development of an elongated vortex pair at the ring center and wider 'heads' near the ends (with pinching off just behind the heads). The boundaries of these regimes and theoretical reasons for the vortex behavior in each case are described.

Marshall, J. S. and Grant, J. R.

"PENETRATION OF A BLADE INTO A VORTEX CORE: VORTICITY RESPONSE AND UNSTEADY BLADE FORCES"

Journal of Fluid Mechanics, Vol. 306, 1996, pp. 83-109.

Numerical calculations are performed for the problem of penetration into a vortex core of a blade travelling normal to the vortex axis, where the plane formed by the blade span and the direction of blade motion coincides with the normal plane of the vortex axis at the point of penetration. The calculations are based on a computational method, applicable for unsteady three-dimensional flow past immersed bodies, in which a collocation solution of the vorticity transport equation is obtained on a set of Lagrangian control points. Differences between this method and other Lagrangian vorticity-based methods in the literature are discussed. Lagrangian methods of this type are particularly attractive for problems of unsteady vortex-body interaction, since control points need only be placed on the surface of the body and in regions of the flow with non-negligible vorticity magnitude. The

computations for normal blade-vortex interaction (BVI) are performed for an inviscid fluid and focus on the relationship between the vortex core deformation due to penetration of the blade into the vortex ambient position and the resulting unsteady pressure field and unsteady force acting on the blade. Computations for cases with different vortex circulations are performed, and the accuracy of an approximate formulation using rapid distortion theory is assessed by comparison with the full computational results for unsteady blade force. The force generated from blade penetration into the vortex ambient position is found to be of a comparable magnitude to various other types of unsteady BVI forces, such as that due to cutting of the vortex axial flow.

Marshall, J. S. and Krishnamoorthy, S.

"ON THE INSTANTANEOUS CUTTING OF A COLUMNAR VORTEX WITH NON-ZERO AXIAL FLOW"

J. Fluid Mech., Vol. 351, 1977, pp. 41-74

A study of the response of a columnar vortex with non-zero axial flow to impulsive cutting has been performed. The flow evolution is computed based on the vorticity-velocity formulation of the axisymmetric Euler equation using a Lagrangian vorticity collocation method. The vortex response is compared to analytical predictions obtained using the plug-flow model of Lundgren & Ashurst (1989). The plug-flow model indicates that axial motion on a vortex core with variable core area behaves in a manner analogous to one-dimensional gas dynamics in a tube, with the vortex core area playing a role analogous to the gas density. The solution for impulsive cutting of a vortex obtained from the plug-flow model thus resembles the classic problem of impulsive motion of a piston in a tube, with formation of an upstream-propagating vortex 'shock' (over which the core radius changes discontinuously) and a downstream-propagating vortex 'expansion wave' on opposite sides of the cutting surface. Direct computations of the vortex response from the Euler equation reveal similar upstream- and downstream-propagating waves following impulsive cutting for cases where the initial vortex flow is subcritical. These waves in core radius are produced by a series of vortex rings, embedded within the columnar vortex core, having azimuthal vorticity of alternating sign. The effect of the compression and expansion waves is to bring the axial and radial velocity components to nearly zero behind the propagating vortex rings, in a region on both sides of the cutting surface with ever-increasing length. The change in vortex core radius and the variation in pressure along the cutting surface agree very well with the predictions of the plug-flow model for subcritical flow after the compression and expansion waves have propagated sufficiently far away.

Marshall, J. S. and Yalamanchill, R.

"VORTEX CUTTING BY A BLADE, PART II: COMPUTATIONS OF VORTEX RESPONSE"

AIAA Journal, Vol. 32, No. 7, July 1994, pp. 1428-1436.

Computations of the interaction between a line vortex and blades of various thicknesses and angles of attack traveling in a direction normal to the vortex axis have been performed. A procedure to enable instantaneous cutting of the vortex is used in the case of thin blades to study vortex interaction with

the blade both before and after vortex cutting has occurred. To isolate the effect of blade thickness on vortex bending, additional computations have been performed of the interaction between a line vortex and circular cylinders of various diameters. The vortex is represented by a filament model which includes axial flow within the core and nonuniform core area, and the effect of the blade or cylinder on the vortex is obtained using a vortex sheet panel method. The study particularly examines bending of the vortex and the subsequent variation in vortex core radius. It is found that the amount of vortex bending is primarily dependent on the blade thickness T (or diameter D of a circular cylinder) to ambient vortex core radius a . For blades with T/a of order unity or less, very little bending is observed for attack angles under the stall limit. For cases in which significant vortex bending is observed (T/a or D/a greater than order unity), increase in blade or cylinder forward speed results in a decrease in vortex core radius for a given amount of bending of the vortex axis. Vortex shocks and expansion waves are also observed to propagate on the vortex after cutting by a blade, as predicted in Part I of the study.

"INTERACTION OF UNEQUAL ANTI-PARALLEL VORTEX TUBES"

J. Fluid Mechanics, Vol. 446, 2001, pp. 229-252

A computational study is reported of the close interaction of nominally anti-parallel vortex tubes with unequal strengths, S_1 and S_2 , where S_2 is less than or equal to S_1 . The computations are performed using a spectral method, with periodic boundary conditions and vortex Reynolds number $Re = 1500$, and the vortices are perturbed by a wavelength for which the pair is unstable because of their mutual interaction. The numerical method is tested for the case of equal-strength vortices, which exhibits the classic vortex reconnection phenomenon typified by bridging between the vortex cores and formation of thin vorticity threads as the bridged sections advect away under their self-induced velocity. Computations for vortices of unequal strengths are reported for cases with small, moderate, and large strength differences, for which $S_2/S_1 = 0.82, 0.54$ and 0.25 are chosen as representative values. The bridges between the vortex structures form loops that twist owing to the unequal vortex strengths. In the thread region, the vortex interaction is controlled by competition between the effects of stretching of the weak vortex as it wraps around the stronger vortex and the core distortion induced on each vortex owing to the straining imposed by the opposing vortex. For cases with large vortex strength difference, the strong vortex remains nearly straight as the weak vortex wraps around it, inducing an interlaced pattern of positive and negative vorticity spirals within the core of the strong vortex. Over a long time, the bridge regions form loops that propagate away from the thread region for cases with small strength difference and wrap around the nearly columnar strong vortex for cases with large strength difference.

"VORTICITY TRANSPORT ON A LAGRANGIAN TETRAHEDRAL MESH"

Journal of Computational Physics, Vol. 161, 2000, pp. 85-113

An integral vorticity method for computation of incompressible, three-dimensional, viscous fluid flows is introduced which is based on a tetrahedral mesh that is fit to Lagrangian computational points. A fast method for approximation of Biot-Savart type integrals over the tetrahedral elements is introduced, which uses an analytical expression for the nearest few elements, Gaussian quadratures for moderately distant elements, and a multipole expansion acceleration procedure for distant elements. Differentiation is performed using a moving least-squares procedure, which maintains between first- and second-order accuracy for irregularly spaced points. The moving least-squares method is used to approximate the stretching and diffusion terms in the vorticity transport equation at each Lagrangian computational point. A new algorithm for the vorticity boundary condition on the surface of an immersed rigid body is developed that accounts for the effect of boundary vorticity values both on the total vorticity contained within tetrahedra attached to boundary points and on vorticity diffusion from the surface during the time step. Sample computations are presented for uniform flow past a sphere at Reynolds number 100, as well as computations for validation of specific algorithms.

Marshall, M. S. and Beninati, M. L.

"EXTERNAL TURBULENCE INTERACTION WITH A COLUMNAR VORTEX"

J. Fluid Mech., Vol. 540, 2005, pp. 221-245

A study was performed using direct numerical simulation to examine the interaction of external turbulence with a nominally columnar, large-scale vortex at a vortex Reynolds number of 3000. A multi-step procedure is used to generate initial conditions in which the external turbulence has the wrapped, neatly azimuthal form characteristic of turbulence around a large-scale vortex structure. The proper-orthogonal decomposition method is used to extract specific modes of the vortex turbulence that dominate the kinetic energy and enstrophy fields. The effect of turbulence initial intensity and length scale on the turbulence structure and its influence on the large-scale vortex are examined. It is observed that the external turbulence wraps around the large-scale vortex and advects radially inward toward the vortex core. The dominant axial length scale of the external turbulence appears to scale with the vortex core diameter, with the mode with the largest enstrophy having a wavelength of about twice the core diameter. The turbulence induces a bending wave on the vortex core with axial wavelength approximately equal to the dominant wavelength of the external turbulence. The turbulent enstrophy decays according to a power-law expression for cases with moderate initial turbulence intensity. For sufficiently strong initial turbulence intensity, the turbulence breaks up the large-scale vortex core, creating strong turbulence within the vortex core.

"WAKE VORTEX RADAR SIMULATION STUDIES"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 309-323

Wake vortex radar reflectivity models in clear air and fog; and 35 GHz Wake Vortex pulse compression radar simulations in fog are presented.

Marshall, R. E. and Mudukutore, A. S.

"SPATIO-TEMPORAL CHARACTERISTICS OF RADAR VOLUME REFLECTIVITY IN WINGTIP GENERATED WAKE VORTICES IN CLEAR AIR"

Twenty-eighth Conference on Radar Meteorology, Austin, TX, September 7-12, 1997, Preprints, American Meteorological Society, 1997, pp. 266-267

The NASA Terminal Area Simulation System (TASS) has been modified to predict the mean wind and thermodynamic variables for aircraft 2D wakes with a 1-m resolution. The TASS-derived turbulent kinetic energy dissipation rate and kinematic viscosity have been used to calculate the Kolmogorov microscale and a corresponding maximum radar frequency at each grid point within aircraft wakes.

Marshall, R. E. and Mudukutore, A. S.

"RADAR REFLECTIVITY FACTOR IN THE WAKES OF AIRCRAFT IN FOGS"

Proceedings 28th Conf. on Radar Meteorology, American Meteorology Society, Austin, TX, September 1997, pp. 159-160

Doppler radar has been suggested as a remote sensor for aircraft wake vortex quantification in adverse weather, with a view to the dynamic adjustment of wake vortex separation distances between aircraft at takeoffs and landings. Results are presented from predictions of the radar reflectivity factor in the wakes of aircraft flying in fogs.

Marshall, R. E. and Myers, T.

"WINGTIP GENERATED WAKE VORTICES AS RADAR TARGETS"

IEEE Aerospace and Electronic Systems Magazine, Vol. 11, No. 12, December 1996, pp. 27-30

Previous radar wake vortex detection experiments have resulted in measured beam averaged values of radar reflectivity from wake vortices in clear air. We have employed average wind and thermodynamic variable output from a two-dimensional wake vortex model in clear air and fog to predict radar reflectivity in a wake vortex on a one-meter grid. The results agree well, compared to data in the literature. In the clear air case, scales of turbulence were analyzed at each grid point to determine the appropriate maximum radar frequency for detection. Initial wake structure, transport, and vortex persistence are related to atmospheric winds, atmospheric stability, and generating aircraft characteristics.

Marshall, R. E., Montoya, J., Richards, M. A. and Galliano, J.

"CHARACTERISTICS OF CIVIL AVIATION ATMOSPHERIC HAZARDS"

Fifth and Final Combined Manufacturers' and Technologists' Conference, Part 2, Airborne Windshear Detection and Warning Systems, NASA Langley Research Center, VA, July 1994, pp. 545-568

Clear air turbulence, wake vortices, dry hail, and volcanic ash are hazards to civil aviation that have not been brought to the forefront of public attention by a catastrophic accident. However, these four hazards are responsible for major and minor injuries, emotional trauma, significant aircraft damage, and in route and terminal area inefficiency. Most injuries occur during clear air turbulence. There is significant aircraft damage for any volcanic ash encounter. Rolls induced by wake vortices occur near the ground. Dry hail often appears as an area of weak echo on the weather radar. This paper will present the meteorological, electromagnetic, and spatiotemporal characteristics of each hazard. A description of a typical aircraft encounter with each hazard will be given. Analyzed microwave and millimeter wave sensor systems to detect each hazard will be presented.

"RADAR REFLECTIVITY IN WINGTIP-GENERATED WAKE VORTICES"

NASA/CR-97-206259, December 1997, Center for Aerospace Technology, Research Triangle Institute, Hampton, VA

This report documents new predictive models of radar reflectivity, with meter-scale resolution, for aircraft wakes in clear air and fog. The models result from a radar design program to locate and quantify wake vortices from commercial aircraft in support of the NASA Aircraft Vortex Spacing System. The radar reflectivity model for clear air assumes: 1) turbulent eddies in the wake produce small discontinuities in radar refractive index; and 2) these turbulent eddies are in the 'inertial subrange' of turbulence. From these assumptions, the maximum radar frequency for detecting a particular aircraft wake, as well as the refractive index structure constant and radar volume reflectivity in the wake can be obtained from the NASA Terminal Area Simulation System (TASS) output. For fog conditions, an empirical relationship is used to calculate radar reflectivity factor from TASS output of bulk liquid water. Currently, two models exist: 1) Atlas -- based on observations of liquid water and radar reflectivity factor in clouds; and 2) de Wolf -- specifically tailored to a specific measured dataset (1992 Vandenberg Air Force Base).

"THREE-CENTIMETER DOPPLER RADAR OBSERVATIONS OF WINGTIP-GENERATED WAKE VORTICES IN CLEAR AIR"

NASA/CR-97-206260, December 1997, Center for Aerospace Technology, Research Triangle Institute, Hampton, VA

This report documents a high risk, high pay-off experiment with the objective of detecting, for the first time, the presence of aircraft wake vortices in clear air using X-band Doppler radar. Field experiments were conducted in January 1995 at the Wallops Flight Facility to demonstrate the capability of the 9.33 GHz (3 cm) radar, which was assembled using an existing nine-meter parabolic antenna reflector and the receiver/transmitter from the NASA Airborne Windshear Radar Program. A C-130 aircraft, equipped with wingtip smoke generators, created visually marked wake vortices, which were recorded by video cameras. A C-band radar also observed the wake vortices during detection attempts with the X-band radar. Rawinsonde data was used to calculate vertical soundings of wake vortex decay time, cross aircraft bearing wind speed, and water vapor mixing ratio for aircraft passes over the radar measurement range. This experiment was a pathfinder in predicting, in real time, the location and persistence of C-130 vortices, and in setting the flight path of the aircraft to optimize X-band radar measurement of the wake vortex core in real time.

"COMPUTATION AND MODELING OF BLADE PENETRATION INTO A VORTEX IN AN INVISCID FLUID"

AIAA Paper 1995-2239, June 1995, San Diego, CA.

The penetration of a blade into the core region of a three-dimensional vortex structure, where the blade centerplane is normal to the vortex axis, is studied numerically. The computations are performed using a new type of Lagrangian vortex method, in which the amplitudes of the vortex blobs are obtained by iterative solution of an inverse problem. The algorithm used for solution of blade surface pressure is also new and is based on a boundary-integral formation of the pressure-Poisson equation. The variation with time of the force on the blade is obtained for vortices of a variety of strengths. The computed results are found to compare to those which would be obtained under the rapid distortion approximation, but to differ significantly from results obtained under the 'frozen vortex' assumption.

Martin, A.

"AN ACOUSTIC TOMOGRAPHY SYSTEM FOR MAKING HIGH RESOLUTION MEASUREMENTS OF AIRCRAFT WAKE VORTICES"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

An acoustic tomography system has been successfully deployed at Melbourne Airport. The system uses acoustic chirp pulses over the range 1000 Hz to 2000 Hz of 0.5 sec in length and has a matched filter receiver. Preliminary measurements show that high spatial and temporal measurements of aircraft wake vortices can be made on landing and departing aircraft. The system provides spatial resolution of around 2 m, temporal resolution of 2.7 sec with exceptional signal-to-noise ratio providing the opportunity for all weather operation. The measurement window is 110 m on both sides of the runway centerline up to a height of 100 m. A very high-resolution wind profiler that uses the same acoustic technology as the wake vortex detector will be collocated and provide essential information

about the local structure of the atmosphere, information that should be useful to assist with the completion of the development of wake evolution models and theory.

Martin, A. L.

"MEASUREMENT OF AIR CHARACTERISTICS IN THE LOWER ATMOSPHERE"

US Patent 7,317,659 B2, January 2008.

Sodar systems and methods for acoustically sounding air are disclosed in which chirps longer than 300 ms -- and preferably with durations of tens of seconds -- are used along with matched filter and/or Fourier processing methods to derive phase signals indicative of air characteristics in range. A listen-while-transmit strategy is preferred, the direct signal being removed by subtracting the phase signals from two or more receivers located near the transmitter so as to be in the same noise environment. The resultant differential signals can be related to cross-range wind with range distance. In one example, apparatus is employed comprising a reflector dish over which one central loudspeaker and four microphones are mounted, the microphones preferably being located on cardinal compass points and having their axes slightly angled with respect to the vertical transmission axis.

Martin, A. L.

"DETECTION OF WAKE VORTICES AND THE LIKE IN THE LOWER ATMOSPHERE"

U.S. Patent 2007/0089502 A1, April 2007

Two SODAR systems for detecting and characterizing vortices shed from landing or departing aircraft as at an airport are positioned so that one, the active system is located beneath the likely vortices and the other, the reference system is located away from the vortices but in the same ambient environment. Thus, where a wind duct or thermal inversion is present, both SODAR systems will detect echoes and generated thereby, whereas only the active system will detect echoes from wake vortices. By differencing the outputs of the reference and active systems, better vortex identification and discrimination is achieved. Only one SODAR system need be used where sufficiently normal conditions prevail between aircraft activity, since readings taken in the absence of aircraft can be used as reference data for subtraction from 'active' data recorded during the presence of aircraft.

"IMAGE SYSTEM SOLUTION FOR STORE AERODYNAMICS WITH INTERFERENCE - PART II"

J. Aircraft, Vol. 12, No. 3, 1975, pp. 156-161

The mutual aerodynamic interference problem for external aircraft-stores has been analyzed using the image system technique. To facilitate this analysis, it has been assumed that small perturbation solutions are valid. It is further assumed that the external stores are slender, axisymmetric bodies and that the mutual interference can be analyzed by first assuming a cross-flow solution. Both body-body

and wing-body interference solutions have been obtained. The first were considered in Part I of this paper. For the wing-body solution, the image systems in the cross-flow plane consist of vortex pairs appropriately located by using the Milne-Thomson circle theorem. The strengths of the image vortex system are then determined by satisfying the body boundary conditions at designated control points on the external stores. Good agreement has been found between the theoretical and experimental results.

Martin, P. B.

"MEASUREMENTS OF THE TRAILING VORTEX FORMATION, STRUCTURE AND EVOLUTION IN THE WAKE OF A HOVERING ROTOR"

PhD Thesis, 2001, University of Maryland, College Park, Maryland.

High-resolution velocity field measurements and flow visualization images were acquired in the flow field near the tip of a rotor blade operating in hover. Using three-dimensional laser Doppler velocimetry (LDV), the measurements documented the trailing vortex formation, initial structure, and the viscous evolution of the core. The test conditions covered a range of wake ages from as young as one degree, up to about one rotor revolution. For each wake age, vortex core properties were estimated from the velocity field measurements. The test conditions also included different tip shapes including rectangular, tapered, swept, and a sub wing tip. Preliminary measurements were used to refine the technique by understanding the sources of uncertainty and the spatial resolution requirements. This task included developing a new procedure for three-component LDV alignment using a laser beam profiler. A detailed uncertainty analysis of the LDV measurement technique was conducted and applied to helicopter rotor blade tip vortex measurements. Finally, spatial resolution requirements were formally established to enable a more accurate reconstruction of the velocity field associated with blade tip vortices. A set of benchmark test cases was acquired using LDV for each of the tip shapes. The measurements were supported by detailed flow visualization. The high spatial resolution obtained with LDV has shown that the tip vortex core radius can be less than 3 percent chord at early wake-ages, but grows asymptotically as it ages. A significant axial velocity deficit existed in the vortex core that was of the order of the peak swirl velocity at early wake-ages, but which quickly diminished as the vortex aged. The evidence suggests that the entire tip vortex structure is neither fully laminar or fully turbulent, but is instead in a continuous state of dynamic evolution with a region of relatively slow laminar diffusion and a region of accelerated turbulent diffusion.

Martin, P. B. and Leishman, J. G.

"TRAILING VORTEX MEASUREMENTS IN THE WAKE OF A HOVERING ROTOR BLADE WITH VARIOUS TIP SHAPES"

58th Annual Forum and Technology Display of the American Helicopter Society International, Montreal, Canada, June 2002

This work examined the wake aerodynamics of a single helicopter rotor blade with several tip shapes operating on a hover test stand. Velocity field measurements were conducted using three-component laser Doppler velocimetry (LDV). The objective of these measurements was to document the vortex velocity profiles and then extract the core properties, such as the core radius, peak swirl velocity, and axial velocity. The measured test cases covered a wide range of wake-ages and several tip shapes, including rectangular, tapered, swept, and a sub wing tip. One of the primary differences shown by the change in tip shape was the wake geometry. The effect of blade taper reduced the initial peak swirl velocity by a significant fraction. It appears that this is accomplished by decreasing the vortex strength for a given blade loading. The sub wing measurements showed that the interaction and merging of the sub wing and primary vortices created a less coherent vortical structure. A source of vortex core instability is shown to be the ratio of the peak swirl velocity to the axial velocity deficit. The results show that if there is a turbulence producing region of the vortex structure, it will be outside of the core boundary. The LDV measurements were supported by laser light-sheet flow visualization. The results provide several benchmark test cases for future validation of theoretical vortex models, numerical free-wake models, and computational fluid dynamics results.

"STEREOSCOPIC PIV MEASUREMENTS IN THE WAKE OF A HOVERING ROTOR"

56th Annual Forum of the American Helicopter Society, Virginia Beach, VA, May 2000

Phase-resolved stereoscopic particle image velocimetry (PIV) measurements were made in the wake of a hovering sub-scale helicopter rotor. The results were compared with three-component laser Doppler velocimetry (LDV) measurements when using the same seeding medium. The various challenges of using PIV and LDV to study the formation and evolution of helicopter tip vortices are discussed. Results are presented for a test case using a hovering rotor with a tapered tip blade. The relatively small tip vortex core size and high tangential velocities produced by the blade provided a particularly good challenge to the spatial resolution of the PIV technique. The large image area covered by the PIV measurements provided insight into the rotor flow physics. Compared to LDV, however, it was found that PIV was generally unable to resolve the steep velocity gradients present in the tip vortex. While PIV provides certain advantages when used as a complimentary technique to LDV, the results show that it is not yet a substitute when three-dimensional vortex velocity profile measurements with high spatial and temporal resolution are required.

Martina, A. P.

"METHOD FOR CALCULATING THE ROLLING AND YAWING MOMENTS DUE TO ROLLING FOR UNSWEPT WINGS WITH OR WITHOUT FLAPS OR AILERONS BY USE OF NONLINEAR SECTION LIFT DATA"

NASA TN 1167, January 1954, Langley Aeronautical Laboratory, Langley Field, VA.

The methods of NACA Reports 865 and 1090 have been applied to the calculation of the rolling-moment and yawing-moment coefficients due to rolling for unswept wings with or without flaps or

ailerons. The methods are based on lifting-line theory and allow the use of nonlinear section lift data. The method presented herein permits calculations to be made somewhat beyond maximum lift for wings having no twist or continuous twist and employing airfoil sections which do not display large discontinuities in the lift curves. Calculations can be made up to a maximum lift for wings with discontinuous twist such as that produced by partial-span flaps or ailerons, or both. Two calculated examples are presented in simplified computing forms in order to illustrate the procedures involved.

Martinez-Val, R.

"FLYING WINGS, A NEW PARADIGM FOR CIVIL AVIATION"

Acta Polytechnica, Vol. 47, No. 1, 2007, pp. 32-43.

Over the last 50 years, commercial aviation has been mainly based what is currently called the conventional layout, characterized by a slender fuselage mated to a high aspect ratio wing, with aft-tail planes and pod-mounted engines under the wing. However, it seems that this primary configuration is approaching an asymptote in its productivity and performance characteristics. One of the most promising configurations for the future is the flying wing in its distinct arrangements: blended-wing-body, C-wing, tail-less aircraft, etc. These layouts might provide significant fuel savings and, hence, a decrease in pollution. The present paper discusses the main features of flying wings, their advantages over conventional competitors, and some key operational issues, such as evacuation and vortex wake intensity.

Maskew, B.

"SUBVORTEX TECHNIQUE FOR THE CLOSE APPROACH TO A DISCRETIZED VORTEX SHEET"

J. Aircraft, Vol. 14, No. 2, 1977, pp. 188-193.

The close-approach problem associated with flow calculation methods based on vortex-lattice theory is examined numerically using two-dimensional discretized vortex sheets. The analysis first yields a near-field radius of approximately the distance apart of the vortices in the lattice; only within this distance from the sheet are the errors arising from the discretization significant. Various modifications to the discrete vortices are then considered with the objective of reducing the errors. This study leads to a near-field model in which a vortex splits into an increasing number of sub vortices as it is approached. The sub vortices, whose strengths vary linearly from the vortex position, are evenly distributed along an interpolated curve passing through the basic vortices. This sub vortex technique can be extended to the three-dimensional case and is efficient because the number of vortices is effectively increased, but only where and when needed.

Maskew, B.

"ON THE INFLUENCE OF CAMBER AND NON-PLANAR VORTEX WAKE ON WING CHARACTERISTICS IN GROUND EFFECT"

ARC CP-1264, 1973, Loughborough Univ. of Technology, Loughborough, England

The theoretical influence of camber and non-planar wake on the change of lift, vortex drag and center of pressure of a wing with ground effect is examined. Potential flow calculations are performed for both two- and three-dimensional conditions, the former using a multi-vortex method and the latter using an arbitrary geometry quadrilateral vortex-ring method with a vortex wake relaxation iterative scheme. The results demonstrate the importance of including the influence of camber, incidence, and non-planar wake in practical ground effect calculations.

"THE NONLINEAR CRITICAL LAYER FOR KELVIN MODES ON A VORTEX WITH A CONTINUOUS VELOCITY PROFILE"

SIAM Journal on Applied Mathematics, Vol. 68, Issue 3, 2008, pp. 825-843.

We consider in this paper the propagation of neutral modes along a vortex with velocity profile $V(r)$, r being the radial coordinate. In the linear inviscid stability theory for swirling flows, modes that are singular at some value of r denoted r_c , the critical point, are particularly significant. The singularity can be dealt with by adding viscous and/or nonlinear effects within a thin critical layer centered on the critical point. At high Reynolds numbers, the case of most interest in applications such as aeronautics and geophysical fluid dynamics, nonlinearity is the appropriate choice, although viscosity may still play a subtle role. We determine here the scaling and equations that govern the nonlinear critical layer. The method of characteristics is then employed to obtain an exact solution of the governing inviscid system composed of four coupled PDE's, of which two are nonlinear and two are linear. Finally, assuming zero phase change across the critical layer, solutions are obtained for the outer eigenvalue problem demonstrating the existence of modes not possible in a linear theory. This result may have important implications for the short wake cooperative instability mechanism that has received so much attention in the context of aircraft trailing vortices.

"COMPUTATIONAL AERO-OPTICS AND ELECTROMAGNETICS: COMPRESSIBLE VORTICES AND LASER BEAM PROPAGATION"

IASME Transactions, Issue 1, Vol. 2, January 2005, pp. 19-27

Computational modeling of electromagnetic-wave propagation, such as laser-beam propagation, through turbulent flows involves, as basic elements, the interactions between each vortex and each optical wavefront. We consider a compressible vortex as a flow model relevant to the large-scale as well as small-scale structure of turbulence. The compressibility is essential for applications associated with airborne platforms such as mobile laser communication or directed-energy projection. A weakly-compressible two-dimensional axisymmetric steady isentropic vortex model is employed. The full

nonlinear eikonal equation is numerically integrated to propagate the optical wavefronts through the vortex. For near-field aero-optics applications at low beam energies, geometrical optics is sufficient. The optical-path-length profile of the propagated distorted wavefronts is computed, confirming the acceleration of the beam wavefronts through the density low of the vortex. The optical distortion is found to be weakly sensitive to an approximation of the aero-optical interaction where bending of individual light rays is neglected. This provides a computationally-efficient means of simulating aero-optical distortions through low-compressibility vortices in the near-field of the laser beam.

Mason, W. H. and Marchman iii, J. F.

"THE FARFIELD STRUCTURE OF AIRCRAFT WAKE TURBULENCE"

AIAA Paper No. 72-40, Jan. 1972, San Diego, CA.

Detailed mean flow measurements were obtained at stations up to thirty chord lengths downstream in an airfoil trailing vortex using a yawhead pressure probe in the Virginia Tech Six-Foot Subsonic Tunnel. Mass injection at the wingtip was shown to hasten the vortex decay. A theoretical method has been developed to show the effect of wing circulation distribution on the structure of the outer portion of the vortex and excellent agreement with the experimental data is demonstrated. Experimental results indicate a much slower decay and higher tangential velocities than previously expected.

Mason, W. H. and Marchman, III, J. F.

"FAR-FIELD STRUCTURE OF AIRCRAFT WAKE TURBULENCE"

J. Aircraft, Vol. 10, No. 2, February 1973, pp. 86-92

Detailed mean flow measurements were obtained at stations up to thirty chord lengths downstream in an airfoil trailing vortex using a yawhead pressure probe in the Virginia Tech Six-Foot Subsonic Tunnel. Mass injection at the wingtip was shown to hasten the vortex decay. A theoretical method has been developed to show the effect of wing circulation distribution on the structure of the outer portion of the vortex and excellent agreement with the experimental data is demonstrated.

"FARFIELD STRUCTURE OF AN AIRCRAFT TRAILING VORTEX, INCLUDING EFFECTS OF MASS INJECTION"

NASA CR-62078, April 1972, Virginia Polytechnic Inst. and State Univ., Blacksburg, VA.

With the introduction of the 'Jumbo Jet' class of aircraft it has become important to predict the aircraft wake turbulence due to the tip trailing vortex accurately. A yawhead pressure probe has been used in the Virginia Tech 6-Foot Subsonic Tunnel to obtain detailed mean flow measurements at stations up to thirty chord lengths downstream in an aircraft trailing vortex. Mass injection at the wingtip has been shown to hasten the decay of the trailing vortex. A theoretical method has been given to show the effect of the circulation distribution on the wing on the structure of the outer portion

of the vortex, and excellent agreement with experiment has been shown. Experimental results indicate a much slower decay and higher tangential velocities than previously expected.

Mason, W. H. and Marchman, III, J. F.

"INVESTIGATION OF AN AIRCRAFT TRAILING VORTEX USING A TUFT GRID"

VPI-E-71-17, September 1971, Virginia Polytechnic Institute and State University, Blacksburg, VA

A study of the trailing vortex of a wing has been made using a tuft grid in the Virginia Tech 6 Foot Wind Tunnel. The study included an investigation of the use of mass injection at the wing tip as a means of destroying the vortex. Test results show that a fully developed, stable, vortex exists at least a distance of thirty chord lengths downstream of the wing, and that the 'swirl' of the vortex can be reduced or eliminated by mass injection at the wing tip.

"SIMULTANEOUS INDEPENDENT AND DEPENDENT PARALLEL INSTRUMENT APPROACHES;
ASSUMPTIONS, ANALYSIS, AND RATIONALE"

MP 06W0000127, July 2006, MITRE Corporation, McLean, VA.

The Federal Aviation Administration has successfully conducted simultaneous independent approaches to parallel runways for over 40 years using Instrument Landing System (ILS) navigation and terminal radar monitoring. Parallel dependent approaches have also been conducted for many years. Recent advances in navigation and surveillance have sparked interest in reviewing the current standards for these approaches. This paper will attempt to describe the process that led to the current standards, including relevant assumptions, testing, and methodology. Future work will identify the most promising assumptions for further review.

Massouh, F. and Dobrev, I.

"INVESTIGATION OF WIND TURBINE FLOW AND WAKE"

Journal of Fluid Science and Technology, Vol. 9, No. 3, 2014, pp. 1-9.

This paper is dedicated to the investigation and analysis of wind turbine wake. An experimental work is undertaken in wind tunnel on a horizontal axis wind turbine model. The velocity field in the wake is measured using PIV with phase synchronization to relate velocity and vortices to the rotating blades. The tip vortices are investigated in successive azimuthal positions of the rotor. A specially developed algorithm based on the circulation maximum detects the positions of the vortex cores and permits to use conditional averaging technique. The analysis of obtained velocity fields enables to determine the vortex core diameter, the swirl velocity distribution, and the vortex diffusion as functions of the vortex age. The quality of obtained results permits to use them as reference for the validation of numerical computations.

Mast, E. H. M., Vermeer, L. J. and van Bussel, G. J. W.

"ESTIMATION OF THE CIRCULATION DISTRIBUTION ON A ROTOR BLADE FROM DETAILED NEAR WAKE VELOCITIES"

Wind Energy, Vol. 7, 2004, pp. 189-209

The circulation distribution over a blade of a wind turbine model is estimated by use of a vortex model, which is matched with measured wake properties. With near wake velocities and the Biot-Savart law an optimization scheme is constructed to estimate the circulation distribution over the blade using a polynomial function series to approximate the circulation distribution. The velocities resulting from the calculated distribution are compared with the measured data, and deviations are discussed and explained. The vortex model offers insight into how the measured velocities can be separated into induced velocities of the different parts of the vortex system, such as the influence of the tip vortex. Finally, the circulation distribution obtained with the vortex model is compared with the circulation distribution obtained through application of a blade element momentum (BEM) code. The BEM results show an underestimation of the circulation near the root and an overestimation of the circulation near the tip with respect to the vortex model results.

Matalanis, C. G.

"WAKE VORTEX ALLEVIATION USING RAPIDLY ACTUATED SEGMENTED GURNEY FLAPS"

PhD Thesis, January 2007, Stanford University, Stanford, CA.

All bodies that generate lift also generate circulation. The circulation generated by large commercial aircraft remains in their wake in the form of trailing vortices. These vortices can be hazardous to following aircraft due to their strength and persistence. To account for this, airports abide by spacing rules which govern the frequency with which aircraft can take-off and land from their runways when operating in instrument flight rules. These spacing rules have become the limiting factor on increasing airport capacity, and with the increases in air travel predicted for the near future, the problem is becoming more urgent. One way of approaching this problem is active wake alleviation. The basic idea is to actively embed perturbations in the trailing vortex system of an aircraft which will excite natural instabilities in the wake. The instabilities should result in a wake which is benign to following aircraft in less time than would normally be required, allowing for a reduction in current spacing rules. The main difficulty with such an approach is in achieving perturbations large enough to excite instability without significantly degrading aircraft performance. Rapidly actuated segmented Gurney flaps, also known as Miniature Trailing Edge Effectors (MiTEs), have shown great potential in solving various aerodynamic problems. Previous work has shown that they can create a large increment in the section lift coefficient of an airfoil local to the spanwise position where they are actuated. Thus, MiTEs may be used to actively alter the shape of a wing lift distribution. This suggests that they might also be useful for active wake alleviation. We conducted an experimental and computational study to assess the potential for using MiTEs for active wake vortex alleviation. Wind tunnel tests were performed on a half-span model NACA 0012 wing equipped with an array of 13 independent MiTE pairs. The chord-based Reynolds

number was around 350,000. Each MiTE could extend 0.015 chord lengths perpendicular to the freestream on the pressure side of the wing. Pressure profiles and a five-hole probe survey in the near wake were used to examine the influence that the MiTEs had upon the wing aerodynamics and the vortex rollup process. Static and dynamic particle image velocimetry (PIV) were used to measure the static and time-dependent response of the vortex in the intermediate wake to various MiTE actuation schemes. These experiments showed that the MiTEs could deflect the vortex in both the spanwise and lift directions. A maximum spanwise deflection of 0.041 chord lengths was possible while nearly conserving lift. The dynamic PIV results combined with results from the pressure profiles and a five-hole probe survey in the intermediate wake were used to form complete, experimentally-based initial conditions for vortex filament computations that were used to compute the far wake evolution. Results from these computations showed that the perturbations created by MiTEs could be used to excite a variety of three-dimensional inviscid vortex instabilities. Finally, the research performed on MiTEs led to the development of a new, more practical wake alleviation device: the spanwise actuating Gurney flap. A prototype of this device was designed and tested. The tests showed that the same types of perturbations as were seen with the MiTEs could be achieved with this device.

Matalanis, C. G. and Eaton, J. K.

"WAKE VORTEX CONTROL USING RAPIDLY ACTUATED SEGMENTED GURNEY FLAPS"

AIAA Paper No. 2006-481, Reno, NV, January 2006

A study to assess the potential for using rapidly actuated segmented Gurney flaps, also known as Miniature Trailing Edge Effectors (MiTEs), for active wake vortex alleviation is conducted using a half-span model wing with NACA 0012 shape and an aspect ratio of 4.1. All tests are performed with the wing at an 8.9-degree angle of attack and chord based Reynolds number of 350,000. The wing is equipped with an array of 13 MiTE pairs. Each MiTE has a flap that in the neutral position rests behind the blunt trailing edge of the wing, and in the down position extends 0.015 chord lengths perpendicular to the freestream on the pressure side of the wing. Measurements of section lift coefficient are made using pressure taps to assess the effect of various MiTE configurations on the spanwise lift distribution. Static and dynamic PIV measurements are made on the trailing vortex to assess the steady-state and transient effects of different actuation schemes. It is found that the MiTE configurations that nearly conserve the total lift on the wing can also displace the vortex by 0.041 chord lengths in the spanwise direction and 0.016 chord lengths in the liftwise direction. These perturbations can be produced at axial wavelengths corresponding to short and long wavelength vortex instabilities.

Matalanis, C. G. and Eaton, J. K.

"WAKE VORTEX ALLEVIATION USING RAPIDLY ACTUATED SEGMENTED GURNEY FLAPS"

AIAA Journal, Vol. 45, No. 8, August 2007, pp. 1874-1884

A study to assess the potential for using rapidly actuated segmented Gurney flaps, also known as miniature trailing-edge effectors, for active wake vortex alleviation is conducted. Experiments are

performed using a half-span model wing with NACA 0012 shape and an aspect ratio of 4.1. The wing is at an 8.9-deg angle of attack and the chord-based Reynolds number is around 350,000. It is equipped with an array of miniature trailing-edge effectors that extend 0.015 chord lengths perpendicular to the freestream on the pressure side of the wing when deployed and sit just behind the blunt trailing edge when retracted. Measurements of section lift coefficient and the velocity field in the intermediate wake using dynamic particle image velocimetry and a five-hole probe delineate the time-varying perturbation imparted by the miniature trailing-edge effectors upon the trailing vortex while keeping the lift nearly constant. The data are used to form a complete initial condition for a vortex filament computation of the far-wake evolution. Cases at the model-scale and full-scale configurations are computed. The results show that actuator-induced perturbations can be used to excite a variety of inviscid vortex instabilities.

Matalanis, C. G. and Eaton, J. K.

"WAKE VORTEX CONTROL USING STATIC SEGMENTED GURNEY FLAPS"

AIAA Journal, Vol. 45, No. 2, February 2007, pp. 321-328

A study to assess the potential for using static segmented Gurney flaps, also known as miniature trailing edge effectors, for active wake vortex alleviation is conducted using a half-span model wing with NACA 0012 shape and an aspect ratio of 4.1. All tests are performed with the wing at an 8.9 deg angle of attack and chord-based Reynolds number around 350,000. The wing is equipped with an array of 13 miniature trailing edge effector pairs. Each miniature trailing edge effector has a flap that in the neutral position rests behind the blunt trailing edge of the wing, and in the down position extends 0.015 chord lengths perpendicular to the freestream on the pressure side of the wing. Measurements of section lift coefficient are made using pressure taps to assess the effect of various miniature trailing edge effector configurations on the spanwise lift distribution. Particle image velocimetry and five-hole probe measurements are made on the trailing vortex to assess the steady-state effects of different flap configurations. It is found that the miniature trailing edge effector configurations with a large fraction of the span actuated down can deflect the vortex predominantly in the lift direction, whereas miniature trailing edge effector configurations with a small fraction of the span actuated down are able to deflect the vortex in both the spanwise and lift direction. A maximum spanwise deflection of 0.041 chord lengths is possible while nearly conserving total lift. These results suggest that certain miniature trailing edge effector configurations, if varied in time, may be useful for wake alleviation.

"NOVEL AERODYNAMIC DEVICE FOR WAKE VORTEX ALLEVIATION"

AIAA Journal, Vol. 45, No. 9, September 2007, pp. 2348-2350

Previous work conducted on rapidly actuated segmented Gurney flaps for wing tip vortex control has led to the development of a novel aerodynamic device specifically designed for active wake alleviation. The spanwise actuating Gurney flap constitutes a simple, practical, and implementable device capable of perturbing a trailing vortex in a manner that may excite wake instability. Although dynamic effects were not examined here, results from other Gurney flap-type devices suggest that at the slow actuation speeds that would be necessary to excite long wavelength instabilities, the response will likely be quasi steady. More work will be required to determine the optimal shape and configuration for such a device as well as the best way to implement it on a multi-element high lift wing.

"DYNAMIC WAKE VORTEX SEPARATION COMBINING WITH TRAFFIC OPTIMIZATION"

ICAS 2014, September 2014, St. Petersburg, Russia.

Current wake vortex separation minima are a major impediment to increasing air traffic capacity since they are greater than radar separation minima. The concept of dynamic wake vortex separation, which allows reduced separations in favorable weather conditions when wake durations on flight paths become shorter, would allow an increase in capacity. To realize dynamic wake vortex separation, the Japan Aerospace Exploration Agency (JAXA) is developing a wake vortex advisory system (WVAS) that calculates reduced separations that have equal safety to current separations. In addition, JAXA is developing a traffic pattern optimization system (TPOS) that optimizes runway allocation and take-off/landing sequences to maximize airport capacity. An airport traffic simulation indicates that 4.5 percent and 3.4 percent airport capacity gains can be achieved by introducing WVAS and TPOS individually.

Matayoshi, N.

"REDUCED WAKE VORTEX SEPARATION USING WEATHER INFORMATION"

Lecture Notes in Electrical Engineering, Vol. 290, 2014, Springer Japan, pp. 49-68.

Current wake vortex separation minima are a major impediment to increasing traffic capacity since they require greater separations than radar separation minima. The concept of dynamic wake vortex separation, which allows reduced separation in favorable weather conditions when wake durations on flight paths become shorter, would allow an increase in capacity. The Japan Aerospace Exploration Agency (JAXA) has developed a methodology that calculates a reduced wake vortex separation that is equally safe as current separation minima. The methodology uses a probabilistic wake vortex prediction model to probabilistically assure that the wake vortex encounter risks at reduced separations do not exceed those at current separation minima. JAXA has also developed an airport terminal traffic simulation environment to demonstrate the traffic capacity gain at a congested airport when reduced wake vortex separations are introduced and take-off/landing sequences are optimized. The simulation result showed a greater than 10 percent capacity gain, and confirmed the effectiveness of the proposed methodology.

Matayoshi, N.

"DYNAMIC WAKE VORTEX SEPARATION ACCORDING TO WEATHER CONDITIONS"

AIAA Paper 2013-4425, August 2013, Los Angeles, CA.

Current wake vortex separation minima are a major impediment to increasing traffic capacity since they require greater separations than radar separation minima. The concept of dynamic wake vortex separation, which allows reduced separation in favorable weather conditions when wake durations on flight paths become shorter, would allow an increase in capacity. The Japan Aerospace Exploration Agency (JAXA) has developed a methodology that calculates a reduced wake vortex separation that is equally safe as current separation minima. The methodology uses a probabilistic wake vortex prediction model to probabilistically assure that the wake vortex encounter risks at reduced separations do not exceed those at current separation minima. JAXA has also developed an airport terminal traffic simulation environment to demonstrate the traffic capacity gain at a congested airport when dynamic wake vortex separations are introduced and take-off/landing sequences are optimized. The simulation result showed a greater than 10 percent capacity gain, and confirmed the effectiveness of the proposed methodology.

"EVALUATION OF HELICOPTER ENCOUNTERS WITH WAKE VORTICES"

35th European Rotorcraft Forum, September 2009, Hamburg, Germany.

This paper reports on pilot-in-the-loop flight simulations of helicopter wake vortex encounters conducted by the Japan Aerospace Exploration Agency. To clarify the characteristics of helicopter wake vortex encounters, helicopter responses were compared with those of fixed-wing aircraft in the same conditions. The simulation results indicate that helicopters are less susceptible to wake vortex disturbances than fixed-wing aircraft in the same weight category, with helicopters experiencing half or

less the attitude disturbance and height loss than fixed-wing aircraft. The helicopter pilots consequently felt that there was no risk to flight safety even for encounters at distances somewhat less than the current ICAO wake vortex separation minima. This finding supports the feasibility of reducing wake vortex separation for helicopters compared to fixed-wing aircraft.

Matayoshi, N. and Yoshikawa, E.

"DYNAMIC WAKE VORTEX SEPARATION COMBINING WITH AMAN/DMAN CONCEPT"

AIAA Paper 2015-3397, June 2015, Dallas, TX.

To increase airport capacity, the Japan Aerospace Exploration Agency is developing two technologies: a wake vortex advisory system (WVAS) that calculates reduced wake vortex separations that have equal safety to current separations, and a traffic pattern optimization system (TPOS) that optimizes take-off/landing sequences and runway allocation to increase airport capacity. Based on wake vortex observations of over 3,000 landing aircraft, the dynamic separations of WVAS were verified to be safe and separations could be reduced in 49 percent of cases. The simulation study also revealed that TPOS can reduce delays by 20-70 percent at airports with complex runway layouts by combining TPOS with RECAT. These results indicate that WVAS and TPOS would be effective at increasing airport capacity and reducing delays.

"FLIGHT-TEST EVALUATION OF A HELICOPTER AIRBOURNE LIDAR"

Journal of Aircraft, Vol. 44, No. 5, September-October 2007, pp. 1712-1720.

The Japan Aerospace Exploration Agency has conducted ground and flight-test evaluation of a prototype 1.5-micron all-fiber pulsed coherent Doppler lidar produced by Mitsubishi Electric Corporation, which aims to measure three-axis components of airspeed and detect atmospheric turbulence ahead of a helicopter. In the ground test, the lidar has proven its capability to detect atmospheric turbulence with a scale of several tens of meters by accurately measuring helicopter rotor downwash. In the flight test, the lidar was installed in the Japan Aerospace Exploration Agency's MuPAL-e research helicopter and the accuracy of real-time airspeed calculation using lidar outputs and the format of a real-time pilot display were evaluated. The lidar successfully measured three-axis airspeed components accurately even in low-airspeed flight regimes including hovering, backwards, and sideways flight where the conventional pitot-static system does not work and its capability as a helicopter airspeed sensor was proven. Some technical challenges were found for atmospheric turbulence detection, such as increasing the detection range and improving the data analysis and presentation. These results will be used to establish the specifications of practical airbourne lidars.

"AIRPORT TERMINAL TRAFFIC SIMULATION APPLYING REDUCED WAKE VORTEX SEPARATION"

AIAA Paper No. 2010-9338, September 2010, Fort Worth, TX.

The Japan Aerospace Exploration Agency has developed an airport terminal traffic simulation environment that dynamically minimizes aircraft wake vortex separation by considering wake vortex behaviors from meteorological information and using GBAS-based curved approach paths. A traffic simulation of Tokyo International airport using four intersecting runways revealed that the capacity could be increased by up to 12 percent by reducing separations without additional risk of wake vortex encounter. This result demonstrates the benefit to airport capacity of reducing wake vortex separations dynamically.

"WAKE VORTEX MEASUREMENT USING PULSED DOPPLER LIDAR"

19th Coherent Laser Radar Conference (CLRC), Paper Th6, June 2018, Okinawa, Japan.

The Japan Aerospace Exploration Agency (JAXA) developed the original algorithm to detect wake vortex shed from aircraft using spectral data of pulsed Doppler lidar. The JAXA has been conducting the wake vortex measurement at two major airports in Japan using a pulsed Doppler lidar and demonstrated the capability of extracting wake characteristics including wake position and circulation strength from lidar spectral data. The acquired wake characteristics will be used to support safe and efficient aircraft operations.

"A NOTE ON SOME MEASUREMENTS MADE IN VORTEX WAKES BEHIND A DC-8"

National Research Council (Canada), Division of Mechanical Engineering and National Aeronautical Establishment, Quarterly Bulletin, No. 2, 1967, pp. 45-54

A discussion of measurements of maximum circumferential velocities obtained by the NAE T-33 when flying 3500 and 1000 feet directly behind a DC-8, seeking the wing tip vortices. It is found that the measured maximum velocities of these vortices are substantially higher than those predicted by accepted theory. No reduction in vortex strength due to dissipative effects was observed.

"WAKE INTEGRATION TO PREDICT WING SPAN LOADING FROM A NUMERICAL SIMULATION"

J. Aircraft, Vol. 32, No. 5, Sept.-Oct. 1995, pp. 1165-1167

A new method of computing the spanwise lift distribution and induced drag from a CFD solution was developed. An equivalent lifting line model is created by integrating the circulation in the wake and it is used for loads computation. The method was applied to a simple, rectangular wing configuration, and the difference in lift and induced drag coefficients between computation and experiment was less than

3 and 5%, respectively. Results indicate that this method offers a simple alternative to computing lift and induced drag by pressure integration.

"NAVIER-STOKES ANALYSIS OF THE FLOW ABOUT A FLAP EDGE"

J. Aircraft, Vol. 35, No. 6, November-December 1998, pp. 833-838

The current study computationally examines one of the principal three-dimensional features of the flow over a high-lift system, the flow associated with a flap edge. Structured, overset grids were used in conjunction with an incompressible Navier-Stokes solver to compute the flow over a two-element high-lift configuration. The computations were run in a fully turbulent mode using the one-equation Baldwin-Barth model. Specific emphasis was given to the details of the flow in the vicinity of the flap edge, and so the geometry was simplified to isolate this region. The geometry consisted of an unswept wing, which spanned a wind-tunnel test section, equipped with a single-element flap. Two flap configurations were computed: a full-span and a half-span Fowler flap. The chord-based Reynolds number was $3.7 \times 1,000,000$ for all cases. The results for the full-span flap agreed with two-dimensional experimental results and verified the method. Grid topologies and related issues for the half-span flap geometry are discussed. Results of the half-span flap case are compared with three-dimensional experimental results, with emphasis on the flow features associated with the flap edge. The results show the effect of the vortex created by the flap edge, including the impact on flow separation and spanwise lift distribution.

"ROTOR WAKE/FIXED WING INTERACTIONS WITH FLAP DEFLECTION"

55th Annual Forum of the American Helicopter Society, May 1999, Montreal, Canada.

The basic features in the interaction of a rotor wake with a wing in low-speed forward flight are studied using low-speed wing tunnel experiments. The configuration captures several of the aerodynamic interactions in the tiltrotor transition phase, and during wake/empennage interactions. Previous work showed that the pressure field on the wing surface below the rotor is dominated by n-per-rev 'blade passage', while the velocity field is dominated by once-per-rev repetition of the vortex geometry, due to vortex interactions. The effect of deflecting trailing edge flaps is studied here. Large area Spatial Correlation Velocimetry is used to enable velocity field acquisition at various sections and test conditions. Flap deflection modifies the spanwise flow on the wing surface, and causes an apparent lateral shift in the wake interaction. This shift influences the effectiveness of inboard vs. outboard flaps, and opens possibilities for augmenting rolling moments. The paper describes both a unique capability for scanning several cross-sections of a periodic velocity field during such interaction

conditions, and the correlation of data from velocity, pressure, and force measurements to synthesize the nature of the complex flowfield with its multiple periodicities.

Matsumoto, Y., Ueno, K. and Saito, T.

"A MOMENT MODEL WITH VARIABLE LENGTH SCALE FOR THE MOTION OF A VORTEX PAIR IN TWO-DIMENSIONAL INCOMPRESSIBLE FLOWS"

Physics of Fluids, Vol. 21, 2009, pp. 047103-1 to 047301-11.

A simple model for the motion of a vortex pair in two-dimensional inviscid flows is presented. In this model the motion of the vortex pair is expressed by a set of ordinary differential equations for the dipole moment, the length scale, and the centroid position. The length scale is the distance between the positive vortex and the negative vortex in the pair. A self-propelling velocity of the model vortex pair is introduced in response to a wide range of the length scale. If a background flow is a linear function of the position, the dipole moment and the length scale of the model are exact. This model works well for a separated vortex pair, although it is not applicable to an asymmetrically deformed vortex pair.

"NUMERICAL ASSESSMENT FOR PIV PRESSURE MEASUREMENTS IN AIRPLANE WAKES"

AIAA Paper 2016-3270, June 2016, Washington, DC.

A pressure estimation system which uses a new model of a Poisson equation and isentropic boundary conditions has been examined. The primary objective of the system is to let stereo PIV measurement more advantageous for a wake survey in aerodynamic design of aircraft. In the wake plane, aerodynamic quantities such as velocity, pressure are no longer two dimensional, then common methods of in-plane two-dimensional (2D) PIV pressure calculation do not work. That is why the new model called two and a half dimensional (2.5D) one has been developed for the system. In this article, the accuracy of estimated pressure by the system is examined for both subsonic and transonic flows. Then, in the view point of its ability for practical application, the effect of measurement velocity fluctuation is simulated on pressure estimation. All the examinations are done by computer simulation, where, instead of PIV measurement velocity data, those of CFD simulation results are used. The results show that the 2.5D model and isentropic boundary conditions work well for both subsonic (incompressible) flows and transonic (compressible) ones. It is also shown the proposed system has good ability to estimate pressure distribution on the PIV measurement plane with less than one percent error if the velocity data have five percent fluctuation.

Matsushima, K., Namba, R. and Kato, H.

"PRESSURE ANALYSIS BASED ON PIV MEASUREMENT IN AIRPLANE WAKES"

ICAS-2016-0594, September 2016, Daejeon, Korea.

A pressure estimation system which uses the two and a half dimensional (2.5D) form of a Poisson equation and isentropic boundary conditions has been applied to a variety of flows. The primary objective of the system is to let stereo PIV measurement more advantageous for a wake survey in aerodynamic design of aircraft and other transport. In wakes, velocity and pressure distributions are no longer two dimensional, then common methods of in-plane two-dimensional (2D) PIV pressure calculation do not work. The accuracy of estimated pressure by the system is investigated for both subsonic and transonic flows around a wing. The results show that the 2.5D model and isentropic boundary conditions work well for both subsonic (incompressible) flows and transonic (compressible) ones. Then, the system is applied to PIV measurement for the wake of a practical automobile. It works well, too, and indicates great promise as a non-intrusive pressure measurement method.

"NUMERICAL COMPUTATIONS OF WAKE VORTICES BEHIND LIFTING SURFACES"

International Council of the Aeronautical Sciences Paper 74-28, Haifa, Israel, 1974

A numerical method is developed for the calculation of the wake vortices behind lifting wings. According to modern three-dimensional methods, discrete vortices are distributed on the camber surface of the wing and upon the wake. The rolled-up vortex sheet is obtained by a convergent interactive procedure. Different numerical schemes investigated are compared for obtaining smooth solutions and minimizing computer time.

Matthews, M. P. and Denneno, A. P.

"INTEGRATION OF MULTIPLE METEOROLOGICAL SENSOR OBSERVATIONS FOR WAKE VORTEX BEHAVIOR COMPARISON"

Proceedings of the 8th Conference on Aviation, Range, and Aerospace Meteorology, Dallas, TX, January 1999

The hazard that wake turbulence presents to following aircraft while operating in the terminal area requires the use of minimum separations between aircraft on final approach. In Instrumented Flight Rules conditions this can be a significant constraint on the airport arrival rate. The National Aeronautics and Space Administration (NASA) Langley Research Center has been researching the development of the Aircraft Vortex Spacing System (AVOSS), which would dynamically change aircraft arrival separations based upon atmospheric conditions and an understanding of vortex behavior (Hinton, 1995). As part of this effort, a collection of meteorological sensor systems have been deployed by Lincoln Laboratory and NASA Langley at the Dallas/Fort Worth International Airport (Matthews, et al., 1997). These sensors, along with many existing FAA and NWS systems, are used to create profiles of the atmosphere at the DFW airport. The suite of sensors available for wake vortex comparison include a Radian LAP-3000 profiler, two Remtech PA-2 sodars, a 150-foot instrumented tower, two nearby Terminal Doppler Weather Radars, and the NWS sounding at Fort Worth. The greatest challenge in the

collection of all this meteorological information is preparing a single atmospheric profile for the wake vortex behavior models. In post-processing, a human can interpret all of the data and create a profile based upon known sensor limitations and analysis of the data. However, a future AVOSS system will require real-time atmospheric profiles representing the state of the atmosphere to apply the wake vortex behavior models. To do this, an automated algorithm is required to perform the data quality editing and data fusion of sensor data. This paper is an overview of the sensor systems available to the wake vortex behavior algorithms and the AVOSS Winds Analysis System that performs the automated data editing and fusion of the atmospheric winds at the Dallas/Fort Worth Airport.

"PLANETARY BOUNDARY LAYER MEASUREMENTS FOR THE UNDERSTANDING OF AIRCRAFT WAKE VORTEX BEHAVIOR"

Proc. Seventh Conf. on Aviation, Range and Aerospace Meteorology, American Meteorological Society, Boston, MA, February 1997, pp. 175-180

This paper described a comprehensive method of collecting meteorological and wake vortex data in an operational airport environment. A method for analyzing the meteorological data for creation of atmospheric profiles was discussed. An example of the meteorological and wake vortex data was shown. Results for this case show that the lateral motion of the wake vortices is closely linked to the crosswind component from the atmospheric winds. Also, the data shown supports the theory that the descent rate and decay rate of the vortex can be influenced by the atmospheric stability. Future work will include more detailed analysis, as well as moving the instrumentation suite from Memphis to the Dallas/Ft. Worth International Airport in the winter of 1997.

Mauel, S.

"FRANKFURT AIRPORT CAPACITY ENHANCEMENT PROGRAM: THE ROLE OF WAKE VORTEX REDUCING MEASURES"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

In 2003, Frankfurt Airport registered 458,865 movements, dealing with over 48 million passengers and 1.5 million tons of cargo. The airport will reach its capacity limit in 2006. Work is underway for the construction of a fourth runway (for landings only) and a third terminal by 2013. Key to the development and implementation of capacity enhancement systems is the handling of wake vortex separations. Three potential solutions are being addressed. First, measures to predict the occurrence of wake vortices (Wake Vortex Warning System with its Wind Temperature Radar). Second, measures to avoid wake vortex encounters (High Approach Landing System with Dual Threshold Operation). Third, measures to reduce the minimum radar separation between two medium aircraft (Precision Approach Monitoring). To date, the High Approach Landing System (HALS) has been tested successfully; the ongoing development of the Dual Threshold Operation is to overcome the procedural

deficits of HALS. The technology to reduce the minimum radar separation has been tested successfully, but the decision to install an operational system and procedures has not yet been taken.

Maurice, M. S.

"LASER VELOCIMETRY SEED PARTICLES WITHIN COMPRESSIBLE, VORTICAL FLOWS"

AIAA Journal, Vol. 30, No. 2, February 1992, pp. 376-383.

The ability of seed particles to penetrate and accurately track vortices is of critical importance to the analysis of laser velocimetry (LV) measurements within these flow structures. In applying a particle equation of motion to vortical flowfields which extend into the supersonic, compressible regime, two approaches are considered. First, an ideal, potential vortex is developed for a compressible flowfield. As an aid to the design and analysis of vortical flowfield surveys over a wide range of independent parameters, this model is used to plot the time and position at which any particle starting at rest within a vortex will begin to track the flow velocity within 3% error. As a specific application, the potential vortex is then used to estimate the dynamic bias of LV measurements taken within a vortex shed from a 75-deg delta wing at 20 deg angle of attack in a Mach 1.9 supersonic flow. The second approach uses a computationally derived Navier-Stokes flowfield solution in place of the potential vortex model. The computational flowfield method predicts that accurate LV measurements within the delta wing flowfield require seed particles no larger than 0.1-0.2 microns in diameter, and defines the unseeded inner vortex core region. Both approaches show an increase in velocity bias which is nearly proportional to particle diameter, stressing the need for a monodisperse seed of known size to resolve particle bias in complex flows.

Maxworthy, T.

"TURBULENT VORTEX RINGS"

Journal of Fluid Mechanics, Vol. 64, part 2, 1974, pp. 227-239.

We consider the motion of the mass of fluid ejected through a sharp-edged orifice by the motion of a piston. The vorticity formed by viscous forces within the separated flow at the sharp edge rolls up to form a concentrated vortex which, after a development period, consists of a core of very fine scale turbulence surrounded by a co-moving bubble of much larger scale turbulence. This bubble entrains outer fluid, mixes with it, and deposits the majority into a wake together with some small fraction of the total vorticity of the ring. Enough fluid is retained to account for the slow growth of the whole fluid mass. A theory which takes account of both the growth process and the loss of vorticity is proposed. By comparison with experimental measurements we have determined that the entrainment coefficient for turbulent vortex rings has a value equal to 0.011 ± 0.001 , while their effective drag coefficient is 0.09 ± 0.01 . These results seem to be independent of Reynolds number to within experimental accuracy.

Maxworthy, T.

"SOME EXPERIMENTAL STUDIES OF VORTEX RINGS"

Journal of Fluid Mechanics, Vol. 81, part 3, 1977, pp. 465-495.

A series of experiments designed to reveal the properties of high Reynolds number vortex rings, using flow-visualization and laser-Doppler techniques, has uncovered several interesting and unexpected results. Starting at the beginning of the motion, at a nozzle, and proceeding downstream, these include the following. (i) A formation process that is strongly Reynolds number dependent. (ii) The amount of vorticity that appears downstream is very close to that predicted by a simple 'slug' model. However, flow-visualization studies show that such a model is an oversimplification and that an excess of ring vorticity is probably cancelled by the ingestion of vorticity of opposite sign at the nozzle lip. (iii) A new, bimodal form of vortex-core instability has been observed at moderate but not high Reynolds numbers. (iv) Azimuthal inhomogeneities in the breaking of these, and the normal instability waves, create an 'axial' flow along the vortex core in the turbulent ring. This axial flow takes the form of a propagating wave that has many characteristics of a solitary wave. It is hypothesized that this axial flow prevents further ring instability. (v) The long-term behavior of the turbulent ring is marked by dramatic changes in its growth rate, which are probably related to changes in the 'organization' of the vortex core. The descriptive turbulent-ring model developed in Maxworthy (1974) is substantially confirmed by these experiments and by observation of ring propagation through a stratified fluid.

Maxworthy, T.

"THE STRUCTURE AND STABILITY OF VORTEX RINGS"

J. Fluid Mech., Vol. 51, Part 1, 1972, pp. 15-32

A series of observations on experimentally produced vortex rings is described. The flow field, ring velocity and growth rate were observed using dye and hydrogen-bubble techniques. It was found that stable rings are formed and grow in such a way that most of their vorticity is distributed throughout a fluid volume which is larger than and moving with the visible dye core. As the vorticity diffuses out of this moving body of fluid into the outer irrotational fluid, it has two effects. It causes some of the fluid, with newly acquired vorticity, to be entrained into the interior of the bubble, while the rest is left behind and accounts for the appearance of ring vorticity in a wake. It was found that the velocity of translation U of these stable rings varies as t^{-1} , at high Reynolds number, where t is the time measured from the start of the motion at a virtual origin at downstream infinity. A simple theoretical model is presented which explains all these features of the observed stable flow. Rings of even higher Reynolds number become unstable and shed significantly more vorticity into the wake. Under some circumstances a new more stable vortex emerges from this shedding process and continues with less vorticity than before. Eventually, the ring motion ceases as all of its vorticity is deposited into the wake and is spread by viscous diffusion. Observations of the interaction between two nearly identical rings travelling a common path showed that, contrary to popular belief, rings do not pass back and forth through one another, but that the rearward one becomes entrained into the forward one. Only when

the rearward ring has a much higher velocity than its partner can it emerge from the joining process and leave a slower-moving ring behind.

Maxworthy, T.

"THE MOTION OF AIRCRAFT TRAILING VORTICES"

J. Applied Mechanics, Vol. 42, No. 2, June 1975, pp. 279-282

Knowledge of the motion of turbulent vortex rings is used to speculate upon the dynamical characteristics of the trailing vortex pair which forms the wake of a lifting surface. An interpretation is presented of common observations which suggests that the gross features of the two systems are similar, at least before the aircraft wake distorts due, among other things, to a self-induced instability. The theory presented by Maxworthy (1974) is extended to the two-dimensional case and predictions of the shape of aircraft trails are displayed in nondimensional form. As a special case a preliminary prediction is given for the wake shape of a 747, in cruise condition, for a set of parameters that are only approximately correct. Only comparison with actual observations can further refine these guesses.

Maxworthy, T.

"WAVES ON VORTEX CORES"

Fluids Dynamics Research, Vol. 3, Issues 1-4, Sept.1988, pp. 52-62

Here we discuss the types of waves which can be supported on compact regions of vorticity. This is a subject first studied by Lord Kelvin for waves propagating along the vortex lines of the Rankine and hollow-core vorticity distributions. Kelvin's major interest was in the stability of vortex rings and the numerous resurgences in interest have usually been driven by practically important phenomena, e.g., the observations of vortex breakdown and waves on tornado and aircraft vortices in the early 1960's and more recently in technologically and geophysically significant flows and on the quantized vortices of super fluid Helium. The major wave-types of interest are of varicose, helicoidal and fluted form and represent a periodic swelling and contraction, a bending and a 'krinkling' of the core, respectively. The first two propagate along and the third around the vortex lines. All have been studied theoretically, experimentally, and numerically in the limit of small wave amplitude and their major characteristics are now clear. Of particular interest is the extension of these results to the non-linear regime in which case the two first types are known to exhibit solitary wave or dominate observations of vortex flows both in nature and in technological applications and which have caused much controversy in the interpretation of results found under complex circumstances of flow and apparatus geometry.

May, D. H. and Vatsistas, G. H.

"TIP VORTEX DEPENDENCE WITH ANGLE OF ATTACK"

Journal of Aircraft, Vol. 43, No. 5, September-October, 2006, pp. 1582-1585

An analysis that explains the dependence of the tip vortex characteristics and their variation with angle of attack and downstream distance, under certain conditions, has been detailed. First, the low wing loading analysis of Moore and Saffman is used as the asymptotic far-field regime. Dimensional analysis presents reasoning for a hypothetical near field. A balance of these two scaling laws is made and is shown to apply in an intermediate-field regime. In the intermediate field, various vortex characteristics are shown to vary as a logarithmic variation with angle of attack. The expressions obtained are shown to hold for some peak tangential velocity data. An expression coupling the circulation and the core radius is obtained. This is used to obtain an expression for the axial vorticity; under the assumption of constant total pressure losses over a range of angle of attack, the expression obtained is shown to agree with some experimental data.

May, N.

"RUNWAY CAPACITY CONSTRAINTS AT HEATHROW AIRPORT"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

The capacity of Heathrow Airport is constrained by the capacity of the two runways. In recent years, many steps have been taken to increase runway capacity but these have been able to produce only small, incremental increases rather than the large, step change increases demanded by the aviation industry. One of the major constraints on runway capacity is the separation required between successive arrivals or between successive departures. These separations are governed in part by the wake vortex separations necessary to ensure the safety of arriving and departing aircraft. The presentation described the process used by NATS to declare runway capacity at Heathrow and identified the factors that constrain increases to that capacity. Particular focus was placed on one of these factors, namely the wake vortex separations between aircraft. Examples were provided that illustrate the potential capacity gains that could be achieved from safely reducing the required separations between aircraft. There was also a discussion around the operational tactics employed by controllers at Heathrow to minimize the effects of wake vortex separations on runway capacity.

Maybey, D. G.

"REVIEW OF AIRCRAFT DYNAMIC LOADS DUE TO FLOW SEPARATION"

Proceedings of Fluid Dynamic Panel Symposium, Vortex Flow Aerodynamics, AGARD, CP-494, Scheveningen, The Netherlands, October 1990, pp. 12-1 to 12-10

This paper presents a detailed review of the 70th meeting of the AGARD Structures and Materials Panel, prepared for the AGARD Fluid Dynamics Panel. Accordingly, emphasis is placed on the Aerodynamic information presented, rather than on the Structural Aspects. Experimental results and computations are described for flows with bubble and vortex separations. Some conclusions are drawn and recommendations are made for further research. In particular, the review suggests that much

greater attention should be given to establishing the magnitude of possible scale effects (both in experiments and calculations) and to the prediction of fin buffeting.

Mayer, E. W. and Powell, K. G.

"SIMILARITY SOLUTIONS FOR VISCOUS VORTEX CORES"

Journal of Fluid Mechanics, Vol. 238, 1992, pp. 487-507.

Results are presented for a class of self-similar solutions of the steady, axisymmetric Navier-Stokes equations, representing the flows in slender (quasi-cylindrical) vortices. Effects of vortex strength, axial gradients and compressibility are studied. The presence of viscosity is shown to couple the parameters describing the core growth rate and the external flow field, and numerical solutions show that the presence of an axial pressure gradient has a strong effect on the axial flow in the core. For the viscous compressible vortex, near-zero densities and pressures and low temperatures are seen on the vortex axis as the strength of the vortex increases. Compressibility is also shown to have a significant influence upon the distribution of vorticity in the vortex core.

Mayer, E. W. and Powell, K. G.

"VISCOUS AND INVISCID INSTABILITIES OF A TRAILING VORTEX"

J. Fluid Mech., Vol. 245, December 1992, pp. 91-114

A spectral collection and matrix eigenvalue method is used to study the linear stability of the trailing line vortex model of Batchelor. For both the inviscid and viscous stability problem, the entire unstable region in the swirl/axial wavenumber parameter space is mapped out for various azimuthal wavenumbers m . In the inviscid case, the non-axisymmetric perturbation with azimuthal wavenumber $m=1$ has an unstable region of larger extent than any other, with an unusual two-lobed structure; also, the location and numerical value of the maximum disturbance growth rate previously reported for this case are shown to be incorrect.

Mayer, R. H.

"ANALYSIS OF POTENTIAL BENEFITS OF WIND DEPENDENT PARALLEL ARRIVAL OPERATIONS"

24th Digital Avionics Systems Conference, Vol. 1, Nov. 2005, pp. 2.B.6-1-2.B.6-12

This paper documents the results of fast-time simulations evaluating potential capacity benefits of procedure concepts developed for parallel approaches to Closely Spaced Parallel Runways (CSPR) at airports with runway spacing less than 2,500 feet. Currently, simultaneous arrival operations at CSPR airports rely on visual meteorological conditions (VMC). In inclement weather when visual procedures can no longer be applied, simultaneous arrivals must be discontinued. Application of standard aircraft separations based on Instrument Flight Rules (IFR) effectively results in the loss of arrival operations on one of the two runways, significantly reducing the arrival capacity of CSPR airports. Proposed wind-

dependent parallel approach concepts promise improvements in arrival capacity at CSPR airports by enabling continued operations of dual arrival streams in instrument meteorological conditions (IMC). The concepts permit dependent parallel arrival operations when meteorological conditions are determined to render approach paths free of wake vortices from preceding aircraft. The operations are expected to increase capacity during IMC and decrease weather-related delays at CSPR airports. Simulation results for 9 CSPR airports in the National Airspace System (NAS) suggest significant potential capacity benefits ranging from 2 to 18 additional arrival operations per hour depending upon the concept and airport. The paper outlines the proposed wake independent straight-in parallel approach concept and 12 procedural derivatives. It describes the model developed to visualize the operations and the Monte Carlo approach taken to quantify potential capacity benefits.

"THE ESTIMATION OF IMPACT AIRCRAFT WAKE VORTICES ON FLIGHT AND WAYS TO IMPROVE THEIR FORECAST"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000.

Aircraft wake vortices are one of the new and little well-known phenomena in the atmosphere. Our research includes the results of numerical, laboratory and natural experiments and allows us to define 8 similar types of fog and cloudy formations which are connected with this effect. Some of them as condensation tracks behind planes, cloudy tracks behind helicopters and cloudy bands behind marine courts have many common features. In poster describes the favorable aero meteorological conditions of appearance of aircraft wake vortices and the opportunities of their impact on aircraft flights. The natural experiments show the intensive circulation in closed contour at the track behind the transport mean. Because the helicopters fulfill the flights on small and extremely small heights, the appearance of cloudy tracks are decreasing the visibility. It's very dangerous to flight safety. Instead of this we can see cloudy bands also behind the marine courts. Its effects were found by meteorological artificial satellites of the Earth. The natural experiments on the Black and Baltic Sea help us to understand some causes of the track's appearance. We also spent the laboratory experiment in aerodynamical tube and numerical modelling of describing the effect. The second dangerous phenomenon which is connected with aircraft vortices is the strong turbulence. Especially its impact on flights of aircraft at marine courts. The big attention relates methods of forecasting the cloudy tracks. The important place has the classification of tracks and the comparison of impact high described phenomena on aircraft flights.

"INTERCOMPARISON OF INSTRUMENTS FOR MEASUREMENTS OF THE ATMOSPHERIC TURBULENCE CHARACTERISTICS"

Russian Meteorology and Hydrology, Vol. 33, No. 11, 2008, pp. 743-747.

In this paper, intercomparison testing of the Wind Master sonic anemometer manufactured by Gill Instruments Ltd. (U.K.) and two sonic anemometers manufactured by the Taifun Scientific Industrial

Association (Obninsk, Russia), ATsAT-3M are described. Data of measurements of the standard deviations and spectrum characteristics of the vertical and horizontal wind speed components, heat and friction fluxes are presented. Dispersion of the measurements and degree of their coherence are characterized by the regression equation coefficients (a and b) and the cross-correlation coefficients. The coherence plot shows compliance of the measurements data throughout the entire frequency range.

"AN EXPERIMENTAL AND NUMERICAL STUDY OF 3-D ROTOR WAKES IN HOVERING FLIGHT"

ICAS 1982, August 1982, Seattle, WA.

Results of comparison between experimental and numerical studies on the 3-D wake of a hovering rotor are presented. The wind-tunnel investigation is conducted by means of X-hot wires and laser Doppler anemometry procedures to measure the 3-D velocity field under the rotor and to determine the tip vortex paths for several rotor configurations. Additional flow visualization and rotor air load coefficients are also carried out. The prediction model is based on the classical vortex theory with an empirically prescribed geometry of the wake. From the blade circulation distribution, the rotor wake is represented by vortex lines which are allowed to freely adapt until a converged wake geometry is obtained. Then a new estimate of the blade circulation repartition can be deduced. The procedure is repeated, iterating until the compatibility between the adapted wake geometry and the blade circulation repartition is obtained. The validity range of the circulation model is deduced from comparison with experimental data obtained on instantaneous velocities and tip vortex paths, for different rotor parameters including solidity, number of blades, pitch angle, blade twist, and tip shape.

"MEASUREMENTS IN THE NEAR WAKE OF A HOVERING ROTOR"

AIAA Paper No. 1996-1958, New Orleans, LA, June 1996

Primarily an experimental effort, this study focuses on the velocity and vorticity fields in the near wake of a hovering rotor. Drag terminology is reviewed, and the theory for separately determining the profile- and induced-drag components from wake quantities is introduced. Instantaneous visualizations of the flow field are used to center the laser velocimeter measurements on the vortex core and to assess the extent of the positional meandering of the trailing vortex. Velocity profiles obtained at different rotor speeds and distances behind the rotor blade clearly indicate the position, size, and rate of movement of the wake sheet and the core of the trailing vortex. The results also show the distribution of vorticity along the wake sheet and within the trailing vortex.

McAlister, K. W.

"ROTOR WAKE DEVELOPMENT DURING THE FIRST REVOLUTION"

American Helicopter Society 59th Annual Forum, May 2003, Phoenix, AZ.

The wake behind a two-bladed model rotor in light climb was measured using particle image velocimetry, with particular emphasis on the development of the trailing vortex during the first revolution of the rotor. The distribution of vorticity was distinguished from the slightly elliptical swirl pattern. Peculiar dynamics within the 'void' region may explain why the peak vorticity appeared to shift away from the center as the vortex aged, suggesting the onset of instability. The swirl and axial velocities (which reached 44 and 12 percent of the rotor-tip speed, respectively) were found to be asymmetric relative to the vortex center. In particular, the axial flow was composed of two concentrated zones moving in opposite directions. The radial distribution of the circulation rapidly increased in magnitude until reaching a point just beyond the core radius, after which the rate of growth decreased significantly. The core-radius circulation increased slightly with wake age, but the large-radius circulation appeared to remain relatively constant. The radial distributions of swirl velocity and vorticity exhibit self-similar behaviors, especially within the core. The diameter of the vortex core was initially about 10 percent of the rotor-blade chord, but more than doubled its size after one revolution of the rotor. According to vortex models that approximate the measured data, the core-radius circulation was about 79 percent of the large-radius circulation, and the large-radius circulation was about 67 percent of the maximum bound circulation on the rotor blade. On average, about 53 percent of the maximum bound circulation resides within the vortex core during the first revolution of the rotor.

McAlister, K. W.

"ROTOR WAKE DEVELOPMENT DURING THE FIRST REVOLUTION"

J. American Helicopter Soc., Vol. 49, Oct. 2004, pp. 371-390

The wake behind a two-bladed model rotor in a shallow climb was measured using particle image velocimetry. The distribution of vorticity was distinguished from the slightly elliptical swirl pattern. Peculiar dynamics within the 'void' region were found to accompany a shift in the peak vorticity away from the center as the vortex aged. The swirl and axial velocities (that reached 44 and 12 percent of

the rotor-tip speed, respectively) were found to be asymmetric relative to the vortex center. In particular, the axial flow was composed of two concentrated zones moving in opposite directions. The radial distributions of swirl velocity and vorticity exhibit self-similar behaviors, especially within the core. The diameter of the vortex core was initially about 10 percent of the rotor-blade chord, but more than doubled its size after one revolution of the rotor. According to vortex models that approximate the measured data, the core-radius circulation was about 79 percent of the large-radius circulation, and the large-radius circulation was about 67 percent of the maximum bound circulation on the rotor blade. On average, about 53 percent of the maximum bound circulation resides within the vortex core during the first revolution of the rotor.

"NACA 0015 WING PRESSURE AND TRAILING VORTEX MEASUREMENTS"

NASA TP-3151, November 1991, NASA Ames Research Center, Moffett Field, CA

A NACA 0015 semispan wing was placed in a low-speed wind tunnel, and measurements were made of the pressure on the upper and lower surface of the wing and of the velocity across the vortex trailing downstream from the tip of the wing. A two-component laser velocimeter was used to measure

velocity profiles across the vortex at numerous stations behind the wing and for various combinations of conditions. These conditions include three aspect ratios, three chord lengths, a square- and a round-lateral tip, presence or absence of a boundary-layer trip, and three image plane positions located opposite the wing tip. The addition of a round-lateral edge to the wing tip was found to eliminate the secondary vortex near the wing tip, but had little effect on the downstream characteristics of the trailing vortex.

McAlister, K. W., Huang, S. S. and Abrego, A. I.

"A MODEL ROTOR IN AXIAL FLIGHT"

NASA/TM-2001-210925, AFDD/TR-01-A-004, July 2002, Army/NASA Rotorcraft Division, Moffett Field, CA

A model rotor was mounted horizontally in the settling chamber of a wind tunnel to obtain performance and wake structure data under low climb conditions. The immediate wake of the rotor was carefully surveyed using 3-component particle image velocimetry to define the velocity and vortical content of the flow, and the data used in a subsequent study to validate a theory for the separate determination of induced and profile drag. Measurements were obtained for two collective pitch angles intended to render a predominately induced drag state and another with a marked increase in profile drag. A majority of the azimuthally directed vorticity in the wake was found to be concentrated in the tip vortices. However, adjacent layers of inboard vorticity with opposite sense were clearly present. At low collective, the proximity of the tip vortex from the previous blade caused the wake from the most recent blade passage to be distorted. The deficit velocity component that was directed along the azimuth of the rotor blade was never more than 15% of the rotor tip speed, and except for the region of the tip vortex, appeared to have totally disappeared from the wake left by the previous blade.

McAlister, K. W., Tung, C. and Heineck, J. T.

"DEVICES THAT ALTER THE TIP VORTEX OF A ROTOR"

NASA/TM-2001-209625, AFDD/TR-01-A-003, February 2001, Aeroflightdynamics Directorate, US Army Aviation and Missile Command, Ames Research Center, Moffett Field, CA

Small devices were attached near the tip of a hovering rotor blade to alter the structure and trajectory of the trailing vortex. Stereo particle image velocimetry (PIV) images were used to quantify the wake behind the rotor blade during the first revolution. A procedure for analyzing the 3D-velocity field is presented that includes a method for accounting for vortex wander. The results show that a vortex generator can alter the trajectory of the trailing vortex and that a major change in the size and intensity of the trailing vortex can be achieved by introducing a high level of turbulence into the core of the vortex.

McAlister, K. W., Tung, C. and Heineck, J. T.

"ALTERING THE TIP VORTEX OF A ROTOR"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Small devices were placed near the tip of a hovering rotor blade to alter the structure of the trailing vortex. This was achieved through the generation of either a secondary vortex (positive or negative sense) or massive turbulence. The impact of these devices on the primary trailing vortex during the first revolution was quantified using detailed three-component presentations of the rotor wake obtained with a stereo particle image velocimeter. Even without a device attached to the rotor, the trailing vortex wandered from revolution to revolution by an amount that increased with wake age. In addition, the point of maximum vorticity did not always coincide with the apparent center of the vortex. These issues were addressed by conditionally averaging the images according to a realignment of the velocity measurements based on the position of the vortex and by defining the center of the vortex to be the center of swirl. The variation in circumferential velocity along a radius anchored to the center of swirl was used to identify the peak vortex velocity, which in turn defined the size of the vortex core.

"PRELIMINARY STUDY OF A MODEL ROTOR IN DESCENT"

NASA/TM-2000-208785, AFDD/TR-99-A-001, November 2000, Aeroflightdynamics Directorate, US Army Aviation Research and Technology Activity, Ames Research Center, Moffett Field, CA

Within a program designed to develop experimental techniques for measuring the trajectory and structure of vortices trailing from the tips of rotor blades, the present preliminary study focuses on a method for quantifying the trajectory of the trailing vortex during descent flight conditions. This study also presents rotor loads and blade surface pressures for a range of tip-path plane angles and Mach numbers. Blade pressures near the leading edge and along the outer radius are compared with data obtained on the same model rotor, but in open jet facilities. A triangular procedure based on two directable laser-light sheets, each containing an embedded reference, proved effective in defining the spatial coordinates of the trailing vortex. When interrogating a cross section of the flow that contains several trailing vortices, the greatest clarity was found to result when the flow is uniformly seeded. Surface pressure responses during blade-vortex interactions appeared equally sensitive near the leading edge and along the outer portion of the blade, but diminished rapidly as the distance along the blade chord increased. The pressure response was virtually independent of whether the tip-path plane angle was obtained through shaft tilt or cyclic pitch. Although the shape and frequency of the pressure perturbations on the advancing blade during blade-vortex interaction are similar to those obtained in open-jet facilities, the angle of the tip-path plane may need to be lower than the range covered in this study.

McAllister, L. G.

"ACOUSTIC SOUNDER"

US Patent 3,675,191, July 1972.

A method of recording upper atmospheric characteristics which comprises transmitting in a generally upward direction recurrent pulses of acoustic energy at a selected frequency band of operation at a repetition interval longer than that required to receive back a reflected signal from a target, receiving the back-scattered energy on a facsimile recorder or other indicating mechanism which records the time and/or intensity and/or duration of the backscattered energy to permit upper atmospheric characteristics to be determined at airports or other localities where such information is of vital importance, the apparatus including a transmitter to radiate the pulses of acoustic energy and to receive the backscattered energy and to record from it the required data.

"COMPUTATIONAL ANALYSIS OF A PASSIVE WAKE ALLEVIATION SCHEME"

AIAA Paper No. 2006-2820, San Francisco, CA, June 2006

The vortex wake generated by a large aircraft induces sizeable vertical forces and rolling moments on trailing aircraft during an encounter. Recent studies of wake alleviation have focused on experimental observations of both active and passive techniques for accelerating the breakdown of the vortical structures in these wakes through vortex instabilities. A subset of these studies have concentrated on the addition of outboard triangular flaps for passively inciting Crow-like instabilities in the trailing vortices. Accompanying computational studies have been limited to qualitative analyses of the general wake features and vortex breakdown. To help bridge the quantitative gap between experimental and computational results, a spectral Navier-Stokes simulation was used to analyze the evolution of the vortical structures in the wake to calculate the forces and rolling moments induced on a trailing wing. Significant reductions in both downwash and rolling moment are clearly present in the numerical work; the magnitude and time scale of these reductions correlate well with recent experimental studies.

McConville, R. P.

"DOPPLER ACOUSTIC VORTEX SENSING SYSTEM"

FAA-RD-75-28, October 1978, Avco, Wilmington, MA

This is the final report on the Doppler Acoustic Vortex Sensing System, (DAVSS) program carried out by Avco Corporation's Systems Division for the U.S. Department of Transportation, Transportation Systems Center. The objective of the program was the design of an engineered DAVSS capable of real-time detection, tracking, recording, and graphic display of aircraft trailing vortices. Problems related to such vortices are currently under intensive study by the U.S. Department of Transportation for the Federal Aviation Administration. This report presents hardware and software design aspects of the

system. The design of the acoustic antennas and transducers is described. System control, computer hardware and software, and system/subsystem interfaces are discussed.

McConville, R. P.

"INSTALLATION AND TEST OF DOPPLER ACOUSTIC SENSOR"

FAA-RD-76-223, October 1977, Avco, Wilmington, MA

This report presents details of the installation of a Doppler acoustic vortex sensing system at JFK Runway 31R, the hardware and software improvements made since installation, vortex diagnostic and tracking data and analysis, and conclusions and recommendations.

McConville, R. P. and Pfeiffer, G.

"A DOPPLER ACOUSTIC VORTEX SENSING SYSTEM FOR AUTOMATIC REAL TIME TRACKING OF AIRCRAFT TRAILING VORTICES"

Third Workshop on Atmospheric Acoustic, York University, Toronto, Canada, June 1975

An automatic real time vortex tracking system using Doppler acoustic scattering techniques has recently been built and installed at the J. F. Kennedy International Airport. The system is capable of operating in either the pulsed or cw mode and in the monostatic backscatter or the bistatic forward scatter configuration. Acoustic signals in the band 3-6 KHz are transmitted from fan beam antennas. The vortex scattered signals with their characteristic Doppler spectra are received in any of four receiving antennas each consisting of 12 pencil beams. The scattered signals are Doppler processed to determine the angle and, in the case of pulsed signals, the range of the scattering center. The angle or range-angle estimates are automatically interpreted using the actual geometry of the antenna elements to form vortex altitude-displacement tracks.

McCormick, B. W.

"HYDRODYNAMICS TO OUTBOARD TO ROTORS TO WAKE TURBULENCE TO EXPERT WITNESS: THE EXPERIENCES OF AN AERONAUTICAL ENGINEER OVER 60 YEARS"

AIAA Paper 2013-2402, June 2013, San Diego, CA.

Many think of the aeronautical engineer as someone with narrow interests and expertise. Yet, most programs leading to a BS in Aerospace Engineering require a myriad of classes in diverse areas like solid and fluid mechanics, thermodynamics, mathematics, controls, and structural mechanics. Thus the 'aero' engineer can do more than simply design and analyze aircraft. To illustrate the foregoing, your author would like to take advantage of the opportunity afforded by this lecture. In a sense, this is a brief condensation of his professional career to date and license is taken to use first person in the paper. I hope the paper does not come across as 'blowing my own horn.' I just want to point out some

of the many different and interesting experiences that I have enjoyed during more than 60 years of teaching, industrial and consulting practice.

McCormick, B. W.

"A STUDY OF THE MINIMUM PRESSURE IN A TRAILING VORTEX SYSTEM"

Ph.D. Thesis, June 1954, Penn. State Univ., University Park, PA

Theoretical, experimental, and semi-empirical investigations of the minimum pressure in trailing vortex systems of elliptic, rectangular, and delta wings are presented. The magnitude of the minimum pressure coefficient in the trailing vortex system of a wing increases nearly linearly with the angle of attack of the wings. This magnitude is almost independent of aspect ratio for elliptic wings but for rectangular wings is slightly higher, the greater the aspect ratio, for a given angle of attack. At a given angle of attack the magnitude of the minimum pressure coefficient increases with increasing Reynolds number. The thickness of the tip-vortex core, or the thickness of the edge of the trailing vortex sheet is determined by the thickness of the boundary layer on the lower surface of the wing at the trailing edge of the tip and not by any considerations of induced drag and kinetic energy of the vortex sheet itself.

McCormick, B. W.

"AIRCRAFT WAKES: A SURVEY OF THE PROBLEM"

Symposium on Turbulence, Federal Aviation Administration, Washington, DC, March 1971

A large aircraft generates a vortex system which can present a hazard to lighter aircraft. The rollup, geometry, decay, and instabilities of trailing vortices are discussed. Their effect on other aircraft is considered and it is concluded based on a simplified analysis and accident records that relatively large aircraft can be susceptible to vortices from large jet transports. A brief history of the problem is included as well as an extensive bibliography covering the behavior of vortex systems and aircraft response.

McCormick, B. W.

"AN ASSESSMENT OF THE EFFECT OF A TRAILING VORTEX ON A FOLLOWING AIRCRAFT"

Proceedings of the AFFDL/NASA/FAA Wake Turbulence Work Shop, Air Force Flight Dynamics Laboratory, AFFDL-TM-75-16-FGC, 1974, pp. 65-69

The various factors affecting the static rolling moment on an aircraft encountering wake turbulence are considered. The expressions for the total rolling moment are derived for a logarithmic velocity profile and for a Lamb or Rankine vortex.

McCormick, B. W.

"WAKE TURBULENCE"

Flight in an Adverse Environment, AGARD-LS-197, November 1994, pp. 1-1 - 1-15

Wake turbulence is a misnomer. Turbulence implies a random process whereas the term 'wake turbulence' refers to the hazard posed to smaller airplanes by the ordered, rotational flow in the trailing vortex systems behind larger airplanes. This lecture begins by examining the relationship of aircraft size, geometry, and operating conditions to the strength of an aircraft's trailing vortex system. Next, the velocity field initially induced close behind the generating airplane by its trailing vortex system is defined. This is followed by a discussion of the various ways in which a vortex system can dissipate and the many factors which affect the dissipation. In particular, the effects of atmospheric turbulence, ground proximity and vortex bursting on the ensuing behavior of the vortex system are considered. The paper continues with a study of the dynamics of an aircraft encountering the wake of a larger airplane. The degree to which an aircraft is threatened by a given vortex system of known characteristics is analyzed and the hazard posed by a given vortex system to a following aircraft quantified. Finally, the paper concludes with recommendations on possible ways to alleviate the safety and operational problems associated with wake turbulence.

McCormick, B. W. and Padakannaya, R.

"THE EFFECT OF A DROPPED WING TIP ON ITS TRAILING VORTEX SYSTEM"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 157-169

The effect of wing tip droop on the structure and position of its trailing vortex is studied. Spanwise load distributions determined by vortex lattice theory show that the stronger vortex moves from the tip of the wing to the hinge of the drooped tip as the droop angle increases. Experimental results on model wings are given which present the strength and the induced velocity profiles of the rolled-up vortex as a function of tip geometry. It is concluded that a droop angle approximately 90 degrees is optimum and results in a maximum induced velocity which is half of that produced by a plane wing.

McCormick, B. W. and Schumacher, W. J.

"AN INVESTIGATION OF THE TRAILING VORTEX SYSTEM GENERATED BY A JET FLAPPED WING OPERATED AT HIGH WING LIFT COEFFICIENTS"

AFFDL-TR-70-90, June 1970, Penn. State Univ., University Park, PA

The purpose of the investigation was to measure the geometry of the trailing vortex generated behind a jet flapped wing. Such vortices can pose a serious hazard to aircraft that penetrate them. Previous investigations performed on conventional wings indicate that these vortices persist for some time and have maximum tangential velocities which increase linearly with the lift coefficient. As future aircraft may employ high lift devices such as jet-flapped wings, the vortices generated could be even stronger. Two semispan models of a jet-flapped wing were tested in a subsonic wind tunnel.

Parameters varied during testing included the jet flap angle, angle of attack, aspect ratio and jet momentum coefficient. Vortex measurements were obtained using a vortex meter which measured the rotational speed of the fluid within the vortex. Values obtained were numerically integrated to yield the tangential velocity and circulation distributed through the vortex. Experimental results indicate that the maximum tangential velocity increases to a maximum and then decreases with continually increasing jet blowing. At high values of jet blowing, the vortex was found to decay rapidly downstream.

McCormick, B. W. and Surendraiah, M.

"A STUDY OF ROTOR BLADE-VORTEX INTERACTION"

26th Annual National Forum, American Helicopter Society, Washington, DC, June 1970

An experimental and analytical study of the rotor blade-vortex interaction problem was conducted. Time-dependent surface pressures were measured on a model rotor blade as it passed through a vortex generated by a fixed wing, mounted upstream of the rotor. The pressures were integrated to obtain the time-wise variation of the rotor section lift coefficients. The geometry of the test setup was varied to study the effect of such parameters as the distance of the vortex axis from the rotor plane, the angle at which the rotor blade intersects the vortex, the vortex size and strength, and the rotor rpm. Results of an approximate quasi-steady and unsteady two-dimensional analysis are compared with the measured section lift-coefficients.

McCormick, B. W., Tangler, J. L., and Sherrieb, H. E.

"STRUCTURE OF TRAILING VORTICES"

J. Aircraft, Vol. 5, No. 3, May-June 1968, pp. 260-267

A study of aircraft trailing vortex systems, involving actual flight testing as well as model testing and analytical considerations, has resulted in a method for predicting the vortex geometry and velocity field downstream of an aircraft. It is found that the vortex decay can be described by geometric similarity considerations and not by any modification of the Navier-Stokes equations. This conclusion is based on detailed velocity measurements made through the vortex immediately behind a test aircraft up to distances of approximately 1000 chord lengths downstream of the aircraft. This report includes a presentation of the data on which the conclusions are based, as well as a description of test equipment and procedures.

McCroskey, W. J.

"THE CHARACTERIZATION AND MODIFICATION OF WAKES FROM LIFTING VEHICLES IN FLUIDS"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. T-1 to T-10

The Fluid Dynamics Panel of AGARD arranged a Symposium on 'The Characterization and Modification of Wakes from Lifting Vehicles in Fluids' on 20-23 May 1996 in Trondheim, Norway. The purpose of the Symposium was '... to review and discuss recent developments in wake research for aircraft and the implications for air traffic regulations,' with a clear emphasis on the hazard of vortex encounters in civil aviation. Sessions were devoted specifically to operational procedures and aircraft spacings in airport terminal areas; to the aerodynamic interactions between trailing vortices and following aircraft; to trailing vortex structures, instabilities, atmospheric effects on wakes and vortex breakdown; and to miscellaneous issues, such as vortices generated by other vehicles and the interactions between vortex wakes and engine exhausts.

McCroskey, W. J.

"VORTEX WAKES OF ROTORCRAFT"

AIAA Paper 1995-0530, Reno, NV, Jan. 1995

This paper presents an overview of the complex unsteady vortical flows that comprise the wakes of rotary-wing aircraft; of the effects these tangled vortical structures have on the performance, noise, and vibration; and of some of the recent attempts to measure, predict, and control the phenomena. The main points are illustrated with several examples from the recent literature and technical conferences.

McCroskey, W. J. and Goorjian, P. M.

"INTERACTIONS OF AIRFOILS WITH GUSTS AND CONCENTRATED VORTICES IN UNSTEADY TRANSONIC FLOW"

AIAA Paper No. 1983-1691, Danvers, MA, July 1983

Unsteady interactions of concentrated vortices and distributed free-stream gusts with a stationary airfoil have been analyzed in two-dimensional transonic flow. A simple method of introducing such disturbances has been implemented numerically in the well-known transonic small-disturbance code LTRAN2, and calculations have been performed for two important classes of current aerodynamic problems. The first, which demonstrates many of the essential features of the interactions between helicopter rotor blades and their trailing-vortex wakes, is that of a discrete potential vortex convecting past an airfoil. The second is the response of a transonic airfoil to a transverse periodic gust, with and without the alleviation that can be achieved by the proper active control motion of a trailing-edge flap. In both cases, unsteady effects are found to play important roles in the shock-wave motion, in the overall flow-field development, and consequently, in the air loads on the airfoil.

McCutchen, C. W.

"INDUCED DRAG AND THE IDEAL WAKE OF A LIFTING WING"

J. Aircraft, Vol. 26, No. 5, May 1989, pp. 489-493

The wake of a lifting wing in inviscid flow is a pair of downward-sloping vortices with distributed vorticity in which the vortex lines are approximately helical. Within the vortices, fluid flows aft relative to fluid at infinity, and its Kelvin impulse more than nullifies the forward Kelvin impulse caused by the slope of the vortex pair. The momentum drag is therefore negative. Suction in the vortex cores more than counterbalances the negative momentum drag, and the difference between the two is the induced drag. The negative momentum drag is much smaller in magnitude than the drag due to suction except at high span loading. The induced drag is the integral over any transverse plane behind the wing of the difference between the energies of lateral and longitudinal motion per unit length. The drag contributed by the portion of the wing, or of any distribution of bodies, between any two transverse planes is equal to the growth of the above integral between the forward and after of these planes.

McCutcheon, G., McColgan, A. H., Hurst, D. and Grant, I.

"WAKE STUDIES OF A NACA 0015 WING USING PIV"

2nd World Engineering Congress, Sarawak, Malaysia, July 22-25, 2002

Detailed wake surveys were performed with an untwisted NACA 0015 airfoil section in a low-speed wind tunnel. The tests were conducted at a freestream velocity of 20/ms giving a Reynolds number of 200,000 based on the model wing chord. PIV was used to obtain cross-flow velocities at three downstream wake survey locations. At one wake position the effect of varying the angle of attack was investigated. Using a wake integration technique, lift and induced drag distributions were obtained along the model wing. Total lift and induced drag acting on the wing were then obtained using this flow field data.

McDonald, H., Ross, J., Driver, D. and Smith, S.

"WIND TUNNELS AND FLIGHT"

10th International Symposium on Applications of Laser Techniques in Fluid Mechanics, July 2000, Lisbon, Portugal.

The problem of extrapolating wind-tunnel data to flight conditions has been with us since the early days of aviation. The Wright brothers faced the problem, as has everyone else who used wind-tunnel data as part of their aircraft design process. The techniques used for correcting wind-tunnel data for wall and mounting effects are applied meticulously, but they are usually limited to linear flow approximations. The remaining issues for extrapolation are geometric differences between models and airplanes, non-linear effects of wind-tunnel walls and mounting systems, and the effects of Reynolds number. These effects are poorly understood or difficult to predict and they can result in a new aircraft falling short of its guaranteed performance. The current practice in wind-tunnel data corrections are

summarized and the missing physics identified. Current work on improving our understanding of the pertinent aerodynamics and to improve extrapolation methods are presented along with a discussion of further areas of inquiry.

"A SIMPLE MEANS OF MEASURING VORTEX STRENGTH, AND THE PERFORMANCE OF TRIANGULAR RAMP-TYPE VORTEX GENERATORS IN A UNIFORM VELOCITY FIELD"

Journal of the Royal Aeronautical Society, Vol. 66, December 1962, pp. 783-785.

The performance of triangular ramp vortex generators of a type used for boundary layer separation control, has been compared with that of equivalent wing or vane type of lifting generators, in a uniform velocity field, and was shown to be substantially inferior. Performance was established using a novel vortex strength measuring device of unusual simplicity, for which calibrations are given and applications are discussed.

McGinley, C. B. and Beeler, G. B.

"VORTEX UNWINDING IN A TURBULENT BOUNDARY LAYER"

J. Aircraft, Vol. 24, No. 3, March 1987, pp. 221-222

In this Note, the feasibility of vortex unwinding in a turbulent boundary layer has been demonstrated. While the true optimum unwinding configuration was not reached (i.e., the return to the nominally two-dimensional case), sufficient reduction in the isotach variation was achieved to verify the usefulness of this technique in turbulent boundary-layer vortex control. It is suggested that more detailed measurements of vortex strength and position will improve the optimization process and increase the amount of vortex unwinding. It should be noted that most of the applications suggested in this Note will benefit from vortex reduction as well as from complete vortex unwinding.

McGowan, W. A.

"AVOIDANCE OF AIRCRAFT TRAILING VORTEX HAZARDS"

AGARD, Flight Mechanics Panel, Baden-Baden, Germany, October 1970

Aircraft trailing vortex systems are made up of two counter-rotating cylindrical air masses, about a wing span apart, extending aft along the flight path. Vortex systems of large aircraft contain winds within and about these cylinders which can be hazardous to other aircraft encountering them in flight. Trailing vortices have been the cause of aircraft accidents. The greatest hazard potential exists in areas where aircraft of a wide range of classes are operating (e.g., utility/observation and heavy transport/bomber). Results of accident investigations, theoretical exercises, wind-tunnel experiments, and flight tests are used to describe the formation and severity of trailing vortices and the spatial extent of their influence, including factors governing persistence. This information is then used to

outline procedures for ready application by pilots, tower operators, and those concerned with the flow of traffic during tactical operations. Schemes under investigation to monitor remotely both the trailing vortex location and intensity in the airport area and to prohibit formation of high intensity vortices, through aircraft design, are discussed.

McGowan, W. A.

"NASA AIRCRAFT TRAILING VORTEX RESEARCH"

FAA Symposium on Turbulence, Federal Aviation Administration, Washington, DC, March 1971, p. 25

A brief description is given of NASA's comprehensive program to study the aircraft trailing vortex problem. Wind tunnel experiments are used to develop the detailed processes of wing tip vortex formation and explore different means to either prevent trailing vortices from forming or induce early break-up. Flight tests provide information on trailing vortex system behavior behind large transport aircraft, both near the ground, as in the vicinity of the airport, and at cruise/holding pattern altitudes. Results from some flight tests are used to show how pilots might avoid dangerous areas when flying in the vicinity of large transport aircraft. Other flight tests will be made to verify and evaluate trailing vortex elimination schemes developed in the model tests. Laser Doppler velocimeters being developed for use in the research program and to locate and measure vortex winds in the airport area are discussed. Field tests have shown that the laser Doppler velocimeter measurements compare well with those from cup anemometers.

McGowan, W. A.

"REMOTE DETECTION OF TURBULENCE IN CLEAR AIR"

AIAA/FAA Air Transportation and Society Conference, Key Biscayne, FL, June 1971

Various concepts for remote detection of turbulence in the clear air were reviewed. It was concluded that there is no technique now available for operational use to remotely detect and measure turbulence in the clear air. Several techniques are under both study and development which seem to have good potential for future application; namely, the laser Doppler radar for airborne and ground-based use, and ground-based ultrasensitive microwave Doppler radars. Terminal area turbulence-sensing-techniques, having considerable potential to assist with the aircraft wake problem, include the laser Doppler and acoustic radars. The acoustic radar seems like a simple approach currently. Further work is needed to see if the refinements in the system will result in a sophistication masking the original simplicity.

McGowan, W. A.

"AIRCRAFT WAKE TURBULENCE AVOIDANCE"

J. Aircraft, Vol. 9, No. 3, March 1972, pp. 197-198.

Aircraft trailing vortex systems are made up of two counter-rotating cylindrical air masses, about a wing span apart, extending aft along the flight path. Vortex systems of large aircraft contain winds which can be hazardous to other aircraft encountering them in flight. The greatest hazard potentials exist in areas where aircraft of a wide range of classes are operating (e.g., light utility/observation and heavy transport/bomber). Results of analytical studies and flight tests are used to describe the formation and severity of trailing vortices and the spatial extent of their influence. This information is then used to outline procedures for ready application by pilots, tower operators, and others concerned with the flow of traffic. The procedures provide the necessary appreciation of the physical attributes of trailing vortices, the potential hazards involved when encountering them, and how best to avoid the dangerous portions of the wake during flight operations.

McGowan, W. A.

"CALCULATED NORMAL LOAD FACTORS ON LIGHT AIRPLANES TRAVERSING THE TRAILING VORTICES OF HEAVY TRANSPORT AIRPLANES"

NASA TN D-829, May 1961, NASA Langley Research Center, Langley Station, VA

Results are presented of normal-load-factor calculations made for a light normal-category airplane and a light transport-category airplane traversing the trailing vortices generated by each of three heavy transport airplanes. With each light airplane, the normal load factors were determined for several penetration paths lying in a plane perpendicular to the trailing vortices and for three center-of-gravity locations and velocities. Also determined for the light normal-category airplane were the elevator deflection required to maintain 1 g flight and the vertical displacements of the airplane from the prescribed penetration paths while traversing the vortices. The results indicate that light airplanes traversing the wakes of currently operational heavy transport airplanes can experience loading conditions that exceed the design limit and, in some cases, the design ultimate load factors. For light airplanes traversing the wake generated by a proposed supersonic transport airplane the design ultimate load factors can be greatly exceeded. It was also shown that load factors imposed by the vortex system could be alleviated by elevator deflection; however, because of inherent pilot and control-system lag, the load factors would almost certainly be aggravated rather than alleviated.

McGowan, W. A.

"TRAILING VORTEX HAZARD"

SAE Paper No. 680220, Wichita, KS, April 1968

Light aircraft that encounter the trailing vortex system generated by heavy transport aircraft can experience high roll rates, loss of altitude, and large structural loads. Envelopes of vortex system velocities, duration and movement for various wind conditions have been determined. Specific operational procedures for the take-off, landing, and enroute phases of flight are suggested to enable the light aircraft pilot to avoid the wake turbulence of heavy aircraft.

McGowan, W. A.

"AIRCRAFT WAKE TURBULENCE AVOIDANCE"

12th Anglo-American Aeronautical Conference, Paper No. 72/6, Calgary, Canada, July 1971

Results of analytical studies and flight tests are used to describe the formation and severity of trailing vortices and the spatial extent of their influence. This information is then used to outline procedures for ready application by pilots, tower operator, and others concerned with the flow of traffic.

McGowan, W. A. and Charak, T.

"AIRCRAFT WAKE TURBULENCE"

16th Corporate Aircraft Safety Seminar, Flight Safety Foundation, April 1971, pp. 71-87

The physical characteristics of aircraft wake turbulence, or trailing vortices, are described: their formation, persistence, and whereabouts after being spawned by the wing lift. Analytical and flight test data are used to establish the inflight hazards associated with trailing vortex encounters. Techniques are suggested on how pilots can best avoid the damaging manifestations of aircraft wake turbulence for various flight regimes. The comprehensive aircraft wake turbulence research program supported by the NASA is outlined. Flight and model tests, and instrument development for remote wind sensing are used to better understand the aircraft wake turbulence generated by heavy transport aircraft. Concurrently, other studies are hopeful of uncovering ways to either prevent the trailing vortices from forming or induce early dissipation of dangerous winds.

McKenna, C. and Rockwell, D.

"TOPOLOGY OF VORTEX-WING INTERACTION"

Experiments in Fluids, Vol. 57, 2016, pp. 161-1 to 161-15.

A trailing vortex incident upon a wing can generate different modes of vortex-wing interaction. These modes, which may involve either enhancement or suppression of the vortex generated at the tip of the wing, are classified based on the present experiments together with computations at the Air Force Research Laboratory. Occurrence of a given mode of interaction is predominantly determined by the dimensionless location of the incident vortex relative to the tip of the wing and is relatively insensitive to the Reynolds number and dimensionless circulation of the incident vortex. The genesis of the basic interaction modes is clarified using streamline topology with associated critical points that show compatibility between complex streamline patterns in the vicinity of the tip of the wing. Whereas formation of an enhanced tip vortex involves a region of large upwash in conjunction with localized flow separation, complete suppression of the tip vortex is associated with a small-scale separation-reattachment bubble bounded by downwash at the wing tip.

McKenna, C., Fishman, G. and Rockwell, D.

"INTERACTION OF A TRAILING VORTEX WITH AN OSCILLATING WING"

Experiments in Fluids, Vol. 59, 2018, pp. 18-1 to 118-23.

A technique of particle image velocimetry is employed to characterize the flow structure of a trailing vortex incident upon the tip region of an oscillating wing (plate). The amplitude and velocity of the wing are nearly two orders of magnitude smaller than the wing chord and free stream velocity, respectively. Depending upon the outboard displacement of the incident vortex relative to the wing tip, distinctive patterns of upwash, downwash, and shed vorticity are observed. These patterns are a strong function of the phase of the wing motion during its oscillation cycle. At a given phase, the wing oscillation induces upwash that is reinforced by the upwash of the incident vortex, giving a maximum net upwash. Conversely, when these two origins of upwash counteract, rather than reinforce, one another during the oscillation cycle, the net upwash attains minimum value. Analogous interpretations hold for regions of maximum and minimum net downwash located outboard of the regions of upwash. The magnitude and scale of the vorticity shed from the tip of the wing are directly correlated with the net upwash, which takes different forms related to the outboard displacement of the incident vortex. As the location of the incident vortex is displaced towards the wing tip, both the maximum upwash and the maximum vorticity of the tip vortex initially increase and then decrease. For the limiting case where the incident vortex impinges directly upon the tip of the wing, there is no tip vortex or induced region of upwash. Furthermore, at small values of vortex displacement from the wing tip, the position of the incident vortex varies significantly from its nominal position during the oscillation cycle. All of the foregoing features are interpreted in conjunction with the flow topology in the form of streamlines and critical points, superposed on patterns of vorticity. It is shown that despite the small amplitude of the wing motion, the flow topology is fundamentally different at maximum positive and negative values of the velocity of the wing tip, that is, they are not symmetric.

"THREE-DIMENSIONAL PLANAR DOPPLER VELOCITY MEASUREMENTS IN A FULL-SCALE ROTOR WAKE"

AIAA Journal, Vol. 43, No. 3, March 2005, pp. 489-499

The application of planar Doppler velocimetry (PDV) measurements to three-dimensional velocity vector fields in the tip-vortex flows between the blades of a full-scale UH-60 rotor operating in the 80-by 120-Foot Wind Tunnel at NASA Ames Research Center is described. The unique capabilities of PDV for remotely measuring complex velocity fields in large-scale flows are demonstrated and the factors affecting the quality of PDV data from a large-scale facility are defined. Because the wind tunnel is a non-circulating, in-draft configuration, and very large, the principal factor that prevented the acquisition of time-resolved, instantaneous measurements was the spatially and temporally sporadic behavior of the aerosol seeding in the sample area. Nevertheless, time-averaged velocity fields were obtained that characterize the locations and velocity distributions of the blade tip vortices and that provide magnitudes and directions of the velocity vectors in the surrounding flow with better than 1-cm spatial resolution within a square, 1.2 m x 1.2 m, sample area from distances up to 20 m.

"DISTRIBUTED MULTI-VEHICLE SIMULATION INCLUDING HIGH-ORDER AIRWAKE REPRESENTATION"

60th Annual Forum, American Helicopter Society, June 2004, Baltimore, MD.

Attempts to simulate the dynamic interface (DI) environment of landing aircraft onto Navy ships typically incorporate extensive approximations in both the component aerodynamic models and their interaction. These lower fidelity models are employed to achieve real-time throughput speeds required in manned simulation, or may simply result from lack of data or sufficient analytical tools in the models themselves. A novel fully-coupled aerodynamic simulation that includes multiple aircraft simultaneously operating from a ship has been prototyped, and represents time-accurate couplings between aircraft wakes, ship superstructure, and ship air wake emanating from a moving platform. Various modeling simplifications for far wake decay and dissipation have been applied to this simulation and their effects evaluated to quantify the level of detail necessary to use this software as a DI testing predictive tool. Additional extensions to the model included the capability for full airframe wake modeling and an enhanced treatment of ship air wake effects. Favorable comparisons with a variety of datasets, and several simulation integration exercises, show the prototype model to be sufficiently general and robust to assure successful continued development to support a wide range of simulation applications.

"WAKE ENCOUNTER ANALYSIS FOR A CLOSELY SPACED PARALLEL RUNWAY PAIRED APPROACH SIMULATION"

AIAA Paper 2009-6943, September 2009, Hilton Head, SC.

A Monte Carlo simulation of simultaneous approaches performed by two transport category aircraft from the final approach fix to a pair of closely spaced parallel runways was conducted to explore the aft boundary of the safe zone in which separation assurance and wake avoidance are provided. The simulation included variations in runway centerline separation, initial longitudinal spacing of the aircraft, crosswind speed, and aircraft speed during the approach. The data from the simulation showed that most of the wake encounters occurred near or over the runway and the aft boundaries of the safe zones were identified for all simulation conditions.

McLean, D.

"WINGTIP DEVICES: WHAT THEY DO AND HOW THEY DO IT"

2005 Boeing Performance and Flight Operations Engineering Conference, Article 4, 2005.

In this paper we discuss the benefits of wingtip devices to the operator of an airplane and attempt to provide an accessible explanation of the physics underlying those benefits. We also discuss some of

the issues that affect design decisions and look at the level of benefit that has been achieved in one application, the API winglet on the 737NG.

McMahon, T. A.

"REVIEW OF THE VORTEX WAKE ROLL UP PROBLEM"

ASRL-TR-145-1, June 1967, Mass. Institute of Technology, Cambridge, MA

The near wake problem behind an airfoil is reviewed in the context of some eighteen references, both theoretical and experimental. It is found that the body of theoretical literature makes an inconsistent approximation about the axial component of velocity in the flow. The techniques of self-similar hydrodynamics, vortex system theory, and conservation of energy arguments as they apply to the roll-up problem are discussed. Some important experimental evidence seems to confirm that the near wake problem is basically three-dimensional and should be reexamined as such.

McMahon, T. A. and Widnall, S. E.

"VORTEX WAKE ROLL-UP AND VORTICITY CONCENTRATION BEHIND AN AIRFOIL"

ASRL TR 143-1, June 1967, Mass. Institute of Technology, Cambridge, MA

Some experimental evidence seems to confirm that the near wake problem is basically three-dimensional and should be reexamined as such. A concentration mechanism based on this three-dimensionality is proposed and found to predict a gradient of core circulation which is dimensionally correct and gives realistic answers when specific numerical cases are compared to published experiments. The correlation of experiment with theory involves a uniform translation of the theoretical points a specific distance upstream, implying that rotational fluid in the sheet requires a finite, uniform time to get to the core, no matter which downstream station is considered. A paradox in the role of viscosity in the concentrating mechanism is discussed.

"ROLLING MOMENTS IN A TRAILING VORTEX FLOWFIELD"

J. Aircraft, Vol. 15, No. 5, May 1978, pp. 280-286

Pressure distributions are presented which were measured on a wing near a tip vortex of known structure generated by a larger, upstream semispan wing. Overall loads calculated by integration of these pressures are checked by independent measurements made with an identical model mounted on a force balance. Several conventional methods of wing analysis are used to predict the loads on the following wing. Strip theory is shown to give uniformly poor results for loading distribution, although predictions of overall lift and rolling moment are sometimes acceptable. Good results are obtained for overall coefficients and loading distribution by using linearized pressures in vortex-lattice theory in

conjunction with a rectilinear vortex. The equivalent relation from reverse-flow theory that can be used to give economic predictions for overall loads is presented.

McMillan, R.

"MILLIMETER-WAVE RADIOMETER FOR DETECTING MICROBURSTS"

Fourth Combined Manufacturers' and Technologists' Conference, Part 2, NASA Langley Research Center, Airbourne Windshear Detection and Warning Systems, VA, September 1992, pp. 781-803

This paper describes a millimeter-wave radiometer for the detection of wind shear from airborne platforms or at airport terminals. This proposed instrument will operate near the group of atmospheric oxygen absorptions centered near 60 GHz, which it will use to sense temperature from a distance. The instrument will use two channels to provide two different temperature measurements, providing the basis for solution of two equations in two unknowns, which are range to the wind shear plume and its temperature. A third channel will measure ambient atmospheric temperature. Depending on the temperature difference between the wind-shear plume and ambient, the standard deviation of range measurement accuracy is expected to be about 1 km at 5 km range, while the temperature measurement standard deviation will be about one-fourth the temperature difference between plume and ambient at this range. The instrument is expected to perform usefully at ranges up to 10 km, giving adequate warning of the presence of wind shear even for high performance jet aircraft. Other atmospheric hazards which might be detected by this radiometer include aircraft wakes and vortices, clear-air turbulence, and wind rotors, although the latter two phenomena would be detected by an airborne version of the instrument. A separate radiometer channel will be provided in the proposed instrument to detect aircraft wakes and vortices based on perturbation of the spectrum of microscopic atmospheric temperature fluctuations caused by the passage of large aircraft.

McMillan, R. W.

"A HORIZONTAL ATMOSPHERIC TEMPERATURE SOUNDER: APPLICATIONS TO REMOTE SENSING OF ATMOSPHERIC HAZARDS"

International Journal of Infrared and Millimeter Waves, Vol. 14, No. 5, 1993, pp. 931-948.

Several atmospheric hazards, including wind shear, clear-air turbulence, and wake vortices cause special problems for aircraft. These phenomena are usually characterized by a change in temperature relative to ambient, which may be detected by a millimeter wave radiometer operating on an absorption line in the atmosphere. Because of available componentry with excellent performance and relative freedom from interference by water vapor, the family of oxygen absorptions centered near 60 GHz is considered the best atmospheric feature on which the design of such an instrument could be based. This paper describes a multi-channel radiometer operating near 60 GHz which should be capable of detecting the hazards mentioned above as well as other potential dangers such as the passage of strong fronts and other severe weather. It is shown that a carefully designed instrument will be capable of measuring range to a hazard to an accuracy of about 5 percent and temperature

difference to an accuracy of approximately half the actual measured difference, depending on range and temperature. An actual design is proposed, and graphs of expected performance are included.

McMinn, J. D.

"EXTENSION OF A KOLMOGOROV ATMOSPHERIC TURBULENCE MODEL FOR TIME-BASED SIMULATION IMPLEMENTATION"

AIAA Paper 1997-3532, August 1997, New Orleans, LA.

The development of any super/hypersonic aircraft requires the interaction of a wide variety of technical disciplines to maximize vehicle performance. For flight and engine control system design and development on this class of vehicle, realistic mathematical simulation models of atmospheric turbulence, including winds and the varying thermodynamic properties of the atmosphere, are needed. A model which has been tentatively selected by a government/industry group of flight and engine/inlet controls representatives working on the High-Speed Civil Transport is one based on the Kolmogorov spectrum function. This report compares the Dryden and Kolmogorov turbulence forms, and describes enhancements that add functionality to the selected Kolmogorov model. These added features are: an altitude variation of the eddy dissipation rate based on Dryden data, the mapping of the eddy dissipation rate database onto a regular latitude and longitude grid, a method to account for flight at large vehicle attitude angles, and a procedure for transitioning smoothly across turbulence segments.

McWilliams, I. G.

"HAZARD EXTENT ABOUT AIRCRAFT TRAILING WAKE VORTICES - ANALYTIC APPROACH"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 23-30

The proposed Vortex Advisory System makes use of the fact that under certain wind conditions, vortices cannot be detected within a protected corridor after 80 seconds. The width of the corridor is dependent upon the hazard extent about vortices. Two methods for estimating the hazard extent are presented: a static calculation of the rolling moment on a generic aircraft as a function of distance from the vortex axis; and a dynamic simulation of a B-720 encountering vortices at varying distances. Both methods were found to closely agree and yielded a value of 30 meters as a conservative estimate for the hazard extent about vortices.

McWilliams, J. C.

"THE EMERGENCE OF ISOLATED COHERENT VORTICES IN TURBULENT FLOW"

Journal of Fluid Mechanics, Vol. 146, 1984, pp. 21-43.

A study is made of some numerical calculations of two-dimensional and geostrophic turbulent flows. The primary result is that, under a broad range of circumstances, the flow structure has its vorticity

concentrated in a small fraction of the spatial domain, and those concentrations typically have lifetimes long compared with the characteristic time for nonlinear interactions in turbulent flow (i.e. an eddy turnaround time). When such vorticity concentrations occur, they tend to assume an axisymmetric shape and persist under passive advection by the large-scale flow, except for relatively rare encounters with other centers of concentration. These structures can arise from random initial conditions without vorticity concentration, evolving amid what has been traditionally characterized as the 'cascade' of isotropic, homogeneous, large-Reynolds-number turbulence: the systematic elongation of isolines of vorticity associated with the transfer of vorticity to smaller scales, eventually to dissipation scales, and the transfer of energy to larger scales. When the vorticity concentrations are a sufficiently dominant component of the total vorticity field, the cascade processes are suppressed. The demonstration of persistent vorticity concentrations on intermediate scales -- smaller than the scale of the peak of the energy spectrum and larger than the dissipation scales -- does not invalidate many of the traditional characterizations of two-dimensional and geostrophic turbulence, but I believe it shows them to be substantially incomplete with respect to a fundamental phenomenon in such flows.

McWilliams, J. C.

"THE VORTICES OF TWO-DIMENSIONAL TURBULENCE"

Journal of Fluid Mechanics, Vol. 219, 1990, pp. 361-385.

A solution of decaying two-dimensional turbulence at large Reynolds number is analyzed by means of an automated vortex census. The census identifies the flow structures which approximately conform to the idealized shape of an isolated, coherent vortex. It also determines vortex characteristics, such as amplitude, size, radial profile, and deformation from the ideal axisymmetric shape. The distributions of these characteristics within the vortex population are examined, as are their time evolutions. Interpretation of these distributions is made with reference to both the random initial conditions for the solution and the dynamical processes of vortex emergence, survival, and interaction.

"A COMPUTATIONAL STUDY ON THE INTERACTION BETWEEN A VORTEX AND A SHOCK WAVE"

AIAA Paper 1989-1043, April 1989, San Antonio, TX.

A computational study of two-dimensional shock vortex interaction is discussed in this paper. A second order upwind finite volume method is used to solve the Euler equation in conservation form. In this method, the shock wave is captured rather than fitted so that the cases where shock vortex interaction may cause secondary shocks can also be investigated. The effects of vortex strength on the computed flow and acoustic field generated by the interaction are qualitatively evaluated.

Meadows, K., Kumar, A. and Hussaini, M.

"COMPUTATIONAL STUDY ON THE INTERACTION BETWEEN A VORTEX AND A SHOCK WAVE"

AIAA Journal, Vol. 29, No. 4, February 1991, pp. 174-179.

A computational study of two-dimensional shock vortex interaction is discussed in this paper. A second-order upwind finite volume method is used to solve the Euler equations in conservation form. In this method, the shock wave is captured rather than fitted so that the cases where shock vortex interaction may cause secondary shocks can also be investigated. The effects of vortex strength on the computed flow and acoustic field generated by the interaction are qualitatively evaluated.

"DRAG PREDICTION AND WAKE SURVEY TECHNIQUES"

CEAS Katnet Conference on Key Aerodynamic Technologies, June 2005, Bremen, Germany.

This paper focuses on methods to calculate the drag components from flow field wake measurements. For many years, ONERA has developed an original method which aims at improving the understanding of local flow phenomena and wakes. The approach consists in writing the drag and the lift in terms of variables measured inside the wake to determine viscous, wave and lift-induced drag components. The first part of the paper is devoted to the theoretical formulations. The second part is dedicated to the wall influence on induced drag in wind tunnel. Direct Numerical Simulation is done to foresee these effects. In the last part, several examples are presented with subsonic and transonic tests. An original method allows the extraction of viscous and wave components from the profile drag to be carried out.

Meheut, M. and Bailly, D.

"DRAG-BREAKDOWN METHODS FROM WAKE MEASUREMENTS"

AIAA Journal, Vol. 46, No. 4, April 2008, pp. 847-862

This paper focuses on drag-extraction methods from flowfield wake surveys. For many years, ONERA has developed an original method which aims at improving the understanding of local flow phenomena. The approach consists in decomposing lift and drag into profile and induced components

from wake measurements. The definition of drag allows a phenomenological breakdown of the different drag sources, for which the physical interpretation requires an accurate description of the wake phenomena. It is the aim of this paper to closely analyze these drag sources and to establish an accurate breakdown. In the first section, the analytical definition of profile drag is reviewed. Several formulations commonly found in the literature are compared to determine their physical meaning and limits of applicability. From this analysis, a new drag-breakdown method is proposed and discussed. Computational fluid dynamics simulations are carried out to complete this study and to evaluate the accuracy of the new formulation. The latter is then applied to subsonic and transonic flows from wind-tunnel measurements.

Mehrle, A. H. and Gittler, P.

"COMPARISON OF ANALYTICAL AND NUMERICAL SOLUTION FOR OPTIMAL VORTEX DIFFUSER DESIGN"

PAMM, Vol. 5, Issue 1, 2005, pp. 471-472

This contribution deals with optimization of wing tip devices, so called vortex diffusers. A comparison is given between an analytical approach for obtaining the optimal circulation loading and the results of a numerical investigation using a lifting line method. The purpose of most wing tip devices is to reduce the induced drag of the main wing by converting vortex energy into thrust. To achieve an optimal design, a variational formulation originally proposed by Betz and Prandtl for air screws is applied to the circulation distribution of the diffuser blades. In extension to the inviscid formulation, a viscous correction is applied to account for frictional forces. To validate the analytical results, a comparison is given with numerical solutions from a lifting line method. The loading of the diffuser blades is parametrized and optimized with respect to resulting thrust by use of a quasi-Newton gradient method. Comparison shows that, knowing the velocity distribution in the near wake of the wing, considerable decrease of induced drag may be achieved making use of vortex diffusers. Although actual circulation loading may differ between the analytical and numerical estimation, resulting thrust agrees within a few percent.

Mehta, J. M.

"SELF-PRESERVATION OF TURBULENT WAKES"

J. Aircraft, Vol. 26, No. 1, January 1989, pp. 93-96

An experiment has been presented that describes wake flow development behind NASA GA(W)-1 airfoils. The measurements show that in the far wake, the mean velocity profiles demonstrate self-similar behavior irrespective of the nature of the upstream boundary layer. However, the processes by which different wakes reach the asymptotic state are much different for different types of wake generators.

Mehta, R. D. and Lim, T. T.

"FLOW VISUALIZATION STUDY OF A VORTEX-WING INTERACTION"

NASA TM-86656, November 1984, NASA Ames Research Center, Moffett Field, CA

A flow visualization study in water was completed on the interaction of a streamwise vortex with a laminar boundary layer on a two-dimensional wing. The vortex was generated at the tip of a finite wing at incidence, mounted perpendicular to the main wing, and having the same chord as the main wing. The Reynolds number based on the wing chord was about 5000. Two different visualization techniques were used. One involved the injection of two different colored dyes into the vortex and the boundary layer. The other technique utilized hydrogen bubbles as an indicator. The position of the vortex was varied in a direction normal to the wing. The angle of attack of the main wing was varied from -5 to +12.5 deg. The vortex induced noticeable cross flows in the wing boundary layer from a distance equivalent to 0.75 chords. When very close to the wing, the vortex entrained boundary layer fluid and caused a cross flow separation which resulted in a secondary vortex.

Meier, G. E. A.

"HELICOPTERS AND VORTICES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Helicopters and vortices have a special relation. Vortices are generating in an interaction with the rotor blades a major part of the noise of a helicopter. In a lot of research activities it was found, the interaction of the blade tip vortices with the following blade is generating the slap noise of helicopters heard in special directions. We focus our considerations in this paper on the mechanisms of noise generation by vortex blade encounters and on the observation and measurement techniques for locating the vortices in the wake of the rotor. The first part is therefore dealing with experiments and numerical calculations showing a two-dimensional vortex interaction with a two-dimensional airfoil section. The sound generation is clearly visible in the results and documents two different mechanisms of sound generation. The first one is a kind of bow shock which is radiated because the approaching vortex increases the incoming wind speed and the blade is producing a kind of bow shock this way. A second mechanism of generating steep sound waves is due to an increase of flow velocity on the surface of the airfoil. Here a supersonic flow pocket can be generated and the closing shock wave is radiated as a sound wave later when the vortex has passed the airfoil section. The rotor experiments with the flying helicopter have been made possible by a new optical technique, which is called BOS (Background Oriented Schlieren). This technique enables field recordings of density gradients in unlimited viewing fields. This way the interaction areas of a rotor flow field can be recorded. Results for two different helicopters have been achieved and show the generated vortices but also some spectacular vortex interactions.

Melander, M. V. and Hussain, F.

"POLARIZED VORTICITY DYNAMICS ON A VORTEX COLUMN"

Phys. Fluids A, Vol. 5, No. 8, August 1993, pp. 1992-2003.

It is shown that vortex core dynamics results from the interaction of two slowly deforming, but overlapping, helical vortex structures. These are the left- and right-handed components of the vortex, and are obtained by a generalized Helmholtz decomposition (the complex helical wave decomposition) of the vorticity field. This decomposition is based on a Fourier expansion in eigenfunctions of the curl operator, which has only real eigenvalues λ . The sum of eigenmodes with $\lambda > 0$ ($\lambda < 0$) constitutes the right (left) polarized component, and the vector lines of the field (e.g., vortex lines) are locally right (left) handed helices. It is found that for a localized vortex the polarized structures are also localized, a crucial result for physical space applications. The polarized vortex structures deform slowly (compared to unpolarized structures) and behave almost like solitary waves when isolated. It is shown that this is because the nonlinearity in the Navier-Stokes equations is largely suppressed between eigenmodes of the same polarity. Moreover, the helicity of polarized structures is very high. The interaction between overlapping polarized structures however gives each structure a different propagation velocity and results in some additional deformation. The latter is shown to occur mainly in two places: at the front of the structure where a low enstrophy bubble forms (which is a permanent feature in each of the polarized packets), and at the back where a tail develops. Otherwise, the deformation occurs on a much slower time scale compared to that for unpolarized vortices. Thus the rapid changes in the total vorticity field result from the superposition of two slowly deforming structures moving in opposite directions, as is the case for the one-dimensional (1-D) wave equation.

"SYMMETRIC VORTEX MERGER IN TWO DIMENSIONS: CAUSES AND CONDITIONS"

J. Fluid Mech., Vol. 195, October 1988, pp. 303-340.

Two like-signed vorticity regions can pair or merge into one vortex. This phenomenon occurs if the original two vortices are sufficiently close together, that is, if the distance between the vorticity centroids is smaller than a certain critical merger distance, which depends on the initial shape of the vortex distributions. The conclusions are based on an analytical/numerical study, which presents the first quantitative description of the cause and mechanism behind the restricted process of symmetric vortex merger.

"AERODYNAMIC ANALYSIS OF JET-BLAST USING CFD CONSIDERING AS EXAMPLE A HANGAR AND AN AIRBUS A380 CONFIGURATION"

Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 92, 2006, pp. 152-159.

The paper describes the setup and validation of a process-chain based on the DLR-TAU code with adaptation and flow solver for the determination of the jet-wake behind jet engines for viscous flows is

shown. This jet-wake (often called jet-blast) plays an important role for the design and the operation of airports. As an example of the process-chain the jet-blast impact on a hangar by an Airbus A380 configuration is simulated using this technique.

"NUMERICAL HIGH LIFT RESEARCH II/III"

High Performance Computing in Science and Engineering '04, Springer, 2005, pp. 237-259.

The project NHLRes is concerned with the simulation of aircraft aerodynamics and thus belongs to the research field of computational fluid dynamics for aerospace applications. NHLRes comprises the numerical simulation of the viscous flow around transport aircraft high lift configurations based on the solution of the Reynolds-averaged Navier-Stokes equations. The project NHLRes consists of five parts representing the analysis of complex 3D-flow features, wake vortex simulation, optimization for three-dimensional high lift flow, aerodynamic interactions between the propeller and high lift wings and finally the usage of large eddy simulation of the flow around high lift configurations.

"ADVECTION OF A VORTEX PAIR ATMOSPHERE IN A VELOCITY FIELD OF POINT VORTICES"

Physics of Fluids A, Vol. 4, No. 12, December 1992, pp. 2779-2797.

Two-dimensional inviscid flows governed by a vortex pair in the presence of another point vortex or vortex pair on an unbounded plane are considered analytically and via numerical simulations. For some integrable cases of vortex motion, the stirring process of a fixed closed volume of surrounding fluid ('atmosphere') initially trapped by vortex pair is investigated. Using the full classification of vortex movement types, it is shown that for all cases of vortex pair direct and exchange scattering the stirring process is regular. Some internal atmosphere regions conserve their existence and form after vortex interaction, resulting a 'soliton like' behavior. For general cases of vortex pair mutual trapping, the stirring process is chaotic. For limiting cases of vortex motions, the fluid particles reveal a regular behavior. A simple model for the qualitative description of recent experiments on vortex dipoles interaction is discussed. Although clearly an extreme idealization, the model appears to shed some light on what to expect in laboratory experiments.

"A BIBLIOGRAPHY OF VORTEX DYNAMICS 1858-1956"

Advances in Applied Mechanics, Vol. 47, 2007, pp. 197-292.

The early papers in the new field of vortex dynamics were scattered among many journals in many countries and were written in a multitude of languages, primarily English, French, German, Italian and Russian. This diversity of publication venue and language, unfortunately, often makes the literature

rather difficult to identify and access for the modern researcher. About a century after Helmholtz's paper two major journals devoted to fluid mechanics would be started, *Journal of Fluid Mechanics* in 1956 and *Physics of Fluids* in 1957. After their initiation these journals attracted many of the major papers in vortex dynamics. Furthermore, the vast literature about vortex dynamics since the 1950's may be accessed through serial publications such as *Advances in Applied Mechanics* (published since 1948), *Progress in Aeronautical Sciences* (published since 1961), *Annual Review of Fluid Mechanics* (published since 1969), and several volumes devoted to 'Stromungsmechanik' of the extensive *Handbuch der Physik* (published since 1956). Other valuable sources are the proceedings of the International Congresses of Theoretical and Applied Mechanics (held every four years since 1924), along with other topical symposia, conferences, and workshops. There also exist many general treatises, surveys, textbooks, Ludwig Prandtl and (since 1957) Lanchester Memorial Lectures, etc. Hence, and this may be a somewhat optimistic assessment, the period that is most in need of a comprehensive bibliography is the century from 1858 to about 1956. It is such a bibliography that we have tried to provide in this paper.

"VORTEX RINGS: HISTORY AND STATE-OF-THE-ART"

Journal of Mathematical Sciences, Vol. 173, No. 4, July 2011, pp. 1-37.

In the present paper, we describe the fascinating 150-year history of vortex dynamics, which started from the classical work by H. Helmholtz (1858). This work contains not only the general theorems on vortex motion, but also a special section devoted to axisymmetric circular vortex filaments and, in particular, to vortex rings. The aim of our investigation is both to clarify some purely mathematical questions connected with the Dyson model for coaxial vortex rings with a small circular cross-section in a perfect incompressible fluid to provide a historical overview of the achievements in experimental, analytical, and numerical studies of the interaction of vortex rings. The model is illustrated by several examples of the motion of vortex rings. Finally, we present a complete classification of the interactions of two coaxial vortex rings in a perfect fluid.

"INTERACTION OF TWO-DIMENSIONAL TRAILING VORTEX PAIR WITH A SHEAR LAYER"

International Applied Mechanics, Vol. 37, No. 7, 2001, pp. 948-957

The basic laws governing the interaction of a two-dimensional vortex pair with a shear layer of constant thickness are considered. The main idea of the study is to develop and adapt a simplified representation of a hydrodynamic flow based on a point-vortex model simulating the actual interaction of full-scale vortex patterns over the ground surface. It is shown that vortices with vorticity opposite in sign to the shear layer may stop or even ricochet from this layer, while the other vortex may penetrate through the layer. Numerical results are presented as plots and analyzed.

"A NOVEL FRAMEWORK TO ASSESS THE WAKE VORTEX HAZARDS RISK SUPPORTED BY AIRCRAFT IN EN-ROUTE OPERATIONS"

Seventh SESAR Innovation Days, November 2017, Belgrade, Serbia.

This paper presents the simulation environment developed within the framework of R-WAKE project, funded by SESAR 2020 Exploratory Research. This project aims to investigate the risks and hazards of potential wake vortex encounters in the en-route airspace, under current and futuristic operational scenarios, to support new separation standards aimed at increasing airspace capacity. The R-WAKE simulation environment integrates different components developed by different partners of the R-WAKE consortium, including simulators for weather, traffic, wake vortex phenomena, wake vortex interactions and different tools and methodologies for safety and risk assessment. A preliminary example is presented in this paper, in which 200 historical trajectories were simulated to show that the novel framework works properly. A WVE encounter has been detected in such first scenario, however with no significant safety effect on the follower aircraft. A second controlled scenario has been then run to force the detection of a severe wake encounter under realistic en-route conditions. Such scenario has given evidences that confirm the safety relevance of the underlying research concept.

"PIV INVESTIGATION INTO CROSS-STREAM BEHAVIOR IN WING WAKE FREE SHEAR LAYERS: CHALLENGES AND RESULTS"

AIAA Paper 2017-1461, January 2017, Grapevine, TX.

A fresh look at the cross-stream flow in the wake of a wing has revealed some surprising results and posed some experimental challenges. The wake behind a three-dimensional wing is formed through the interplay of different sources of drag. Lift induced drag is generated as a byproduct of downwash from wingtip vortices. Parasite drag results from form/pressure drag and a combination of the upper and lower surface boundary layers. These parasite effects amalgamate to create the free shear layer in the wake. Particle Image Velocimetry (PIV) experiments were performed in the cross-stream direction in the wake of an AR 6 wing with a Clark-Y airfoil in the UD Low Speed Wind Tunnel. The objective was to investigate flow topology of and around the wing wake free shear layer. Performing PIV in the cross-stream plane to capture and correctly resolve the entire wingtip vortex poses several challenges.

Resolving cross-stream flow in the free shear layer in the wake behind a wing is more challenging as the cross-stream flow is typically only small fraction of the freestream (out of plane) velocity. Reliable results can be systematically obtained by careful manipulation of test parameters, many beyond the range of existing commonly accepted heuristics. The resulting velocity components in and around the free shear layer in the wing wake showed counter flow in the cross-flow plane presumably corresponding to behavior associated with the flow over the upper and lower surfaces of the wing. An indication of the possibility of the transfer of momentum (from inboard to outboard of the wing) was identified through spanwise flow corresponding to the upper and lower surfaces through the free shear layer in the wake. A transition from minimal cross flow in the free shear layer to a well-established shear flow in the spanwise direction occurs in the vicinity of maximum lift-to-drag ratio (max L/D) angle of attack.

Memon, M. O. and Altman, A.

"WINGTIP VORTEX BEHAVIOR IN THE VICINITY OF THE MAXIMUM LIFT TO DRAG RATIO LIFT CONDITION"

AIAA Paper 2016-1847, January 2016, San Diego, CA.

Adverse effects of lift induced drag on the aerodynamic efficiency of aircraft are well known. Lift induced drag is generated as a byproduct of downwash from the wingtip vortices. The flow physics associated with wingtip vortex core axial flow transformation from wake-like (velocity less-than the freestream) to jet-like (velocity greater-than the freestream) behavior in the vicinity of the maximum lift to drag ratio (L/D) lift condition is explored. Particle Image Velocimetry (PIV) experiments were performed in the UD Low Speed Wind Tunnel in the near wake of an AR 6 wing with a Clark-Y airfoil to investigate the characteristics of the wingtip vortex at angles of attack ranging from 2 and 8 degrees. Results showed changes in the velocity distribution in the vortex inner and outer cores. Vorticity and energy distributions indicated the existence of the wake-like to jet-like transformation in the range of 4 to 6 degrees angle of attack. This range corresponds with the maximum L/D angle of attack of the Clark-Y tested. A relationship between the vortex core axial velocity profile changeover and the angle of attack at maximum L/D was identified. Improved understanding of this relationship could be extended not only to improve aircraft performance through the reduction of lift induced drag, but also to air vehicle performance in off-design cruise conditions.

"WINGTIP VORTICES FROM AN EXERGY-BASED PERSPECTIVE"

AIAA Paper 2014-0955, January 2014, National Harbor, MD.

The lens of exergy is used to investigate a wingtip vortex in the near wake over a range of angles of attack. Exergy is a concept commonly found in thermodynamically related disciplines in engineering; however, it has not been widely applied within the field of aerodynamics. In short, exergy is the measure of thermodynamically 'available' energy as determined through the more discriminating

second law of thermodynamics. The experiment in this paper was conducted in a circular water tunnel at the ILR Aachen. The data was taken three chord lengths downstream in the Trefftz plane of an aspect ratio (AR) 5 Clark-Y wing with a square edged wingtip using Particle Image Velocimetry (PIV). Intuitively, the minimum available energy state is expected to correspond to the maximum lift to drag ratio angle of attack. This, however, is not found to be the case in the present results. In general, points of inflection in the traditional lift and drag curves are identifiable in the wake by distinguishable changes in the exergy distribution across the wingtip vortex under the associated conditions. There are numerous additional surprises offered by looking at the wingtip vortex from the exergy perspective. Perhaps the most intriguing result is that although only 2-d Trefftz plane data was used to obtain the exergy distribution across the individual wingtip vortices, the crossover point for the out of plane change from wake-like to jet-like wingtip vortex core axial flow (indicating the peak lift to drag ratio) is identified by the in-plane exergy distribution. This crossover point is not identifiable in the evaluation of any other characteristics calculated from in-plane quantities. Consequently, the exergy method holds promise as a metric for the improvement of aircraft performance through the reduction of lift induced drag.

Memon, M. O., Wabick, K., Altman, A. and Buffo, R.M.

"WING TIP VORTICES FROM AN EXERGY-BASED PERSPECTIVE"

Journal of Aircraft, Vol. 52, No. 4, July-August 2015, pp. 1267-1276.

The lens of exergy is used to investigate a wingtip vortex in the near wake over a range of angles of attack. Exergy is the measure of thermodynamically 'available' energy as determined through the more discriminating second law of thermodynamics. Experiments were conducted in a water tunnel at Institute of Aerospace Systems at Aachen. The data were taken three chord lengths downstream in the Trefftz plane of an aspect ratio 5 Clark-Y wing with a square-edged wing tip using particle image velocimetry. Intuitively, the minimum available energy state is expected to correspond to the maximum lift-to-drag ratio angle of attack. This, however, is not the case here. Most interestingly, although only two-dimensional Trefftz plane data were used to obtain the exergy distribution across the individual wing-tip vortices, the crossover point for the out-of-plane change from wakelike to jetlike wing-tip vortex core axial flow (indicating the peak lift-to-drag ratio) is identified by the in-plane exergy distribution. This crossover point is not identifiable in the evaluation of any other characteristics calculated from in-plane quantities. Consequently, the exergy method holds promise as a metric for the improvement of aircraft performance through the reduction of lift-induced drag.

"WAKE-INDUCED AERODYNAMICS ON A TRAILING AIRCRAFT"

Applied Aerodynamics Conference, Royal Aeronautical Society, July 2016, Bristol, UK.

NASA conducted flight tests to measure the exhaust products from alternative fuels using a DC-8 transport aircraft and a Falcon business jet. An independent analysis of the maximum vortex-induced

loads on the Falcon in the DC-8 wake was conducted for pre-flight safety analysis and to define safe trail distances for the flight tests. Static and dynamic vortex-induced aerodynamic loads on the Falcon were predicted at a matrix of locations aft of the DC-8 under flight-test conditions, and the maximum loads were compared with design limit loads to assess aircraft safety. Trajectory simulations for the Falcon during close encounters with the DC-8 wake were made to study the vortex-induced loads during traverses of the DC-8 primary trailing vortex. A parametric study of flight traverses through the trailing vortex was conducted to assess Falcon flight behavior and motion characteristics.

Mendenhall, M. R., Lesieutre, D. J. and Kelly, M. J.

"TRAILING VORTEX-INDUCED LOADS DURING CLOSE ENCOUNTERS IN CRUISE"

AIAA Paper 2015-3300, June 2015, Dallas, TX.

The trailing vortex induced aerodynamic loads on a Falcon 20G business jet flying in the wake of a DC-8 are predicted to provide a preflight estimate of safe trail distances during flight test measurements in the wake. Static and dynamic loads on the airframe flying in the near wake are shown at a matrix of locations, and the dynamic motion of the Falcon 20G during traverses of the DC-8 primary trailing vortex is simulated. Safe trailing distances for the test flights are determined, and optimum vortex traverse schemes are identified to moderate the motion of the trailing aircraft during close encounters with the vortex wake.

"A FREE WAKE VORTEX LATTICE MODEL FOR VERTICAL AXIS WIND TURBINES: MODELING, VERIFICATION AND VALIDATION"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012072-1 - 012072-8.

Since the 1970s several research activities had been carried out on developing aerodynamic models for Vertical Axis Wind Turbines (VAWTs). In order to design large VAWTs of MW scale, more accurate aerodynamic calculation is required to predict their aero-elastic behaviors. In this paper, a 3D free wake vortex lattice model for VAWTs is developed, verified and validated. Comparisons to the experimental results show that the 3D free wake vortex lattice model developed can make an accurate prediction of the general performance and the instantaneous aerodynamic forces on the blades. The comparison between momentum method and the vortex lattice model shows that free wake vortex models are needed for detailed loads calculations and for calculating highly loaded rotors.

Meng, H., Liu, Y. Q., Li, L. and Han, S.

"A NOVEL 3-D NEAR WAKE VORTEX MODEL FOR FAR WAKE SIMULATION"

2nd IET Renewable Power Generation Conference (RPG 2013), September 2013, Beijing, China.

Wake effect widely exists in wind farms, which causes output power loss and higher fatigue load. Consequently, wake simulation, especially far wake, is significant for the wind farm micro-siting and wind farm operation. Interestingly, the simulation of near wake, which governs the initial condition of far wake, cannot be avoided in far wake simulation. Due to the complicate flow characteristics of near wake region, some simple near wake processing methods have been proposed, which cannot effectively depict details in near wake region. Combined with the Prandtl's approximation for the tip-root loss factor, a vortex model is proposed in this paper to calculate the near wake flow field for far wake simulation. To improve the efficiency of this vortex method, Particle Swarm Optimization (PSO) algorithm is employed to optimize the parameters, the helix angle and vortex core radius of tip and root vortex. A good agreement with Prandtl's approximation is achieved, and the 3 directional components of velocity are predicted, which is more detailed than the near wake description of Jensen wake model.

Meng, J. C. S.

"THE PHYSICS OF VORTEX-RING EVOLUTION IN A STRATIFIED AND SHEARING ENVIRONMENT"

J. Fluid Mech., Vol. 84, Part 3, 1978, pp. 455-469

A semi-analytical numerical study was performed to simulate the development of a vortex ring in a stratified and/or shearing environment. Practical applications of the results of this study can be found in turbulence modelling and in studies of plumes and wakes. The objective is to follow exactly the evolution of a vortex ring so that the three-dimensional vortex-stretching mechanisms due to stratification and the shear effects, respectively, can be understood.

Meng, J. C. S. and Thomson, J. A. L.

"LASER DOPPLER VELOCIMETER SYSTEM SIMULATION FOR SENSING AIRCRAFT WAKE VORTICES, PART II: PROCESSING AND ANALYSIS OF LDV DATA"

PD-75-077, February 1975, Physical Dynamics Inc., Berkeley, CA.

A data analysis program has been constructed to assess the Scanning Laser Doppler Velocimeter system performance, to validate the simulation model, and to test various vortex location algorithms. The program takes either real or simulated Doppler spectra versus range and elevation, calculates the spatial distributions of various spectral moments (mean velocity, variance, skewness, kurtosis) or other spectral characteristics and presents these in a 3-D display. Each of the real or simulated scans can be processed by one of three different procedures: simple frequency or wavenumber filtering, matched filtering, and deconvolution filtering. Vortex tracks and system range resolutions are compared with theoretical predictions.

Meng, J. C. S. and Thomson, J. A. L.

"SIMULATION AND DATA ANALYSIS OF A SCANNING LASER DOPPLER VELOCIMETER SYSTEM FOR SENSING AIRCRAFT WAKE VORTICES"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 94-105

The objectives of this study are to simulate the response of a Scanning Laser Doppler Velocimeter System (SLDVS) in an aircraft wake environment and to display the expected spatial signatures. From analysis of these simulated signatures as well as flight data, optimal tactics for determining wake location and strength can be established.

Menkes, J. and Abernathy, F. H.

"AN ESTIMATE OF THE POWER REQUIRED TO ELIMINATE TRAILING VORTICES BY SUCTION"

P-514, May 1970, Institute for Defense Analyses, Arlington, VA

The use of suction devices in controlling the trailing vortex hazard for closely spaced parallel runways is examined. The feasibility of this proposal is examined by means of a computer simulation. It is established conclusively that the scheme has merit and that the power required to bring the hazard to acceptable levels is of the order of 2,000 hp per runway.

Menkes, J. and Abernathy, F. H.

"AN ESTIMATE OF THE POWER REQUIRED TO ELIMINATE TRAILING VORTICES BY SUCTION"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 575-576

A descending aircraft is affected by the interaction of its vortex system with the ground; if the ground effect could be modified, the vortex reaction would be affected. Such a modification is induced by suction. The conceptual scheme involves placing one or more ditches which house the suction blowers between the runways.

Menshov, I.

"TEARING INSTABILITY OF ISOLATED COMPRESSIBLE VORTICES"

Aeroacoustics, Vol. 13, No. 1, 2014, pp. 113-140.

The present paper addresses the instability of a compressible vortex flow. We consider a family of so-called isolated vortices -- the circular planar vortices that have zero circulation (net vorticity). The term 'isolation' implies the presence of a shield in the vorticity field -- a region of vorticity of common sign surrounding the central domain where the vorticity is oppositely signed. To model such a vorticity field, a generalized Taylor-type profile for the swirl velocity in the radial direction is employed, which involves two parameters: intensity I (proportional to the maximal velocity) and steepness S (characterizing the

scale of the shield zone). Vortices are assumed to be compressible and homentropic. The linear-stability analysis is carried out, which shows that isolated vortices can exhibit both stable and unstable behavior depending on the model parameters I and S . By numerical simulations of the non-linear stage, the unstable normal modes are shown to evolve towards tearing of the basic vortex with formation of smaller secondary vortical structures.

Men'shov, I. and Nakamura, Y.

"INSTABILITY OF ISOLATED COMPRESSIBLE ENTROPY-STRATIFIED VORTICES"

Physics of Fluids, Vol. 17, March 2005, pp. 034102-1-034102-15

The normal mode linear analysis is applied to investigate the stability of a circular isolated compressible vortex with the emphasis on studying the effect of entropy stratification of the basic flow on stability properties. We study a family of vortices that have zero total circulation, with the swirl velocity being presented by a Taylor-type distribution in the radial direction. The stratification of entropy is modeled by a Gaussian two-parametric profile whose parameters control the maximal of entropy is modeled by a Gaussian two-parametric profile whose parameters control the maximal deviation from the homentropic distribution and the extent of the entropic zone. Results presented concern the effect of these parameters and the vortex intensity on instability characteristics. In particular, in the case of homentropic flow, vortices considered are found to be stable only for sufficiently high intensities and cease to be stable as the intensity weakens. As an example of the situation where unstable normal modes can be excited, the scattering of sound waves by the vortex flow is considered. By simulating this process numerically, we show that the scattered field becomes unstable in the course of time and acquires a typical periodical pattern in polar angle. The characteristics of this instability (viz., the growth rate and the azimuthal phase frequency) coincide with those of the linear analysis very closely. This fact shows conclusively that the instability is caused by the induction of unstable normal modes in the vortex by means of sound irradiation.

Men'shov, I. and Nakamura, Y.

"ON INSTABILITY AND BREAKDOWN OF ISOLATED VORTICES"

AIAA Paper No. 2005-4674, Toronto, Canada, June 2005

The present paper addresses the instability and breakdown of a compressible vortex flow. We study a family of circular planar vortices that have zero total circulation, with the swirl velocity being presented by a generalized Taylor-type distribution in the radial direction. The vortex is assumed to be compressible and homentropic; its azimuthal velocity is characterized by two parameters: intensity that is proportional to the maximal velocity and 'steepness' that defines the typical scale of the opposite vorticity zone surrounding the core of the vortex. The linear analysis is conducted to investigate the evolution of normal mode disturbances imposed on the field of the basic flow. Results obtained concern the effect of the parameters and on instability characteristics. The far field analysis shows that the instability evolution in the linear stage is accompanied by radiation of monochromatic

sound waves with the frequency that equals the phase frequency of the unstable mode. Also included are results of the numerical simulation of the non-linear stage, which is related to the vortex breakdown. Initial disturbances of two types are considered that correspond to the eigenfunctions of $m = 2$ and $m = 3$ azimuthal numbers, respectively. The first evolves into a stable symmetrical rotating structure that contains two pairs of counter-rotating eddies and a central eddy. Oppositely, the evolution of the $m = 3$ mode is strictly unstable and results in complete distortion of the basic vortex.

Men'Shov, I. and Nakamura, Y.

"INSTABILITY MODES ACOUSTICALLY EXCITED IN BAROCLINIC VORTICES"

AIAA Paper No. 2002-2986, St. Louis, MO, June 2002

The normal mode linear analysis is applied to investigate stability of a circular compressible vortex with the emphasis of studying the baroclinic effect, i.e., the effect of entropy stratification of the basic flow on stability properties. The vortex to be studied has a Taylor-type velocity distribution. The stratification of entropy is modelled by a Gaussian two-parametric profile, whose parameters control the maximal deviation from the homentropic distribution and the extent of the entropic zone. The results presented concern the effect of these parameters and the vortex intensity as well on instability characteristics, as the growth rate and the azimuthal phase frequency. Particularly, the Taylor homentropic vortex is found to be stable for sufficiently high intensities only, and ceases to be stable as the vortex intensity weakens. It also presented an example situation, where unstable normal modes are excited. This is the scattering of sound waves by the vortex. By simulating this process numerically, we show that the scattered field due to incident of sound waves on the vortex becomes unstable, and takes a typical angular regular structure. The characteristics of this instability, i.e., the growth rate and the azimuthal phase frequency coincides with those of unstable normal modes very closely, which indicates the excitation of these normal modes in the sound scattering process.

Men'shov, I. and Nakamura, Y.

"A MECHANISM OF SOUND GENERATION FROM VORTEX PREDOMINANT FLOWS"

ICAS 2004 Paper 2004-3.4.1, August-September 2004, Yokohama, Japan.

The present paper addresses the vortex instability as a possible source mechanism of wake vortex sound. We study a family of circular planar vortices that have zero total circulation, with the swirl velocity being presented by a generalized Taylor-type distribution in the radial direction. The vortex is assumed to be compressible and homentropic; its azimuthal velocity is characterized by two parameters: intensity I that is proportional to the maximal velocity and 'steepness' S that defines the typical scale of the opposite vorticity zone surrounding the core of the vortex. The linear analysis is conducted to investigate the evolution of normal mode disturbances imposed on the field of the basic flow. Results obtained concern the effect of the parameters I and S on instability characteristics. The far field analysis shows that the instability evolution in the linear stage is accompanied by radiation of monochromatic sound waves with the frequency that equals the phase frequency of the unstable

mode. Also included are results of the numerical simulation of the non-linear stage, which is related to the vortex breakdown and subsequent sound emission.

"COHERENT DOPPLER LIDAR FOR MEASUREMENTS OF WIND FIELDS"

Proceedings of the IEEE, Vol. 77, No. 3, March 1989, pp. 449-462.

The use of coherent Doppler lidar for remote measurements of atmospheric wind fields is receiving increasing consideration as a valuable tool for studies of atmospheric dynamics, both on a local scale using ground-based systems and on a global scale from an earth-orbiting satellite platform. The signal processing techniques for obtaining the velocity estimates, and the fundamental factors that influence coherent lidar performance in this context, are reviewed. The similarities and distinctions between Doppler lidar and Doppler radars are discussed. Coherent Doppler lidars now have the capability to map wind fields over selected regions in the lower atmosphere and greatly enhance the capability to visualize flow patterns in real time. Examples of this capability are presented. The concluding discussion concerns several of the salient features of the NASA concept for an earth-orbiting Doppler lidar to be launched in the late 1990s.

Mercan, B., Ostovan, Y., Dogan, E. and Uzol, O.

"EFFECT OF CHORDWISE MODULATED WAVEFORM TIP INJECTION ON THE CHARACTERISTICS OF THE TIP VORTEX"

AIAA Paper No. 2010-4270, June 2010, Chicago, Illinois.

This paper investigates the effect of chordwise modulated tip injection on the flow and turbulence characteristics of the tip vortex through experimental measurements downstream of a rectangular half-wing that has an aspect ratio of three. This injection technique involves spanwise jets at the tip that are issued from a series of holes along the chord line normal to the freestream flow direction. The injection mass flow rate from each hole is individually controlled using computer driven solenoid valves and therefore the flow injection geometrical pattern at the tip can be adjusted to any desired waveform shape, and can be steady or pulsed as well as moving or stationary waves along the chord. The measurements are performed in a blow-down wind tunnel using Constant Temperature Anemometry as well as Kiel probe traverses. Current data show consistent trends with previously observed effects of steady uniform tip injection such as the upward and outward motion of the vortex as well as increased levels of turbulence within the vortex core. The vortex size gets bigger with injection and the total pressure levels get reduced significantly near the vortex core. The injection pattern also seems to affect the size of the wing wake as well as the wake entrainment characteristics of the tip vortex. Depending on the injection waveform pattern the helicoidal shape of the tip vortex also seems to get affected.

"FLOW VISUALIZATION OF HELICOPTER BLADE TIP VORTICES -- A QUANTITATIVE TECHNIQUE TO DETERMINE THE TRAJECTORY AND THE POSITION OF THE TIP VORTEX PATTERN OF A MODEL ROTOR"

18th European Rotorcraft Forum, Sept. 1992, Avignon, France.

A visualization has been conducted of the tip vortex pattern of a descending model helicopter rotor, using a system that employs a continuous single-laser light sheet, a triggerable fast-motion video camera, a powerful strobe-light, and an oil smoke generator. The laser light sheet can be cast in any desired cross-section perpendicular to the plane by means of a two-degree-of-freedom traverse system. A reference grid was placed in the plane of the light sheet after the rotor and airstream were stopped, to quantify the distance between a given blade and the corresponding tip vortices.

"WAKE GROWTH AND COLLAPSE IN STRATIFIED FLOW"

AIAA Journal, Vol. 12, No. 7, July 1974, pp. 940-949

The objective of this research was to obtain data that could be used to predict the effect of stratification on the development of a momentumless wake. Experiments were performed in which a grid was oscillated in a stably stratified flow to produce the steady-state counterpart of the momentumless wake of a self-propelled vehicle. A pH-sensitive indicator was used to produce a neutrally-buoyant tracer to visualize wake development and subsequent vertical collapse. Measured velocity profiles in the simulated wake indicated that it was nearly momentumless, and vertical temperature surveys revealed the degree of mixing in the wake. The wake growth before and after collapse and the distance to collapse were correlated by using power laws and a theoretical analysis of wake collapse. The scaling relations established for predicting stratified flow wake dimensions revealed that the important parameters were the Froude number, defined as the product of the flow velocity and the Brunt-Vaisala period divided by the initial wake size, and the ratio of the time after wake generation to the Brunt-Vaisala period. Using these parameters, two unique curves were obtained for estimating the horizontal width and vertical height of a wake in a stratified flow.

Merritt, G. E. and Russo, A. L.

"THE EFFECT OF INITIAL CONDITIONS ON STRATIFIED FLOW WAKE COLLAPSE"

AIAA Paper No. 1975-0118, Pasadena, CA, January 1975

The effect of initial conditions on wake growth and collapse in a stratified flow has been studied experimentally and analytically. A turbulence generator was in a flowing stream of thermally stratified water, and measurements were made with a laser Doppler velocimeter of turbulence intensity in the wake. The measured rate of turbulence intensity decay along the wake axis for different values of initial turbulence level was observed to agree well with an analysis based on the assumption that the turbulence is proportional to the measured rate of wake expansion in unstratified flow. Good agreement was noted between analytical predictions, based on a critical Richardson number from

atmospheric data limiting vertical growth and measurements of wake growth and collapse for different ambient stratifications (Froude numbers) and wake turbulence levels. The measurements revealed the considerable effect that the initial wake turbulence intensity has on subsequent wake development.

"AN INVESTIGATION OF THE TRAILING VORTICITY BEHIND A STOL AIRCRAFT"

AFFDL-TR-73-138, December 1973, Mississippi State University, MS.

This report presents the results of a test program to measure the near-field wake behind the wing of a test aircraft, out of the ground effect. The test aircraft was a high-lift L-19 aircraft incorporating a distributed-suction boundary layer control system. The wake measurement probe was supported from the fuselage of the test aircraft and was mounted on a trolley which moved along a boom structure. The velocity measurements were made with a six-element hot-film anemometer. The near field wake data were obtained in two measurement planes located 0.64 and 5.10 feet behind the wing. Data were obtained at zero and full-flap deflection and true speeds of 46, 66, and 85 mph. The data are presented as contours of constant nondimensional longitudinal velocity increment within the measurement planes.

Mertaugh, L. J. and Devarayalu, K.

"FURTHER INVESTIGATIONS OF THE NEAR FIELD TRAILING VORTICITY BEHIND A STOL AIRCRAFT"

AASE-75-142, December 1975, Miss. State Univ., Mississippi State, MS

This report presents results of a test program to measure the velocity field in the near-wake behind the wing of a high-lift test aircraft. A direct measurement of the 3-component velocity vectors was made in several measurement planes located at various longitudinal positions behind the trailing edge of the aircraft wing. The test aircraft was a STOL L-19 equipped with a distributed suction boundary layer control system. Measurements were taken such that the velocity derivatives along all three coordinate axes could be computed. Thus, the three components of the vorticity vector could be determined at each point of the measurement matrix. It was found that, in general, velocity and vorticity vectors are not collateral. A design study was conducted to determine feasibility of a trailing probe support system which would allow detailed mapping of the wing wake velocity field at least 4 chord lengths behind the trailing edge of the generating wing. Such a system appears to be feasible and would provide a mechanism for further experimental study of the vortical flow at a point in the wake where roll-up is more developed.

Mertaugh, L. J., Damania, R. B. and Paillet, F. L.

"AN INVESTIGATION OF THE NEAR-FIELD WAKE BEHIND A FULL-SCALE TEST AIRCRAFT"

J. Aircraft, Vol. 14, No. 9, September 1977, pp. 894-902

Three-dimensional velocity field measurements were made on three transverse measurement planes located at 7.7, 33.3, and 61.2 inches behind the inboard-wing trailing edge of an aircraft in flight. The test aircraft as an L-19 modified to incorporate a distributed suction boundary-layer control system. Test data were obtained at various lift coefficients and with both zero and full flap deflections. Flowfield measurements were made with a total-vector hot-film probe mounted to a boom and traversing mechanism attached to the rear fuselage of the test aircraft.

Mertens, J.

"GLIDER MOTION IN THE VORTEX FIELD BEHIND A TOWING AIRCRAFT"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002.

One common method to start gliders is towing by aircraft. Experience by many pilots in towed gliders and experimental investigations provided strong influence of the vortex flow on the performance and the handling characteristics of the towed glider. Pupils or people not well trained in towing or not flying carefully can produce dangerous situations. Strong pitching motions may follow, and often strong lateral deviations by swinging from one side to the other cannot be avoided. In the past, the most dangerous situation was provoked by the glider climbing high over the towing aircraft. Now, with ultralight aircraft allowed for towing, the towing aircraft can fly so slow, that the glider stalls. The free flying glider has 6 degrees of freedom. This enables several oscillations. Here, the most interesting ones are: in longitudinal motion the (usually strongly damped) pitch oscillation and the phugoid; in lateral motion the dutch roll, usually weakly damped for gliders.

"THE INTERACTION OF A SUPERSONIC STREAMWISE VORTEX AND A NORMAL SHOCK WAVE"

PhD Thesis, August 1989, The Pennsylvania State University, University Park, PA.

A detailed experimental investigation on the generation of a turbulent, supersonic streamwise vortex and subsequent interactions with a normal shock wave are presented. The vortex is generated in the supersonic wind tunnel inviscid freestream of Mach 3 using a streamlined, axisymmetric strut-mounted swirl injector. Flow-angularity probe measurements show that the supersonic vortex core, having a streamwise Mach number of 3.0 and transonic tangential Mach numbers up to 0.9, resembles the incompressible vortex in its three-layered structure: an innermost viscous layer with solid body rotation, a logarithmic middle layer and an outer inviscid layer. Total temperature probe surveys show an isoenergetic vortical flow condition. The vortex is then passed through a normal shock (Mach disc) created by mismatching the static pressure of the vortical flow with that of the Mach 2 freestream. The resulting interaction, primarily observed by way of non-intrusive optical flow diagnostics, is shown to be sensitive to the initial swirl rate of the vortex. Passing a low-swirl vortex through the shock results in a weak interaction which resembles the inviscid, non-swirling flow case. For otherwise similar flow conditions, increasing the initial swirl rate of the vortex results in a strong, highly unsteady interaction as the shock distends upstream in a cone-like behavior and a recompression shock forms downstream.

Flow-angularity probe surveys show that the flow well downstream of both interactions is vortical again with a streamwise Mach number of 1.7. The study then covers two other Mach numbers of 2.2 and 3.5 for different initial swirl rates up to 0.4. Based on the current observations, a physical model that postulates the effect of the vortex breakdown phenomenon on the interaction flow pattern is presented. Navier-Stokes computations, utilizing the present initial flow conditions, partially support the physical model in predicting several key features of the observed strong interaction flow pattern.

"MEASUREMENTS OF A SUPERSONIC TURBULENT VORTEX"

Proceedings 11th Symposium on Turbulence, October 1988, Rolla, Missouri.

Mean-flow measurements of a supersonic turbulent streamwise vortex are presented. This vortex was produced by the injection of a swirling flow along the centerline of a supersonic airstream at Mach 3. Directional Mach number distributions, obtained via a five-hole flow-angularity probe, reveal vortex characteristics like those of the incompressible case, even though rotational Mach numbers up to 0.8 were obtained. This work is the first step of a study of the supersonic vortex breakdown phenomenon.

Metwally, O., Settles, G. and Horstman, C.

"AN EXPERIMENTAL STUDY OF SHOCK WAVE/VORTEX INTERACTION"

AIAA Paper No. 1989-0082, January 1989, Reno, NV.

An experimental study of the interaction of a supersonic streamwise vortex with a normal shock wave is presented. The vortex is generated in a supersonic wind tunnel test section using a streamlined, axisymmetric strut-mounted swirl injector. The streamwise Mach number of the vortex has values of 2.2, 3.0 and 3.5, while the inviscid freestream flow in which the vortex is imbedded has a constant Mach number of 2.0. To create such an interaction, the vortex is passed through a Mach disk (normal shock) which results from mismatching the static pressures of the freestream and the vortex. The resulting interaction is observed to be highly unsteady. The Mach disk distends upstream, while a recompression shock forms downstream of the interaction. Five-hole pressure-probe and temperature measurements ahead of the interaction are used as initial conditions for an axisymmetric, Navier-Stokes computation. The computational results support the hypothesis that supersonic vortex breakdown constitutes a strong factor in the observed interaction flow pattern.

"MIXING IN A VORTEX BREAKDOWN FLOW"

Journal of Fluid Mechanics, Vol. 731, 2013, pp. 195-222.

In this paper we present experimental and theoretical results on the mixing inside a cylinder with a rotating lid. The helical flow that is created by the rotation of the disc is well known to exhibit a vortex

breakdown bubble over a finite range of Reynolds numbers. The mixing properties of the flow are analyzed quantitatively by measuring the exponential decay of the variance as a function of time. This homogenization time is extremely sensitive to the asymmetries of the flow, which are introduced by tilting the rotating or the stationary disc and accurately measured using particle image velocimetry (PIV). In the absence of vortex breakdown, the homogenization time is strongly decreased (by a factor of 10) with only a moderate tilt angle of the rotating lid (of the order of 15 degrees). This phenomenon can be explained by the presence of small radial jets at the periphery which create a strong convective mixing. A simple model of exchange flow between the periphery and the bulk correctly predicts the scaling laws for the homogenization time. In the presence of vortex breakdown, the scalar is trapped inside the vortex breakdown bubble, and thus increases substantially the time needed for homogenization. Curiously, the tilt of the rotating lid has a weak effect on the mixing, but a small tilt of the stationary disc (of the order of 2 degrees) strongly decreases (by a factor of 10) the homogenization time. Even more surprising is that the homogenization time diverges when the size of the bubble vanishes. All of these features are recovered by applying the Melnikov theory to calculate the volume of the lobes that exit the bubble. It is the first time that this technique has been applied to a three-dimensional stationary flow with a non-axisymmetric perturbation and compared with experimental results, although it has been applied often to two-dimensional flows with a periodic perturbation.

"SECONDARY STRUCTURES IN A COROTATING VORTEX PAIR"

Journal of Visualization, Vol. 4, No. 2, 2001, p. 115.

This sequence shows the evolution of two perturbed corotating vortices, generated in water using impulsively moved flat plates. The Reynolds number based on the circulation of one vortex is approximately 3000. The vortex cores are visualized using red dye painted on the plate edges. In addition, a nylon thread coated with green fluorescent dye is placed in the middle between the two vortex centers. The corotating vortices, which in their basic state rotate around each other, are perturbed by adding a sinusoidal deformation to the edge of the vortex-generating plates. This creates a periodic perturbation of vorticity between the vortices, near the dyed thread, where the basic flow exhibits a hyperbolic stagnation point.

Meunier, P. and Leweke, T.

"UNSTABLE VORTEX MERGER"

Physics of Fluids, Vol. 12, No. 9, Sept. 2000, p. S6

We present visualizations of the merging of two initially laminar co-rotating vortices. The vortices are generated in water, at the edges of two flat plates impulsively started from rest, and visualized using fluorescent dyes.

Meunier, P. and Leweke, T.

"MERGING AND THREE-DIMENSIONAL INSTABILITY IN A COROTATING VORTEX PAIR"

Lecture Notes in Physics, Vol. 555, 2000, pp. 241-251

We investigate experimentally the interaction between two parallel laminar vortices of equal circulation. They are created by the impulsive displacement of two flat plates in a fluid initially at rest. The temporal evolution of the pair is analyzed with dye visualizations and quantitative measurements using Particle Image Velocimetry. For low Reynolds numbers, the vortices remain two-dimensional and merge into one. The size of the cores increases due to viscosity up to a certain limit, approximately a fourth of the separation distance, at which merging occurs. At higher Reynolds numbers, a three-dimensional instability is discovered, showing the characteristic features of an elliptic instability of the vortex cores. The two vortices still merge, but the final vortex is now turbulent.

Meunier, P. and Leweke, T.

"THREE-DIMENSIONAL INSTABILITY DURING VORTEX MERGING"

Physics of Fluids, Vol. 13, No. 10, October 2001, pp. 2747-2750

The interaction of two parallel vortices of equal circulation is observed experimentally. For low Reynolds numbers (Re), the vortices remain two dimensional and merge into one, when their time-dependent core size exceeds approximately 30% of the vortex separation distance. At higher Re , a three-dimensional (3-D) instability is discovered, showing the characteristics of an elliptic instability of the vortex cores. The instability rapidly generates small-scale turbulent motion, which initiates merging for smaller core sizes and produces a bigger final vortex than for laminar 2-D flow.

Meunier, P. and Villermaux, E.

"HOW VORTICES MIX"

J. Fluid Mech., Vol. 476, 2003, pp. 213-222

The advection of a passive scalar blob in the deformation field of an axisymmetric vortex is a simple mixing protocol for which the advection-diffusion problem is amenable to a near-exact description. The blob rolls up in a spiral which ultimately fades away in the diluting medium. The complete transient concentration field in the spiral is accessible from the Fourier equations in a properly chosen frame. The concentration histogram of the scalar wrapped in the spiral presents unexpected singular transient features and its long-time properties are discussed in connection with real mixtures.

"A MERGING CRITERION FOR TWO-DIMENSIONAL CO-ROTAING VORTICES"

Physics of Fluids, Vol. 14, No. 8, August 2002, pp. 2757-2766

We propose a quantitative criterion for the merging of a pair of equal two-dimensional co-rotating vortices. A cross-validation between experimental and theoretical analyses is performed. Experimental vortices are generated by the roll-up of a vortex sheet originating from the identical and impulsive rotation of two plates. The phenomenon is then followed up in time until a rapid pairing transition occurs for which critical parameters are measured. In the theoretical approach, the nonlinear Euler solution representing a pair of equal vortices is computed for various nonuniform vorticity distributions. The stability analysis of such a configuration then provides critical values for the onset of merging. From this data set, a criterion depending on global impulse quantities is extracted for different shapes of the vorticity distribution. This theoretical statement agrees well with our experimentally based criterion.

Meunier, P., Le Dizès, S. and Lewke, T.

"PHYSICS OF VORTEX MERGING"

C. R. Physique, Vol. 6, 2005, pp. 431-450

This article deals with the interaction of co-rotating vortices, in configurations like those found in the extended near-wake of typical transport aircraft. The fundamental process of vortex merging is analyzed and modeled in detail in a two-dimensional context, giving insight into the conditions for merging and its physical origin, and yielding predictions for the resulting flow. Three-dimensional effects, in the form of an elliptic short-wave instability arising in the initial co-rotating vortex flow, are described and analyzed theoretically. They are found to cause significant changes in the merging process, such as earlier merging and larger final vortex cores. Illustrations from recent experimental, numerical, and theoretical studies are given, and the relevance of the results for applications to real aircraft wakes is discussed.

"THE NCAR IN SITU TURBULENCE DETECTION ALGORITHM"

NCAR Technical Note, NCAR/TN-560+EDD, June 2019, Boulder, CO.

An In Situ Turbulence Detection Algorithm has been developed and implemented in a C code library for use by the aviation community (i.e., typically integrated into an onboard Aircraft Conditioning and Monitoring System (ACM) or other suitable onboard computer), and is described in detail in this report. Note that this In Situ EDR Algorithm described in the report uses vertical wind, and estimates a mean and peak EDR every minute and includes an event-based report triggering algorithm to lower the downlink costs without sacrificing too much data. While there are a few adjustable parameters that are weakly aircraft-dependent, the EDR output itself is developed to be aircraft-independent. An integrated quality control algorithm was designed to limit the amount of false turbulence detection while not impacting estimates of actual turbulence. The algorithm has been carefully tested against

simulations that indicate very good statistical performance. The algorithm is, at the time of writing, operating on about 1,400 aircraft worldwide, with many more expected.

"PLUME AND WAKE DYNAMICS, MIXING, AND CHEMISTRY BEHIND A HIGH SPEED CIVIL TRANSPORT AIRCRAFT"

J. Aircraft, Vol. 30, No. 4, July-August 1993, pp. 467-47.

The environmental perturbations caused by the exhaust of a high-speed civil transport (HSCT) depend on the deposition altitude and the amount and composition of the emissions. The chemical evolution and the mixing and vortical motion of the exhaust need to be analyzed to track the exhaust and its speciation as the emissions are mixed to atmospheric scales. Elements of an analytic model of the wake dynamical processes are being developed to account for the roll-up of the trailing vorticity, its breakup due to the Crow instability, and the subsequent evolution and motion of the reconnected vorticity. The concentrated vorticity is observed to wrap up the buoyant exhaust and suppress its continued mixing and dilution. The chemical kinetics of the important pollutant species will be followed throughout the plume and wake. Initial plume mixing and chemistry are calculated using an existing plume model, standard plume flowfield (SPF), with additional H/C/O, OH/SO₂, and NO_y chemistry and equilibrium H₂O condensation included. The species tracked include those that could be heterogeneously reactive on the surfaces of the condensed solid water (ice) particles when condensation occurs, and those capable of reacting with exhaust soot particle surfaces to form active contrail and/or cloud condensation nuclei.

"THE ORIGINS OF A WIND TURBINE TIP VORTEX"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012074-1 - 012074-13.

The tip vortex of a wind turbine rotor blade originates because of a complex distribution of vorticity along the blade tip thickness. While the tip vortex evolution was extensively studied previously in other work, the mechanism of the initiation of the tip vorticity in a 3D rotating environment is still somewhat obscured due to lack of detailed experimental evidence. This paper therefore aims at providing an understanding of how tip vorticity is formed at the wind turbine blade tip and what happens just behind the tip trailing edge. Stereo Particle Image Velocimetry (SPIV) is used to measure the flow field at the tip of a 2m diameter, two-bladed rotor at the TU Delft Open Jet Facility (OJF). The rotor has a rectangular blade tip. Spanwise measurements were performed for both axial and yawed flow conditions with a very small azimuthal increment. A 3D, unsteady, potential flow panel method is also used for the purpose of better understanding the tip bound vorticity. A validation study is carried out with positive results. This paper is focused on axial flow results. A complex distribution of vorticity is found along the blade tip thickness. Just after release, the tip vortex becomes almost immediately round and well defined. Observations from the MEXICO rotor are confirmed again by a slight inboard convection of the tip vortex. This is explained by means of the effect of chordwise vorticity at the tip from the numerical solutions. The results presented in this work suggest that a more physical interpretation of the tip loss effect is required. Currently, inclusion of the tip effects is based primarily on either wake induced effects or on an empirical 3D correction for airfoil data. This research should stimulate a more rigorous approach, where the effects of the blade tip chordwise vorticity are implemented in tip correction models.

Michalke, A. and Timme, A.

"ON THE INVISCID INSTABILITY OF CERTAIN TWO-DIMENSIONAL VORTEX-TYPE FLOWS"

Journal of Fluid Mechanics, Vol. 29, Part 4, 1967, pp. 647-666.

As a contribution to the breakdown phenomenon of vortices in a two-dimensional free boundary layer, this paper deals with the question whether a single cylindrical (i.e. two-dimensional) vortex can become unstable. For this reason, a single vortex, as it occurs in a free boundary layer, is approximated by an axisymmetric vortex model. The inviscid stability theory of rotating fluids is then applied to this vortex model. By general stability criteria it was found that a vortex consisting of vorticity of one sign only is stable according to the Rayleigh criterion, but, if the vorticity has an extremum value outside the axis, may become unstable with respect to cylindrical disturbances. Furthermore, stability calculations

for three special types of vortices were performed. It was found that they were more unstable with respect to cylindrical disturbances than to three-dimensional ones.

"AERODYNAMIC ROTOR LOADS PREDICTION METHOD WITH FREE WAKE FOR LOW SPEED DESCENT FLIGHTS"

18th European Rotorcraft Forum, Sept. 1992, Avignon, France, pp. 27-1 to 27-12.

A numerical method was developed to simulate a helicopter rotor at low speed and for descent flights. It consists of the coupling between a 3D unsteady full potential code, FP3D, and a new code derived from a lifting line method with vortex elements for the wake with prescribed geometry, METAR. This new code, MESIR, has a free wake analysis to get the capability to compute Blade-Vortex Interactions. Furthermore, the parts of the wake interacting with the blade are isolated and included in FP3D through a lifting surface approach. The method is validated with flight test results from the SA349 Gazelle helicopter and wind tunnel tests for the US Army OLS rotor in the DNW wind tunnel.

Michel, U.

"HISTORY OF ACOUSTIC BEAMFORMING"

Berlin Beamforming Conference (BeBeC), November 2006, Berlin, Germany.

The development of the beamforming method (also called microphone antenna, phased array of microphones, acoustic telescope, or acoustic camera) is reviewed in this paper. The microphone antenna was invented by Billingsley (1974) and has since seen dramatic improvements due to the availability of better data acquisition and computing hardware. Recent mathematical and software developments invert the beamforming process and allow a quantitative determination of the sources. Beamforming is indispensable for the localization of sound sources on moving objects, on flying aircraft, on high-speed trains, on motor cars in motion, on open rotors like helicopter and wind turbine rotors. In these applications, the ability to follow the motion of the sources is important. The second important applications are source localization tests in the test sections of open and closed wind tunnels. The background noise suppression capability of the beamforming method is required here. The various applications are discussed with a long list of references.

Michel, U. and Bohning, P.

"INVESTIGATION OF AIRCRAFT WAKE VORTICES WITH PHASED MICROPHONE ARRAYS"

AIAA Paper No. 2002-2501, Breckenridge, CO, June 2002

Wake vortices of landing aircraft emit a faint noise that is audible when the wind speed is low. The noise might be related to aerodynamic parameters of the vortices. Results from a test of the suitability of phased microphone arrays for the investigation of wake vortices are presented. It is shown that it is possible to localize the two counter-rotating vortices in a horizontal scan plane and to determine their horizontal trajectories. It is also possible to estimate the frequency spectra of wake-vortex noise. The paper presents vortex-noise frequency spectra and sound source distributions of the wake vortices measured behind an Airbus A320, a Boeing 737, and a Boeing 757. The phased microphone array technique is shown to be an appropriate tool for wake vortex investigations. Recommendations for the design of suitable arrays of microphones are given.

Michel, U., Barsikow, B., Helbig, J., Hellmig, M. and Schuettpehl, M.

"FLYOVER NOISE MEASUREMENTS ON LANDING AIRCRAFT WITH A MICROPHONE ARRAY"

AIAA Paper 1998-2336, Toulouse, France, June 1998

The noise sources of landing commercial aircraft were examined with planar arrays consisting of 96 or 111 microphones mounted on an 8 m by 8 m plate under the glide path on the ground. It is shown that important airframe noise sources can be identified despite the presence of engine noise, i.e., landing-gear noise, flap side-edge noise, flap-gap noise, jet-flap interaction noise, slat-horn noise, slat-track noise. A surprising finding is a noise source near the wing tips of some aircraft which is tentatively called wake-vortex wing interaction noise. It is shown to be by far the strongest noise (6 dB(A) louder than the engines) on a regional jet aircraft.

Micheli, F. and Moller, T. J.

"LDV APPLICATIONS IN INDUSTRIAL SIZE WIND TUNNELS"

3rd ONERA-DLR Aerospace Symposium, June 2001, Paris, pp. S4-2/1-9.

LDV techniques are not widely used in large scale wind tunnel, although DLR and ONERA have great skill in those appliances. Some classical and recent aspects of LDV are briefly reminded, as well as some typical results. As was done in the LLF-DNW wind tunnel, partnership could lead to a more efficient use of the time, cutting by more than two the test duration. Working distances of 5m and synchronization with an helicopter rotor were not a problem due to available setup. Vortex fields were measured and qualified with respect to the blade location. One important problem is the ability to measure boundary layers in large wind tunnel. A test on a high lift wing configuration, also in LLF-DNW, is presented. The

model location measurements done during LDV acquisition allowed to compensate for the model movements and to accurately define the flow close to the airfoil. The common knowledge and tools of both partners are ready to be employed to get more turbulent data in such large wind tunnels.

Michelsen, J. A.

"MODELING OF LAMINAR INCOMPRESSIBLE ROTATING FLUID FLOW"

AFM 86-05, Sept. 1986, Dept. of Fluid Mechanics, Technical University of Denmark, Copenhagen, Denmark

A Finite Element Code for simulation of laminar incompressible flow has been established. The Navier Stokes equations are solved using primitive variables, i.e. velocities and pressure, the latter being eliminated via a penalty formulation. To study the special anatomies connected with rotating flow, for example vortex breakdown and Ekman layers, an axisymmetric frame of reference is considered. Computations have been carried out for a cylindrical vessel with rotating cover. The Reynolds number ranged from 0 to 2000. Comparison to measured data reveals excellent agreement. Fully developed pipe flow leaving a rotating pipe into a fixed pipe has also been studied. The vortex breakdown produced by this flow is handled without difficulties by the code. Results are in close agreement with earlier numerical solutions.

Mickle, R. E.

"INFLUENCE OF AIRCRAFT VORTICES ON SPRAY CLOUD BEHAVIOR"

Journal of the American Mosquito Control Association, Vol. 12, No. 2, 1996, pp. 372-379

For small droplet spraying, the spray cloud is initially entrained into the wingtip vortices so that the fate of the spray is controlled by the motion of these vortices. In close to 100 aerial sprays, the emitted spray cloud has been mapped using a scanning laser system that displays diffusion and transport of the spray cloud. Results detailing the concentrations within the spray cloud in space and time are given for sprays in parallel and crosswinds. Wind direction is seen to potentially alter the vortex motion and hence the fate of the spray cloud. In crosswind spraying, the vortex behavior associated with the 2 wings is found to differ, which leads to enhanced deposition from the upwind wing and enhanced drift from the downwind wing.

Migliore, P. G.

"ROTOR INDUCED FLOW FIELDS IN GROUND EFFECT IN THE VICINITY OF A VERTICAL STEP"

TR-12, January 1969, West Virginia University, Morgantown, WV

This analysis devises means of theoretically predicting the flow fields induced by hovering rotors in ground effect and influenced by the proximity of a vertical step. A two-dimensional investigation is

performed. Results appear to be qualitatively accurate within the confines of the wake cylinder and in areas very close to the wake boundaries.

Mikhailov, Y. S.

"EXPERIMENTAL SIMULATION OF THE IMPACT OF A VORTEX WAKE ON A GENERAL AVIATION AIRCRAFT MODEL IN THE TsAGI T-103 WIND TUNNEL"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 188-196

Investigations in the TsAGI T-103 wind tunnel has been an effective means of simulating the influence of the vortex wake behind a heavy aircraft during takeoff or landing on the aerodynamic characteristics of another aircraft moving along a trajectory close to the wake axis. Used for simulation was an airfoil lattice with spanwise differential deflections of its airfoil, which was mounted at the wind tunnel nozzle exit. The study into the flow structure and testing of a general aviation aircraft model have shown that the airfoil lattice creates in the test section flow angularity equivalent in terms of its effects to the vortex wake behind the Boeing 747 aircraft in landing configuration at a distance of 500m and more. "VORTEX WAKE SIMULATION IN A WIND TUNNEL"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 197- 203

The setup modification was effectuated in TsAGI's T-103 wind tunnel to simulate in its test section a flow structure closely like that in the vortex wake behind a heavy aircraft. The original setup that included a cascade of two spanwise-sectioned, differentially deflectable wings was converted into a two-section tapered wing with the sections capable of differential deflection. The results are presented of studying the flow structure behind the modified setup which were obtained for two wing section setting angles (+10, -10, +6 and -6 degrees) and three values of freestream speed (50, 20 and 15 m/s).

"ANALYSIS OF VORTEX WAKE EFFECT ON THE AIRCRAFT MODEL AND SEARCH FOR AERODYNAMIC MEANS TO COMPENSATE IT"

AIAA Paper No. 1998-5591, Anaheim, CA, September 1998

The vortex wake effect on the aerodynamic characteristics of a twin-engine general-aviation aircraft model has been studied in TsAGI's wind tunnel. The airfoil cascade with differentially deflectable sections along the span installed at the wind-tunnel nozzle exit was used to simulate the vortex wake impact. In addition to the landing configuration considered first, this work is devoted to the analysis of

the vortex wake effect on the aerodynamic characteristics of the model in cruise and takeoff configurations. Preliminary researches were carried out on the efficiency of some wing control surfaces to compensate for the vortex induced rolling moment. The results of numerical calculation of the vortex wake impact on the aircraft model in cruise configuration is also presented. The algorithm for computing aircraft aerodynamic characteristics has been modified to account for the vertical velocity component of the vortex wake.

Mikhailov, Y. S.

"ANALYSIS OF THE VORTEX WAKE EFFECT ON AIRCRAFT MODEL AERODYNAMIC CHARACTERISTICS"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 169-179

The vortex wake effect on the aerodynamic characteristics of a twin-engine general-aviation aircraft model with significant mid-section has been studied in TsAGI's T-103 wind tunnel. The airfoil lattice with differential deflection section along the span installed at the wind-tunnel nozzle exit was used to simulate the vortex wake. Tests were conducted with two airfoil lattice angular settings of ± 6 and ± 10 degrees which were equivalent of wake influence formed behind the Boeing 747 aircraft in landing configuration at distances away from it of 1500 and 500 m, respectively. In addition to the landing configuration considered earlier, this work analyzes the aerodynamic characteristics of the model in cruise and take-off configurations. The results are indicative of the model drag reduction when simulating the flight regime along the trajectory close to the axis of one of the vortices. Besides, there is a need for additional wing control surfaces to compensate a disturbing rolling moment. The study covers a wide range of angles of attack including the post-stall ones.

"APPLICATION OF THIN LIFTING SURFACE METHODS TO COMPUTING EFFECTS OF A VORTEX WAKE ON AN AIRCRAFT"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 204-213

An analysis has been performed of the effectiveness of two computational aerodynamics methods developed through thin lifting surface theory in both linear and nonlinear formulations for computing vortex wake effects on aircraft aerodynamic characteristics. The problem of determining the aerodynamic characteristics of an encountering aircraft has been solved within the vortex-wake 'frozen' parameter approximation, ignoring influence of the aircraft on the vortex wake structure. Verification of these numerical methods against experimental data obtained in low-speed wind-tunnels, allows one to determine their application areas as well as to direct possible ways to their improvement.

Mikhailov, Y. S. and Razdobarin, A. M.

"NUMERICAL ESTIMATION OF THE VORTEX WAKE EFFECT ON AIRCRAFT AERODYNAMIC CHARACTERISTICS"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 192-197

The algorithm for computing aircraft aerodynamic characteristics has been modified with the use of the combined vortex lattice method thus allowing the account for the vertical velocity component of the vortex wake generated behind a heavy aircraft. The algorithm modification consisted in the correction of local sectional angles of attack for the downwash induced by the vortex wake. The comparison between the computed results and wind-tunnel experimental data has shown satisfactory agreement of main aerodynamic characteristics of the aircraft model in the wake behind the differentially set airfoil lattice. Computations determine accurately enough the region of changing the sign of the rolling moment as a function of angle of attack due to flow separation from one of the half-wings.

Mikkelsen, T.

"ON MEAN WIND AND TURBULENCE PROFILE MEASUREMENTS FROM GROUND-BASED WIND LIDARS: LIMITATIONS IN TIME AND SPACE RESOLUTION WITH CONTINUOUS WAVE AND PULSED LIDAR SYSTEMS - A REVIEW"

2009 European Wind Energy Conference, March 2009, Marseille, France.

Two principal different coherent laser Doppler wind lidar anemometers have recently become available on the wind energy market for ground-based vertical mean and turbulence measurements. These two types of laser Doppler based wind lidars are: continuous wave (cw) wind lidars and pulsed wind lidars. Although built on the same recent communication technology 1.55-micron telecom fiber technology, there nevertheless exists some fundamental differences between the lidars temporal and spatial resolution capabilities that impacts on their mean wind and turbulence measurements in the atmospheric boundary layer and therefore also of relevance for the wind energy assessment studies, and other existing wind and turbulence research applications. The two lidar types spatial and temporal resolution characteristics is here reviewed as described in the literature and their influence on mean and turbulence profiles as measured from ground-based lidar platforms probing the atmospheric surface layer will be discussed. An intercomparison of the sounding volume characteristics with two specific commercially available wind lidars, one of cw type and one of pulsed type, is presented together with best estimates of these specific lidar systems optical parameters. The two specific wind lidar systems considered here are: the cw wind lidar ZephIR available from National Power U.K., and the pulsed wind lidar named WindCube, Leosphere, Fr..

"LIDAR-BASED RESEARCH AND INNOVATION AT DTU WIND ENERGY A REVIEW"

Journal of Physics, Conference Series, Vol. 524, 2014, pp. 012007-1 - 012007-16.

A brief account of the motivation leading to the development and testing of wind Lidars at DTU is given, followed by a summary of the ongoing investigations in the area of wind sensing and associated Lidar technologies. A new mobile research infrastructure WindScanner.dk has been developed, which measures wind and turbulence fields from sets of three simultaneously in space and time synchronized scanning lidars. One set consists of three fast scanning continuous-wave based wind lidars (short-range system), and another consisting of three synchronized pulsed wind lidar systems (long-range system). Since then, wind lidar profilers and WindScanners are routinely deployed and operated during field tests and measurement campaigns. Lidars have been installed and operated from ground, on offshore platforms, and also as scanning lidars integrated in operating turbines. As a result, wind profiles and also detailed 3D scanning of wind and turbulence fields have been achieved: 1) of the free wind aloft, 2) over complex terrain, 3) at coastal ranges with land-sea interfaces, 4) offshore, 5) in turbine inflow induction zone, and 6) of the complex and turbulent flowfields in the wakes inside wind parks.

Miklosovic, D. S.

"ANALYTIC AND EXPERIMENTAL INVESTIGATION OF DIHEDRAL CONFIGURATIONS OF THREE-WINGLET PLANFORMS"

J. Fluids Engineering, Vol. 130, July 2008, pp. 071103-1 - 071103-10

An analytic and experimental effort was undertaken to assess the effectiveness and efficiency of three winglets mounted chordwise to the tip of a rectangular wing. The winglets, with an aspect ratio of 4.6, were mounted on a half-span wing having an effective aspect ratio of 6.29. 13 configurations of varying dihedral arrangements were analyzed with a vortex lattice method and tested in a low-speed wind tunnel at a Reynolds number of 600,000. The analytic distributions of wake velocity, circulation, and downwash angle verified that highly nonplanar configurations tended to reduce and diffuse the regions of highest circulation and to create more moderate downwash angles in the wake. This was manifest as an overall drag reduction. More specifically, the results showed that the winglets could be placed in various optimum orientations to increase the lift coefficient as much as 65 percent at the same angle of attack, decrease the drag coefficient as much as 54 percent at the same lift coefficient, or improve the maximum L/D by up to 57 percent.

Miklosovic, D. S. and Bookey, P. M.

"AN ANALYTIC AND EXPERIMENTAL INVESTIGATION OF THE AERODYNAMIC PERFORMANCE ENHANCEMENTS OF MULTIPLE WINGLET CONFIGURATIONS"

2005 ASME Fluids Engineering Division Summer Meeting and Exhibition, FEDSM2005-77255, June 2005, Houston, TX

An experimental effort was undertaken to assess the effectiveness and efficiency of three winglets mounted chordwise to the tip of a rectangular wing (NACA 0018 section). The winglets, with an aspect ratio of 3.6, were mounted on a half-span wing having an aspect ratio of 3.1. Twenty configurations of varying dihedral arrangements were analyzed with a vortex lattice method and tested in a low-speed

wind tunnel at a Reynolds number of 600,000. In general, the arrangements involving high dihedral angles had lower performance increments, due to lower lift and higher interference drag. More specifically, the results showed that the winglets placed at 60, 45, and 30 degrees, respectively, produced nominal 4% higher lift and 46% lower drag. The most dramatic findings from this study show that positioning the winglet dihedral angles had the result of adjusting the point of maximum L/D and the magnitude of the pitching moment coefficient. These observations suggest that multiple winglet dihedral changes affect the lift, drag, and pitching moment in such a way that they are feasible for use as actively-controlled surfaces to improve the performance of aircraft at various flight conditions and to 'tune' the longitudinal stability characteristics of the wing.

Miksis, M. J.

"ON VORTICAL FLOW AND SOUND GENERATION"

SIAM Journal of Applied Mathematics, Vol. 50, No. 2, 2006, pp. 521-536.

The acoustic field induced by an unsteady vortical flow is analyzed. In particular, the limit where the reference length scale l of the vortical flow is much smaller than the reference length scale of the acoustic field is considered. At low Mach number M the leading-order solution of the vortical flow is an incompressible viscous flow. The far field behavior of the flow is matched to the five quadrupoles of the acoustic field and their strengths are related to linear combinations of second moments of vorticity. The compressibility effect of the vortical flow, of order M squared, induces an acoustic source which is of the same order as the quadrupoles. We also relate the strength of the acoustic source to the total dissipation energy of the incompressible vortical flow. Hence, if viscous effects are neglected, the acoustic source term will be absent. These results are applied to turbulent flows and their implications to the mean flow are discussed. The results are also employed to study the sound generated by the motion and decay of slender vortex filament(s).

"NEAR-WAKE MEASUREMENTS OF A DELTA WING IN A SUPERSONIC STREAM"

Journal of Aircraft, Vol. 38, No. 2, March-April 2001, pp. 315-325.

The near-wake region of a 75-deg sweptback delta wing was studied experimentally in a Mach 2.49 stream. Five-hole conical probe measurements were conducted vertically and horizontally through the primary vortices at the trailing edge and half-chord downstream of the planform for 7- and 12-deg angles of attack. The Mach number and pressure distribution profiles are summarized, and comparisons of flow properties at different survey stations are presented. A novel calibration approach using a three-dimensional Navier-Stokes solver to generate numerically the calibration data for a blunt-nosed five-hole conical probe over a range of Mach numbers and pitch angles was employed. The magnitude of the pitot, total, and static pressure deficits in the wake region increased with increasing angle of attack for the same measurement plane and decreased with the downstream distance. The swirl profiles have supersonic and high transonic peak magnitudes, and estimated core dimensions

suggest vortex stretching in the vertical direction and convection downstream. A decrease in the radial Mach number component confirms the vortex trajectory changes from a strong downward flow over the planform to a gradual return toward the freestream in the near wake. Unlike the experimental results from transonic and low-speed leading-edge vortices, the axial and total Mach number distributions in supersonic vortices are found to be wake like.

Miley, S. J.

"A CATALOG OF DEVICES APPLICABLE TO THE MEASUREMENT OF BOUNDARY LAYERS AND WAKES ON FLIGHT VEHICLES"

NASA CR-116776, January 1972, Mississippi State University, State College, Mississippi.

A literature search was conducted to assemble a catalog of devices and techniques which have possible application to boundary layer and wake measurements on flight vehicles. The indices used in the search were NACA, NASA, NASA STAR, IAS, USGRDR and Applied Science and Technology Index. The period covered was 1950 through 1970. The devices contained in the catalog were restricted to those that provided essentially direct measurement of velocities, pressures, and shear stresses. Pertinent material was included in the catalog if it contained either an adequate description of a device and associated performance data or a presentation of applicable information on a particular measurement theory and/or technique. When available, illustrations showing the configuration of the device and test condition data were also included.

"THEORETICAL AND EXPERIMENTAL INVESTIGATION OF THE INSTANTANEOUS INDUCED VELOCITY FIELD IN THE WAKE OF A LIFTING ROTOR"

USAAVLABS TR-67-68, January 1968, Dynasciences Corp., Blue Bell, PA

Measurements have been made of the instantaneous and time-averaged values of the induced velocities in the wake of a full-scale helicopter in actual steady flight conditions. Simple, analytical methods are formulated to predict the instantaneous and time-averaged, induced velocities in the rotor wake. Calculated values of the induced velocities are compared with the experimental data, and agreement is obtained for the hovering flight condition.

"ANALYTICAL STUDY OF CONDENSING TRAILING VORTEX BEHIND A PASSENGER AIRCRAFT AT SEA LEVEL"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 375-388

Within the framework of analytical approaches, a problem is solved on a condensing viscous vortex which simulates the trailing vortex behind the aircraft of the Boeing 747 type, flying at sea level. A parametric study was carried out of the condensation region and a simple formula for the 'dew surface', which bounds it, is obtained asymptotically. Along with the Eulerian description of the droplet fraction dynamics, the Lagrangian approach to the problem on droplet motion along the trajectories of air particles was used. Self-similar solutions of the problem are constructed within the Eulerian approach. Eventually, spatial relationships for optical scattering cross-sections of elementary flow volumes are obtained which are of interest in terms of aircraft wake vortex visualization.

"AN ACCURATE METHOD OF MEASURING THE MOMENTS OF INERTIA OF AIRPLANES"

NACA Technical Note No. 351, October 1930, Langley Aeronautical Laboratory, Langley Field, VA.

This note contains a description of an improved apparatus and procedure used by the NACA for determining the moments of inertia of airplanes. The method used, based on the pendulum theory, is similar to that previously used, but a recent investigation of its accuracy has resulted in the improvements described herein. The error, when using the new apparatus and procedure, has been found to be of the order of 1 per cent.

"FEATURES OF ATMOSPHERIC TEMPERATURE PROFILING IN POLAR REGIONS"

9th International Symposium on Tropospheric Profiling (ISTP), September 2012, University of L'Aquila, L'Aquila, Italy.

The most important part of the investigation of climate and meteorological conditions in Polar Regions is the monitoring of atmospheric boundary layer (ABL) parameters. Characteristic feature of the atmospheric boundary layer in polar latitudes is the presence of strong temperature inversions which are important for interactions with radiation cooling processes, advection of warm air and katabatic winds. In this connection the scientists of Central Aerological Observatory jointly with the specialists from the Radiophysical Research Institute in the end of the '90th years of the last century designed the remote method of measuring temperature profiles of ABL based on measurements of self-emitting heat radiation of atmosphere on frequency near 60 GHz. The evolution of the equipment based on experiences and results of temperature profiles measurements with the use of polar version of microwave profilers in 2000-2012 are presented in the report.

"TURBULENT STRUCTURES IN THE TRAILING VORTEX WAKE OF A DELTA WING"

10th Turbulent Shear Flow Conference, August 1995, University Park, PA.

In the present study we investigate the near and far wake instabilities in the wake of a delta wing with a view to understanding the basic instabilities, mixing, and decay rate of the wake. Extensive visualization of the wake as a delta wing glides in free-flight through water reveals a 'braid wake' between the primary vortex pair and shows it imposing its structure on the primary pair. Hot wire measurements of the fluctuating velocity in the immediate near wake demonstrate the periodic shedding of the spanwise vortices in this 'braid wake' but also reveal a low-frequency oscillation nearer to the core of each primary vortex. The subsequent evolution of the wake is remarkable, as the scales of disturbances grow in what appear to be almost discrete steps, until a large-scale instability of the primary pair develops into a sequence of large-scale interconnecting vortex loops. Ultimately, the appearance is similar to a series of vortex rings. The streamwise wavelength of the ring-like structure was measured for these free-flight tests and for tests with the wing towed through water at a variety of speeds and angles of attack, yielding a wavelength between 4 and 5 spans (inter-vortex spacing of the primary pair). Further investigation is required before the relationship of these results to theoretical analyses can be ascertained. Experiments in which the incident velocity is perturbed at selected frequency and amplitude reveal that the wavelength of the final structure is reasonably insensitive to either parameter, unless the forcing becomes as large as 5% of free-stream velocity, also provided the forcing wavelength is far from the natural wavelength. While investigating the vertical mixing of the fluid due to the convecting vortices we found that the vertical extent of mixing is surprisingly large due to the formation of a 'curtain' of vortical fluid left above the descending vortex pair.

Miller, G. D. and Williamson, C. H. K.

"TURBULENT STRUCTURES IN THE TRAILING VORTEX WAKE OF A DELTA WING"

Experimental Thermal and Fluid Science, Vol. 14, 1997, pp. 2-8

In the present study, we investigate the near- and far-wake instabilities in the wake of a delta wing with a view to understanding the basic instabilities, mixing, and decay rate of the wake. Extensive visualization of the wake as a delta wing glides in free flight through water reveals a 'braid wake' between the primary vortex pair and shows it imposing its structure on the primary pair. Hot-wire measurements of the fluctuating velocity in the immediate near wake not only demonstrate the periodic shedding of the spanwise vortices in this 'braid wake' but also reveal a low-frequency oscillation nearer to the core of each primary vortex. The subsequent evolution of the wake is remarkable, as the scales of disturbances grow in what appear to be almost discrete steps, until a large-scale interconnecting vortex loops. Ultimately, the appearance is similar to a series of vortex rings. The streamwise wavelength of the ring-like structure was measured for these free-flight tests and for tests with the wing towed through water at a variety of speeds and angles of attack, yielding a wavelength between 4 and 5 spans (intervortex spacing of the primary pair). Further investigation is required before the relation of these results to theoretical analyses can be ascertained. Experiments in which the incident velocity is perturbed at selected wavelength and amplitude reveal that the wavelength of the final structure is reasonably insensitive to either parameter unless the forcing becomes as large as 5% of free-stream velocity, provided the forcing wavelength is far from the natural wavelength. While investigating the vertical mixing of the fluid due to the descending vortices, we found that the vertical

extent of mixing is surprisingly large owing to the formation of a 'curtain' of vortical fluid left above the descending vortex pair.

"AIRCRAFT TAKEOFF CHARACTERISTICS"

DOT-VNTSC-FA127-PM-01-37, August 2001, Volpe Center, Cambridge, MA

The document investigates three essential characteristics of takeoff: rotation point, liftoff point, and takeoff angle. Distributions of the data are provided and analyzed. Trends in the data can be used to find the ideal location for wake vortex measuring equipment.

Miller, R. H.

"METHODS FOR ROTOR AERODYNAMIC AND DYNAMIC ANALYSIS"

Progress in Aerospace Sciences, Vol. 22, 1985, pp. 113-160.

The complex problems associated with the aerodynamics of blade/vortex interactions, the dynamics of a blade displaced out of its plane of rotation, and the position control of a hovering helicopter are discussed. Simplified models help to describe, and appear to be adequate for analyzing, many aspects of these problems. Free wake analyses are shown to be of importance in determining blade loads and performance for hovering flight or for wind turbines. Unsteady aerodynamics and careful definition of the wake formation are required when computing vibratory air loads in forward flight.

Miller, R. H.

"VORTEX THEORY FOR HOVERING ROTORS"

AIAA Journal, Vol. 20, December 1982, pp. 1754-1756.

The apparent paradox resulting from the application of classical propeller vortex theory to a hovering rotor is shown to be due to the neglect of wake contraction. When wake contraction is included, simple models may be developed which are able to accurately predict blade load distributions and wake geometries to a reasonable degree of accuracy.

Miller, T. S., Kliment, L. K. and Rokhsaz, K.

"DYNAMICS OF COROTATING VORTEX FILAMENTS PART 1: ANALYTICAL MODEL"

Journal of Aircraft, Vol. 43, No. 5, September-October 2006, pp. 1434-1439.

The interactions between two corotating vortex filaments of equal strength are investigated analytically. The Biot-Savart law is used to develop the equations of motion of the filaments, consistent

with Crow's formulation. Consistent with previous work, two modes of motion are defined and analyzed for stability. It is demonstrated that the mutual induction between the vortices leads to unstable motion of the filaments in the antisymmetric mode over a significant range of frequencies. Furthermore, the oscillatory motion of the filaments is proven to have a preferred direction.

Miller, T. S., Kliment, L. K. and Rokhsaz, K.

"ANALYTICAL INVESTIGATION OF CO-ROTATING VORTEX FILAMENTS WITH EXPERIMENTAL VERIFICATION"

AIAA Paper No. 2003-3601, Monterey, CA, May 2003.

The interactions between two co-rotating vortex filaments are investigated analytically. The Biot-Savart law is used to develop the equations of motion of the filaments, consistent with Crow's formulation. It is demonstrated that the mutual induction between the vortices leads to unstable motion of the filaments over a wide range of frequencies. Furthermore, the oscillatory motion of the filaments is proven to have a preferred direction. This behavior is demonstrated through comparison with experimental results obtained in a water tunnel.

Milluzzo III, J. I.

"CONTRIBUTIONS TOWARDS THE DETAILED UNDERSTANDING OF ROTOR FLOW FIELDS IN GROUND EFFECT OPERATIONS"

PhD Thesis, 2014, University of Maryland, College Park, MD.

High-speed flow visualization and high-resolution particle image velocimetry experiments were conducted on a two-bladed rotor that was operated in a hovering state, both out of ground effect (well away from the ground) and in ground effect at several rotor heights. Recent advances in flow diagnostic instrumentation allowed measurements of the rotor wake to be performed with unprecedented levels of resolution. In particular, the goal of the present work was to gain a better understanding of the fluid dynamics of the wake sheets (and the blade tip vortices) that were trailed from the blades. The present work examined the effects produced by two blade sets: 1. A baseline untwisted blade, 2. A twisted blade with -17 degrees of linear twist, and has revealed fluid dynamic details of the wake sheet that were hitherto unknown. For the measurements made with the rotor operating out of ground effect, the blade sets were tested at two blade loading coefficients of 0.053 and 0.08, although only the higher loading condition was tested with the rotors operating in ground effect. For the rotor operating out of ground effect, a helicoidal tip vortex was shown to form at the blade tip and the associated wake sheets were initially laid down as small-scale counterrotating vortical pairs. However, this initial vorticity quickly diffused and the sheet was then convected as concentrated bands of turbulence, including several dominant eddies. Several types of sheet dynamics were documented in the rotor wake, including sheet interactions with the tip vortices, the detailed behavior of this interaction depending on both the blade twist and the rotor thrust. At earlier wake ages, a sinusoidal wave-like perturbation was seen to be formed on the wake sheets, although the growth in

wave amplitude was limited as the sheets were convected and stretched in the velocity gradients in the downstream wake. When the rotor was operated in ground effect, the vorticity in the wake sheets persisted to much older wake ages. Wave-like perturbations did not form on the wake sheets when the rotors were operating in ground effect because the outward radial stretching of the rotor wake in the presence of the ground suppressed their development. The wake sheets were found to convect to the ground and introduce significant vorticity into the near-wall flow field closer to the rotor, contributing to fluctuations in the local flow velocities. The flow field near the ground was also observed to be significantly affected by the use of twist on the blade, with the wake impinging on the ground further inboard and closer to the rotor, which also resulted in higher flow velocities being produced further downstream.

Milluzzo III, J. I. and Leishman, J. G.

"VORTICAL SHEET BEHAVIOR IN THE WAKE OF A ROTOR IN GROUND EFFECT"

AIAA Journal, Vol. 55, No. 1, January 2017, pp. 24-35.

Particle image velocimetry measurements with high spatial resolution were conducted on a hovering two-bladed rotor system operating in ground effect above a planar surface. The objective was to gain a better understanding of the fluid dynamics of the wake sheets trailed behind rotating blades, with specific focus on their contribution to the development of the near-wall flowfield at the ground plane. Two blade sets were tested: 1) a baseline untwisted blade and 2) a twisted blade with 17 degrees of nose-down linear twist. Planar particle image velocimetry measurements were made for multiple regions of interest in the rotor wake to understand the temporal development of the wake sheets as they convected from their origin at the trailing edges of the blades until they interacted with the ground. The wake sheets were shown to contain relatively large amounts of concentrated vorticity, which persisted much longer in the wake than for the corresponding out of ground effect case. The wake sheet substantially influenced the nature of the developing flow over the ground, resulting in relatively large and higher transient excursions in the near-wall flow velocities further inboard and closer to the rotor. Performance measurements were also taken for both blade sets at various heights above the ground, with the untwisted blades showing the most significant increase in performance.

Milluzzo III, J. I. and Leishman, J. G.

"QUANTIFICATION OF THE EVOLUTION OF THE VORTICAL SHEETS IN THE WAKE OF A HOVERING ROTOR"

AIAA Paper 2014-3256, June 2014, Atlanta, GA.

High-resolution particle image velocimetry (PIV) measurements were conducted on a two-bladed rotor that was operated in the hovering state over a ground plane. Two blade sets were tested: 1. A baseline untwisted blade, 2. A twisted blade with about 17 degrees of linear twist. PIV measurements were made for multiple regions of interest in the rotor wake to understand the development and evolution of the wake sheets as a function of their age. Each blade set was tested at the same rotor

thrust and blade loading coefficient, both in and out of ground effect. The initial vorticity trailed into the wake sheets behind the blades was shown to be comprised of small pairs of counterrotating vortices of unequal strength. These wake sheets contained relatively large amounts of concentrated vorticity at early wake ages, with the rotor with the twisted blades having a somewhat stronger wake sheet overall. The concentrated vorticity quickly diffused into smaller scale eddies and turbulence as the sheets convected downstream in the rotor wake, but these structures were found to persist to relatively old wake ages and as far as the ground plane, which significantly affected the flow environment there.

"EXPERIMENTAL INVESTIGATION ON THE EFFECT OF FREE STREAM TURBULENCE ON WINGTIP VORTICES"

AIAA Paper 2017-3037, June 2017, Denver, CO.

The interaction of a wingtip vortex with atmospheric Free Stream Turbulence (FST), a phenomenon that prevails in airport runways, may alter its trajectory and its strength downstream. This work is an experimental investigation on the effects of FST on the evolution and the wanderings of a wingtip vortex in the wake of a NACA0012 wing at an AOA of 5 deg. The measurements were conducted using a Stereoscopic PIV at a Reynolds number, Re , based on the chord of 200,000. FST intensities of 0.5 percent, 3 percent and 6 percent were selected. Measurements in the wake at $x/c=0.5, 2.5, 5$, and 7 show that the FST contributes to the vortex decay namely by decreasing the velocity deficit in the vortex core region. FST decreased circulation, increased the circumferential velocity peak decay and increased meandering amplitude.

"MODIFIED HYBRID NAVIER-STOKES/FREE-WAKE METHOD FOR HOVERING ROTOR ANALYSIS"

Journal of Aircraft, Vol. 55, No. 1, January-February 2018, pp. 38-51.

The analysis of rotors in hover has always been a significant challenge. The presence of strong vortices underneath the rotor requires a large amount of grid points to properly capture the vorticity, and many time steps are required to reach a time-independent state. To bring the simulation cost to a more practical state for industry, a modified hybrid Navier-Stokes/free-wake method has been introduced, which successfully reduced grid count and simulation time by one order of magnitude compared to full Navier-Stokes simulations. In this hybrid method, Navier-Stokes and free-wake solvers are loosely coupled for fast convergence in hover. The S-76 model-scale blades with three tip designs were studied to assess current approaches. The proposed approaches showed reasonable-to-good correlation with measured figure of merit, thrust, and torque data. The effects of tip-design and tip-speed variations were captured well. The physical mechanisms of tip-design impact on hover performance were also studied.

Min, B.-Y., Reimann, C. A., Wake, B. E., Jee, S. and Baeder, J. D.

"HOVERING ROTOR SIMULATION USING OVERFLOW WITH IMPROVED TURBULENCE MODEL"

AIAA Paper 2018-1779, January 2018, Kissimmee, FL.

A transition model coupled with Spalart-Allmaras turbulence model has been recently developed and implemented to OVERFLOW solver. The Delayed Detached Eddy Simulation method in the OVERFLOW also has been modified with improved boundary layer shielding function and modified length scale definition. In this study, OVERFLOW with the improved turbulence model has been validated with simple 2D flat plate, SC-1095 airfoil, and S-809 airfoil. The validation showed good transition prediction and improved airfoil drag and stall angle prediction. Then, the model has been assessed for hovering rotor performance prediction. The selected rotor is the model scale S-76 rotor with swept-tapered tip. Fully turbulent simulation under-predicted the rotor Figure of Merit. Without known freestream turbulence intensity level, variation has been made from 0.5% to 2% intensity level to demonstrate the impact of transition to hover performance. The result showed performance increase significant enough to cover the error between measured data and fully turbulent simulation. The added DDES model slightly lowered the hover performance prediction with current grid.

Miranda, J. A.

"THE STRUCTURE OF A TRAILING VORTEX WAKE"

MS Thesis, May 1996, Virginia Polytechnic Institute and State University, Blacksburg, VA.

Experiments have been performed in the spiral wake that surrounds the vortex shed from the tip of a rectangular NACA 0012 half wing. Both single-point and simultaneous two-point hot-wire measurements were made ten chord lengths downstream of the wing at a Reynolds number of 320,000. The structure of this flow consists of a small concentrated vortex core, surrounded by a circulating velocity field that winds the wake into a spiral about the core. Small amplitude wandering motions of the core were detected and quantitative estimates of the wandering amplitude and its contributions to the Reynolds stress fields were found. Outside of the core region the turbulence structure is dominated by this spiral wake. The maximum turbulence levels exist in the part of the wake that begins to spiral about the core. The 3-D region is the region where the wake is wound about the vortex and the 2-D region is the nearly two-dimensional portion of the wake inboard of the wing-tip. The stresses in the 3-D region, when scaled on local length and velocity scales, increase significantly over those in the 2-D region. This increase is presumably a consequence of the additional rates of strain imposed on the wake by the vortex. Stretching intensifies turbulent structures aligned with the stretching direction. Two-point measurements were made in the 2-D and 3-D regions of the wake to reveal the spanwise extent of the instantaneous turbulent structures in the wake. A high correlation was found at the smallest probe separations. There are stronger correlations and coherence in the 3-D region than in the 2-D region. Correlation length scales and coherence were found to increase significantly from the 2-D region to the peak turbulence region. This reveals that the stretching and additional rates of strain imposed on the wake by the vortex are organizing the spanwise turbulent structures.

"TURBULENCE STRUCTURE IN THE SPIRAL WAKE SHED BY A LIFTING WING"

AIAA Journal, Vol. 36, No. 4, April 1998, pp. 658-660

Velocity measurements have revealed in detail the structure of a spiral wake surrounding a wing-tip vortex. The tip vortex stretches, skews, and curves the wake. As the wake winds around the vortex, lateral stretching dramatically thins and weakens it, reducing the local wake half width and peak axial vortex deficit to about one third of their values in the two-dimensional region. The weakening of the wake influences turbulence stress profiles, all of which show much smaller stress levels in the tightly wound part of the spiral wake than in the two-dimensional region. The stretching also acts directly on the turbulence, producing significant anisotropy among the normal turbulence stresses. The damping effects of the stretching are to some small extent counteracted by skewing of the wake in the vortex tangential velocity field and under the action of its own embedded vorticity. The skewing gives rise to significant crossflow turbulence shear stress. Lateral curvature also plays a role, introducing asymmetry into the turbulence stress profile of the wake.

Miranda, J. A. and Devenport, W. J.

"TWO-POINT MEASUREMENTS IN TRAILING VORTICES"

AIAA Paper No. 1996-0804, Reno, NV, January 1996

Experiments have been performed in the spiral wake that surrounds the vortex core which is shed from the tip of a rectangular NACA 0012 half wing. The structure of this flow consists of a small concentrated vortex core, surrounded by a circulating velocity field that winds the wake into a spiral about the core. Small amplitude wandering motions of the core were detected. Quantitative estimates of the wandering amplitude and its contributions to the Reynolds stress fields were found. Outside of the core region the turbulence structure is dominated by this spiral wake. The maximum turbulence levels exist in the region of the wake that begins to spiral about the core. Two-point measurements were made in the 2-D and 3-D regions of the wake to reveal the spanwise extent of the instantaneous turbulent structures in the wake. A high correlation was found at the smallest probe separations. StroSreedharnger correlations and coherence in the 3-D region than in the 2-D region reveal that the three-dimensionality is organizing the spanwise turbulent structures.

"THE CALCULATION OF SUPERSONIC DOWNWASH USING LINE VORTEX THEORY"

J. Aeronautical Sciences, Vol. 17, No. 1, January 1950, pp. 13-21

A straightforward procedure, based on lifting-line theory, is presented for obtaining the downwash behind lifting surfaces at supersonic speeds. The customary assumptions of an inviscid fluid and small

perturbation velocities are made. In particular, the vortex field associated with a supersonic lifting surface is examined; the vertical perturbation velocity field due to a line vortex segment of constant slope is presented in explicit form and is utilized to discuss some of the properties of line vortices in a supersonic free stream; and a bent lifting-line method and an unbent lifting-line method (horseshoe vortex system) are proposed for determining the downwash field behind swept and unswept wings, respectively. The lifting-line methods are applied to triangular and rectangular wings and give results that are in close agreement with the exact linearized solutions.

Mirels, H. and Haefeli, R. C.

"LINE-VORTEX THEORY FOR CALCULATION OF SUPERSONIC DOWNWASH"

NACA TN-1925, August 1949, NACA Lewis Flight Propulsion Lab., Cleveland, OH

The perturbation field induced by a line vortex in a supersonic stream and the downwash behind a supersonic lifting surface are examined for the purpose of establishing approximate methods for determining the downwash behind supersonic wings. Lifting-line methods are presented for calculating supersonic downwash. An unbent lifting line (horseshoe-vortex system) is used to compute the downwash behind rectangular and triangular wings and the results are compared with the exact linearized solutions. The chordwise position of the lifting line giving the best average agreement with the exact solution is noted for each wing. A bent lifting line is used to approximate the triangular wing, and the results are in good agreement with the exact solution except for points within 1/2 chord of the wing trailing edge. The use of a bent lifting line seems promising for obtaining accurate estimates of the downwash behind swept wings.

Mironer, A.

"ACCELERATED DIFFUSION OF WING TIP VORTICES BY HEATING"

AIAA Paper No. 1971-0616, Palo Alto, CA, 1971

This paper describes the effects of heating on the vorticity diffusion rate in a gas vortex. The heating causes an outward radial convection and an increased kinematic viscosity which greatly enhances the overall rate of vorticity diffusion from the core. The coupled heat conduction and fluid dynamical equations which describe the vortex heating process have been solved on a digital computer using a finite difference technique. For an initial temperature ratio between the outside induced region of the vortex and core of 2:1, the vorticity diffusion rate is very nearly twice as fast as in a vortex with no heating present.

"LARGE EDDY SIMULATION OF WAKE VORTICES IN GROUND EFFECT WITH REALISTIC TERRAIN AROUND AIRPORT"

AIAA Paper 2017-4371, June 2017, Denver, CO.

We conducted large eddy simulation of wake vortices in ground effect with realistic terrain around an airport focusing on the airport specific behavior of wake vortices. We considered here a landing aircraft at Tokyo/Haneda Airport in Japan. We developed a framework for a distributed parallel computer that enables dynamic data management for load balancing and flow adaptive mesh refinement for wake vortex. The impact of a crosswind over airport buildings was only qualitatively evaluated so far by visualized images.

Misaka, T. and Obayashi, S.

"NUMERICAL STUDY ON JET-WAKE VORTEX INTERACTION OF AIRCRAFT CONFIGURATION"

Aerospace Science and Technology, Vol. 70, 2017, pp. 615-625.

The interaction of aircraft exhaust jet and wake vortex generated from a realistic aircraft configuration was numerically studied from the early phase until the complete roll-up. For numerical simulation we employed an unstructured mesh Reynolds-averaged Navier-Stokes (RANS) solver for the flow around an aircraft model, while a Cartesian mesh large-eddy simulation solver implemented on the framework of the building-cube method (BCM) was used for the simulation of the mid- to far-field wake. We especially investigated the feasibility of a coupling approach of the steady RANS solver and the Cartesian LES solver in the simulation of the jet-wake vortex interaction, where unsteady velocity fluctuations are stochastically reproduced based on RANS turbulence variables. The results showed that a multi-level Cartesian mesh of the BCM was effective to capture the evolution of aircraft wake including exhaust jet. The velocity profiles of a wake vortex are compared with several vortex models, which reveals that the velocity profiles fit with different vortex models depending on the vortex ages. The normalized temperature of exhaust jet is compared with the experiment, which confirms that the temperature information is appropriately transferred from the near- to far-field simulation.

"WAKE EVOLUTION OF HIGH-LIFT CONFIGURATION FROM ROLL-UP TO VORTEX DECAY"

AIAA Paper 2013-0362, January 2013, Grapevine, TX.

The development of aircraft's wake in high-lift configuration is studied from the roll-up until vortex decay. An aircraft model and the surrounding flow field obtained from high-fidelity Reynolds-averaged Navier-Stokes simulation are swept through a ground-fixed computational domain to initialize the wake. After the wake initialization, the large-eddy simulation (LES) of the vortical wake is performed until vortex decay. In this paper we consider an aircraft model in high-lift configuration where flaps and slats are deployed. In a few wingspan lengths downstream, the complex vorticity structures of the aircraft wake focus on co-rotating vortex pairs originated from wing- and flap-tips. The co-rotating vortex pairs merge at $t\text{-star} = 0.25$ and a common counter-rotating vortex pair is formed at around $t\text{-star} = 1.0$ entraining the turbulent aircraft wake into the vortex system. The rolled-up vortex features axial velocity in the vortex core with a magnitude of a half of the maximum tangential velocity.

Behavior of the formed vortex pair is like that of a vortex pair defined by a vortex model such as the Lamb-Oseen model. The initial descent speed of the vortices is slightly faster than that of the reference descent speed, i.e., $w = 1.1 w_{\text{zero}}$. In addition, it is confirmed that the ambient turbulence accelerates vortex linking and decay as in the case of a coherent vortex pair. The overall behavior of wake vortices is not affected by the different mesh resolutions considered here, except for vortex core radius.

Misaka, T., Holzaepfel, F. and Gerz, T.

"LARGE-EDDY SIMULATION OF AIRCRAFT WAKE EVOLUTION FROM ROLL-UP UNTIL VORTEX DECAY"

AIAA Journal, Vol. 53, No. 9, September 2015, pp. 2646-2670.

The evolution of aircraft wake vortices from the roll-up until vortex decay is studied by large-eddy simulation. An aircraft model and the surrounding flow field obtained from high-fidelity Reynolds-averaged Navier-Stokes simulations are swept through a ground-fixed computational domain to initialize the wake. After the wake initialization a large-eddy simulation of the vortical wake is performed until vortex decay. In this paper the methodology is tested with a NACA 0012 wing and applied to the DLR-F6 wing-body model in cruise condition and a long-range aircraft model in high-lift configuration which was used in the European Aircraft Wing with Advanced Technology Operation project. The correlation between the detailed roll-up process of the vorticity sheet shedding from the main wing and the characteristics of the rolled-up vortex pair such as vortex circulation, core radius, and separation is investigated with and without ambient turbulence. In both the DLR-F6 wing-body and the long-range aircraft models, the behavior of the formed vortex pair appears similar to that of a vortex pair defined by an analytical vortex model including the impact of ambient turbulence on vortex linking and decay. The velocity profile of a fully rolled-up vortex pair at around $t^* = 1.0$ agrees well with the Rosenhead-Burnham-Hallock vortex model.

Misaka, T., Holzaepfel, F. and Gerz, T.

"WAKE EVOLUTION OF WING-BODY CONFIGURATION FROM ROLL-UP TO VORTEX DECAY"

AIAA Paper No. 2012-0428, January 2012, Nashville, Tennessee.

The development of aircraft's wake vortex from the roll-up until vortex decay is studied. An aircraft model and the surrounding flow field obtained from high-fidelity Reynolds-averaged Navier-Stokes simulation are swept through a ground-fixed computational domain to initialize the wake. After the wake initialization, the large-eddy simulation of the vortical wake is performed until vortex decay. The methodology is tested with the NACA0012 wing and applied to the DLR-F6 wing-body model. The roll-up process of the vorticity sheet from a main wing and the merge of an inboard wing vortex into the wingtip vortex are simulated. Vortex parameters such as the radially averaged circulation, vortex core radius and vortex separation are also evaluated. The growth rate of the vortex core radius is relatively small during the roll-up where the fine mesh resolution in the LES is required to capture the tiny vortex core in the RANS simulation.

Misaka, T., Holzaepfel, F., and Gerz, T.

"LARGE-EDDY SIMULATION OF SPATIALLY DEVELOPING AIRCRAFT WAKE"

Eight International Conference on Flow Dynamics, November 2011, Sendai, Japan, pp. 274-275.

Development of aircraft's wake vortex from the roll-up until vortex decay is studied. An aircraft model and a surrounding flow field obtained from high-fidelity Reynolds Averaged Navier-Stokes simulation are swept through a ground fixed computational domain to initialize the wake. After initialization, large-eddy simulation of the vortical wake is performed until vortex decay, i.e., 2-3 minutes after the passage of aircraft. Here, the methodology and some results from the simulations using the DLR-F6 wing-body model are presented.

Misaka, T., Holzaepfel, F., Gerz, T., Manhart, M. and Schwertfirm, F.

"LARGE-EDDY SIMULATION OF WAKE VORTEX EVOLUTION FROM ROLL-UP TO VORTEX DECAY"

AIAA Paper No. 2011-1003, January 2011, Orlando, FL.

Large-eddy simulation (LES) of wake vortex evolution from vortex generation until decay is performed by combining Reynolds-averaged Navier-Stokes (RANS) simulation and LES. An aircraft model and a surrounding flow field obtained from high-fidelity RANS simulation are swept through a ground fixed computational domain to initialize the wake. After the initialization, time integration of the wake is performed until vortex decay (2-3 minutes). The present paper describes the approach and some results from the simulations where the aircraft is represented by the DLR-F6 wing-body model. The results show that moderate mesh resolution in the wake initialization phase results in lower vortex circulation of wake vortex after roll-up, although the overall distribution of vorticity is not sensitive to the mesh resolution. Boundary condition in the flight direction is one of the key points to continue the time integration of wake vortex after its initialization. Periodic boundary conditions used in this study induce disturbances propagating from boundaries into the computational domain, which leads to faster decay of wake vortex.

Misaka, T., Holzaepfel, F., Hennemann, I., Gerz, T., Manhart, M. and Schwertfirm, F.

"VORTEX BURSTING AND TRACER TRANSPORT OF A COUNTER-ROTATING VORTEX PAIR"

Physics of Fluids, Vol. 24, 2012, pp. 025104-1 - 025104-21.

Large-eddy simulations of a coherent counter-rotating vortex pair in different environments are performed. The environmental background is characterized by varying turbulence intensities and stable temperature stratifications. Turbulent exchange processes between the vortices, the vortex oval, and the environment, as well as the material redistribution processes along the vortex tubes are investigated employing passive tracers that are superimposed to the initial vortex flow field. It is revealed that the vortex bursting phenomenon, known from photos of aircraft contrails or smoke visualization, is caused by collisions of secondary vortical structures traveling along the vortex tube which expel material from the vortex but do not result in a sudden decay of circulation or an abrupt

change of vortex core structure. In neutrally stratified and weakly turbulent conditions, vortex reconnection triggers traveling helical vorticity structures which is followed by their collision. A long-lived vortex ring links once again establishing stable double rings. Key phenomena observed in the simulations are supported by photographs of contrails. The vertical and lateral extents of the detrained passive tracer strongly depend on environmental conditions where the sensitivity of detrainment rates on initial tracer distributions appears to be low.

"MEASUREMENT-INTEGRATED SIMULATION OF WAKE TURBULENCE WITH FOUR-DIMENSIONAL VARIATIONAL METHOD"

Bulletin of the Japan Society for Industrial and Applied Mathematics, Vol. 19, Issue 3, 2009, pp. 150-162.

Realistic retrieval of aircraft wake turbulence at an airport is not straight-forward due to the difficulty in incorporating actual conditions such as an atmospheric boundary layer and a flight trajectory into the numerical simulation. In this study, the numerical simulation of wake turbulence is performed by integrating lidar measurements at Sendai airport. The four-dimensional variational method is employed for the integration with taking an actual measurement process into consideration. The behavior of wake turbulence under realistic wind conditions is shown after the discussion regarding the convergence of a retrieved flow field.

"UNCERTAINTY QUANTIFICATION OF LIDAR-DERIVED WAKE VORTEX PARAMETERS WITH/WITHOUT DATA ASSIMILATION"

AIAA Paper 2016-3271, June 2016, Washington, DC.

In this study, the uncertainty quantification of wake vortex parameters measured by a Doppler lidar is conducted to assess the errors of the lidar-derived parameters due to the measurement process. We employ three methods to estimate vortex parameters from lidar measurements: a simple method to detect velocity peaks on the measurement plane, and a least-square fitting of a vortex model to lidar velocity. In addition, wake vortex parameters along with a surrounding wind field are estimated based on the four-dimensional variational (4D-Var) method assuming a velocity field obtained by the Rosenhead-Burnham-Hallock vortex model. With the last approach, vortex parameters are obtained considering the factors such as insufficient resolution in the line-of-sight direction and vortex movement during a laser scan. It is confirmed from numerical experiments that the average circulation is significantly underestimated and core radius becomes too large with the simple method. The least-square fitting reduces the deviation of output/input parameter ratios. On the other hand, vortex parameters estimated with the help of the 4D-Var method are further improved by compensating the errors due to the measurement process.

Misaka, T., Obayashi, S., Stephan, A., Holzaepfel, F. and Gerz, T.

"SENSITIVITY ANALYSIS OF WAKE VORTEX PARAMETERS MEASURED BY DOPPLER LIDAR"

AIAA Paper 2015-3023, June 2015, Dallas, TX.

In this study, the sensitivity analysis of wake vortex parameters measured by a Doppler lidar is conducted to assess the errors due to the measurement process. To reduce the uncertainty caused by the measurement process as possible, wake vortex parameters along with a surrounding wind field are estimated based on the four-dimensional variational (4D-Var) method assuming a velocity field obtained by the Rosenhead-Burnham-Hallock vortex model. With this approach, vortex parameters are obtained considering the factors such as insufficient resolution in the line-of-sight direction and vortex descent during a laser scan. It is confirmed from numerical experiments that the average circulation is significantly underestimated when it is derived from the lidar measurement, while vortex core radius becomes too large in the lidar measurements. On the other hand, vortex parameters estimated with the help of the 4D-Var method appear sharply by compensating the errors due to the measurement process.

"NUMERICAL SIMULATION OF JET-WAKE VORTEX INTERACTION"

AIAA Paper 2014-0926, January 2014, National Harbor, MD.

The interaction of aircraft jet exhaust and wake vortex is numerically studied. Following the preceding numerical study of wake vortex evolution from roll-up until vortex decay, we aim to simulate the jet-vortex interaction from the early phase until the complete roll-up. For numerical simulation we employ an unstructured mesh Reynolds-averaged Navier-Stokes (RANS) solver for the near-field including the boundary layer around an aircraft, while a Cartesian mesh large-eddy simulation (LES) solver implemented on the framework of the Building-Cube Method (BCM) is used for the mid- to far-field wake development. Here we investigate a coupling approach of the above solvers to simulate the initial phase of jet exhaust and aircraft wake. The results show that a multi-level Cartesian mesh of the BCM is effective to capture the fine structure of aircraft wake including jet exhaust.

"INTEGRATED SIMULATION OF WAKE TURBULENCE USING LIDAR MEASUREMENT"

5th World Congress on Computational Methods in Applied Sciences and Engineering (ECCOMAS), Venice, Italy, July 2008

The Electric Navigation Research Institute set a lidar system for wake turbulence measurements at Sendai Airport in Japan. From the viewpoint of the understanding of flow structure of wake turbulence, however, there are some drawbacks such as the lack of spatial resolution in the line-of-sight (LOS) direction and the difficulty in tracking tip vortices for long periods due to the disturbance of ambient wind. The lidar measurement at Sendai Airport is averaged every 30 m in the LOS direction.

This limitation is especially unfavorable because the core diameter of the wake vortex is in the order of several meters. For the consideration of an actual atmospheric condition in the numerical simulation, the present study attempts to integrate lidar measurements into the numerical simulation using data assimilation technique. Specifically, four-dimensional variational (4D-Var) method was applied to integrate lidar measurements with the three-dimensional computational fluid dynamics simulation, in which actual scanning processes of the lidar was simulated as a measurement operator of the 4D-Var method. And a bogus vortex technique was adopted to ensure the existence of a vortex pair in the flow field. The validation of the method was performed by idealized test cases using 'virtual' lidar measurement which was produced by the reference simulation of a vortex pair. Then, the method was applied to actual lidar measurements at Sendai Airport.

"MEASUREMENT-INTEGRATED SIMULATION OF WAKE TURBULENCE"

AIAA Paper No. 2008-466, Reno, NV, January 2008

Large eddy simulation of wake turbulence was performed by integrating the lidar measurements. Four-dimensional variational method was applied to integrate lidar measurements with the three-dimensional large eddy simulation. In addition, a bogus vortex technique was adopted to ensure the existence of wake vortices in the flow field. The validation of the method was performed by idealized test cases using virtual lidar measurement which is produced by the reference simulation of a vortex pair. The results of the validation cases showed the convergence of vortex parameters such as a circulation to that of reference simulation case. It is also confirmed that the velocity distribution on a measurement plane agrees with reference one.

Misaka, T., Ogasawara, T., Obayashi, S., Yamada, I. and Okuno, Y.

"ASSIMILATION EXPERIMENT OF LIDAR MEASUREMENTS FOR WAKE TURBULENCE"

Journal of Fluid Science and Technology, Vol. 3, No. 4, 2008, pp. 512-518.

Numerical simulation of wake turbulence was performed by integrating the lidar measurements using four-dimensional variational method. A bogus vortex technique was adopted to ensure the existence of wake vortices in the flow field. The validation of the method was performed by an idealized test case using virtual lidar measurement which was produced by the reference simulation of a vortex pair. The results of the validation showed the convergence of a vortex parameter such as a circulation to the parameter of reference simulation case. It was also confirmed that the velocity distribution on a measurement plane agreed with the reference one.

"LARGE EDDY SIMULATION OF WAKE VORTICES UNDER INFLUENCES OF HANGAR WAKE AND THE GROUND"

AIAA Paper 2018-2864, June 2018, Atlanta, GA.

Large eddy simulation of wake vortices in ground effect with realistic terrain around an airport was conducted focusing on the airport-specific behavior of wake vortices. We considered here a landing at Tokyo-Haneda airport in Japan, where a wake of hangar buildings covers landing paths under a certain wind condition. We developed a large eddy simulation code for adaptive mesh refinement capturing fine vortex core of wake vortex. Outer boundary conditions of the simulation were provided by the Weather Research and Forecasting (WRF) numerical prediction model to retrieve the wind condition. The impact of a crosswind over airport buildings on the behavior of wake vortex was evaluated by visualized images so far.

"EXPERIMENTAL STUDY OF FLOW CHARACTERISTICS OF AN OBLIQUE IMPINGING JET"

Experiments in Fluids, Vol. 61, Issue 3, March 2020, Article:90.

An experimental study has been performed by using particle image velocimetry to investigate the effect of nozzle-to-plate separation distance (L) and jet impingement angle on the flow characteristics of an obliquely inclined submerged water jet. Measurements were taken for $L/D = 1D, 2D, 4D$ and $6D$ (where D is the diameter of the nozzle) for the jet impingement angle (θ) of 45° and 26° , and the flow characteristics in the uphill and the downhill regions are investigated at Reynolds number of 2600 (based on the nozzle diameter D and the jet velocity U_0). It is observed that surface spacing has an opposite effect in the uphill and the downhill regions in terms of wall jet flow. In the uphill region, the tendency of the wall jet to grow increases with increase in L/D . However, in the downhill region, the jet velocity and it.

Mitchell, A. M., Barberis, D., Molton, P. and Delery, J.

"CONTROL OF LEADING-EDGE VORTEX BREAKDOWN BY TRAILING EDGE INJECTION"

Journal of Aircraft, Vol. 39, No. 2, March-April 2002, pp. 221-226.

The goal of this research is the control of the vortex breakdown locations over sharp-edged, slender, delta wings at high angles of attack. Water tunnel tests of a 75° delta wing examined symmetric and asymmetric trailing-edge jet injection as a method to control and delay the leading-edge vortex breakdown locations. These tests were accomplished at angles of attack between 20° and 40° at freestream velocities of 10 and 20 cm/s. Flow visualization data provide a description of the leading-edge vortices and of the vortex breakdown locations. The results demonstrate the ability of symmetric and asymmetric trailing-edge jet injection to control the leading-edge vortex breakdown locations. However, elevated trailing-edge injection mass flow rates create dramatic negative influences and accelerate vortex breakdown, especially for asymmetric flow control cases.

"DIRECT COMPUTATION OF THE SOUND FROM A COMPRESSIBLE CO-ROTATING VORTEX PAIR"

J. Fluid Mechanics, Vol. 285, 1995, pp. 181-202

The far-field sound generated by compressible co-rotating vortices is computed by direct computation of the unsteady compressible Navier-Stokes equations on a computational domain that extends to two acoustic wavelengths in all directions. The vortices undergo a period of co-rotation followed by a sudden merger. The directly computed far-field sound is compared to the prediction of the acoustic analogy due to Moehring (1978, 1979), a modified form of the analogy developed by Lighthill (1952), and an acoustic analogy derived by Powell (1964). All three predictions are in excellent agreement with the simulation. Results of far-field pressure fluctuations from an acoustically non-compact, co-rotating vortex pair are also presented. In this case, the vortex sound theory over-predicts the sound by 65% in accordance with the analysis of Yates (1978).

Mitchell, D. G.

"Fifty Years Of The Cooper-Harper Scale"

AIAA Paper 2019-0563, January 2019, San Diego, CA.

The year 2019 marks the fiftieth anniversary of the publication of a seminal document, The Use of Pilot Rating in the Evaluation of Aircraft Handling Qualities, by George E. Cooper and Robert P. Harper, Jr. Despite taking a meager 52 pages to tell its story, NASA TN D-5153 manages to capture the essence of piloted evaluation of handling qualities. The Cooper-Harper handling qualities rating scale has withstood numerous attempts at improvement, simplification, or modernization, and even total replacement. With its continued use, we have learned that there are shortcomings in the scale, and that several of the terms used are not well-defined. Certainly, our interpretation of the scale has evolved over the past five decades. Yet it remains the standard tool for eliciting pilot opinion on aircraft handling qualities. This paper reviews the evolution of the usage of the scale, discusses its strengths and weaknesses, and demonstrates the value of the scale to handling-qualities evaluation for the foreseeable future.

Mitchell, G. A.

"EFFECT OF INLET INGESTION OF A WING TIP VORTEX ON TURBOJET STALL MARGIN"

NASA TM X-71610, September 1974, NASA Lewis Research Center, Cleveland, OH.

A two-dimensional inlet and J85-GE-13 turbojet engine were placed in a Mach 0.4 stream so as to ingest the tip vortex of a forward mounted wing. Results show that ingestion of a wing tip vortex by a turbojet engine can cause a large reduction in engine stall margin. The loss in stall compressor pressure ratio was primarily dependent on vortex location and rotational direction and not on total-pressure variations across the compressor face.

Mitchell, G. A.

"PRELIMINARY INVESTIGATION OF INLET INGESTION OF A WING TIP VORTEX"

NASA TM-X-68225, April 1973, NASA Lewis Research Center, Cleveland, OH

An inlet-coldpipe assembly was placed in a Mach 0.4 stream to ingest the tip vortex of a forward mounted wing. The strongest vortex was produced by a wing angle of attack of 11 degrees. The vortex displayed a tangential velocity of 57 percent of local stream velocity prior to entering the inlet and a tangential velocity of 25 percent of local velocity at the simulated compressor-face. The total-pressure-profiles measured by standard compressor-face rakes were changed by the presence of the vortex only at the highest inlet mass-flow ratios.

Mitchell, G. A.

"EFFECT OF INLET INGESTION OF A WING TIP VORTEX ON COMPRESSOR FACE FLOW AND TURBOJET STALL MARGIN"

NASA TM-X-3246, July 1975, NASA Lewis Research Center, Cleveland, OH

A two-dimensional inlet was alternately mated to a coldpipe plug assembly and a J85-GE-13 turbojet engine, and placed in a Mach 0.4 stream so as to ingest the tip vortex of a forward mounted wing. Vortex properties were measured just forward of the inlet and at the compressor face. Results show that ingestion of a wing tip vortex by a turbojet engine can cause a large reduction in engine stall margin. The loss in stall compressor pressure ratio was primarily dependent on vortex location and rotational direction and not on total-pressure distortion.

"THE EVOLUTION OF KIRCHHOFF ELLIPTIC VORTICES"

Physics of Fluids, Vol. 20, 2008, pp. 054103-1 - 054103-12

A Kirchhoff elliptic vortex is a two-dimensional elliptical region of uniform vorticity embedded in an inviscid, incompressible, and irrotational fluid. By using analytic theory and contour dynamics simulations, we describe the evolution of perturbed Kirchhoff vortices by decomposing solutions into constituent linear eigenmodes. With small amplitude perturbations, we find excellent agreement between the short time dynamics and the predictions of linear analytic theory. Elliptical vortices must have aspect ratios less than $a/b = 3$ to be completely stable. At late times, unstable perturbations evolve to states consisting of filaments surrounding and connecting one or more separate vortex core regions. Even modes have two different evolution paths accessible to them, dependent on the initial phase.

"EULER EQUATIONS ANALYSIS OF THE INITIAL ROLL-UP OF AIRCRAFT WAKES"

J. Aircraft, Vol. 23, No. 8, August 1986, pp. 650-655

A new approach has been developed to study the initial roll-up of aircraft wakes. This approach is based on the solution of the three-dimensional Euler equations subject to inflow and initial conditions predicted by a vortex-lattice method. Thus, solutions are limited to those flowfields generated by wings that are free of flow separation. Results are presented for four configurations: a rectangular wing with part span flap, a rectangular wing, a typical transport-type configuration, and a fighter configuration. In addition, an assessment of an 'unsteady two-dimensional analogy' was undertaken using the two-dimensional time-accurate Euler equation solutions in cross-flow planes. In general, predictions from the two-dimensional unsteady analogy coincided with the three-dimensional results, which were found to be in good agreement with available experimental data.

"ACOUSTIC SOUNDING OF VORTEX RINGS IN A CONTINUOUSLY STRATIFIED FLUID"

Fluid Dynamics, Vol. 36, No. 6, 2001, pp. 934-943

The experimental simulation of solitary vortex rings in a stratified fluid performed using high-frequency echo-sounding and optical visualization methods shows that on the range from turbulent to laminar regimes the vortex is a volume inhomogeneity with a sound scattering cross-section is approximately equal to U^5 , where U is the translational velocity. The absolute value of the sound scattering cross-section is determined by the microscale component of the vortex microstructure, which is commensurable with the sounding sonic wave length.

"LINEAR AND NONLINEAR INTERACTIONS BETWEEN A COLUMNAR VORTEX AND EXTERNAL TURBULENCE"

J. Fluid Mech., Vol. 402, 2000, pp. 349-378

The structure of initially isotropic homogeneous turbulence interacting with a columnar vortex (with circulation and radius) idealized both as a solid cylinder and a hollow core model is analyzed using the inhomogeneous form of linear rapid distortion theory (RDT), for flows where the r.m.s. turbulence velocity is small compared with circulation/radius. The turbulent eddies with scale L are distorted by the mean velocity gradient and, over a distance L from the surface of the vortex, by their direct impingement onto it, whether it is solid or hollow. Calculation of the distortion of small-scale initially random velocity fields shows how the turbulent eddies, as they are wrapped around the columnar vortex, become like vortex rings, with similar properties to those computed by Melander & Hussain (1993) using a fully nonlinear direct numerical simulation. A mechanism is proposed for how interactions between the external turbulence and the columnar vortex can lead to non-axisymmetric vortex waves being excited on the vortex and damped fluctuations in its interior.

Miyazawa, M.

"A TWO-DIMENSIONAL MODEL FOR TRAILING VORTEX STRUCTURE"

AIAA Paper No. 2004-1075, Reno, NV, January 2004

In the analysis of trailing vortex's behavior with time, a fully rolled-up vortex pair, represented by Rankine's vortex, is used as a basic, starting-point vortex model. However, it is hard to predict the basic structure, specifically the core size that determines the maximum swirl velocity. Also, analytical, and experimental data reported to date show a wide variety of the vortex core size. The present paper proposes a simple, hypothetical vortex model that uniquely determines the trailing-vortex core size. It was developed by reviewing the classical lifting-line theory as well as the trailing-vortex rolling-up process, thereby considering the conservation laws. The present analytical results show that the free-vortex core size is independent of the aspect ratio for arbitrarily loaded wings. Also, sample calculations for representative commercial transport with elliptically loaded wings show that the core size increases as the aircraft becomes heavier while the maximum swirl velocity is practically unchanged.

"LASER DOPPLER OPTICAL AIR-DATA SYSTEM: FEASIBILITY DEMONSTRATION AND SYSTEMS SPECIFICATIONS"

Applied Optics, Vol. 33, No. 27, September 1994, pp. 6457-6472

A compact laser Doppler velocimeter with diode-pumped solid-state laser technology at 1.06 microns and a novel solid-block beam-splitting interferometer was demonstrated. This system allows for accurate Doppler velocity measurements even in a vibration environment. A comparison of the backscatter measurements with a backscatter sonde from the University of Wyoming showed excellent agreement. Based on demonstrated performance and technology projection, the system specifications of an optical air-data system at 2.015 microns are determined, and a detailed design concept is presented. In addition, the potential for a multifunctional sensor that can determine air data and detect wind shear and wake vortices is addressed.

Modi, A.

"REAL-TIME VISUALIZATION OF AEROSPACE SIMULATIONS USING COMPUTATIONAL STEERING AND BEOWULF CLUSTERS"

PhD Thesis, August 2002, The Pennsylvania State University, University Park, PA.

In this thesis, a new, general-purpose software system for computational steering has been developed to carry out simulations on parallel computers and visualize them remotely in real-time. The steering system is extremely lightweight, portable, robust and easy to use. As a demonstration of the

capabilities of this system, two applications have been developed. A parallel wake-vortex simulation code has been written and integrated with a Virtual Reality (VR) system via a separate graphics client. The coupling of computational steering of parallel wake-vortex simulation with VR setup provides us with near real-time visualization of the wake-vortex data in stereoscopic mode. It opens a new way for the future Air-Traffic Control systems to help reduce the capacity constraint and safety problems resulting from the wake-vortex hazard that are plaguing the airports today. In another application, an existing computational fluid dynamics code has been integrated with the steering system to enable interactive visualization of complex simulations from any remote workstation. Benefits of scalability and dimensional reduction arising from this approach have been imperative in the development of this system. This system makes the visualization of flow simulations easier, efficient, and most-importantly without any delay as and when the results are generated, thus giving the user much greater flexibility in interacting with the huge amounts of data. At a more basic level, the ability to get 'immersed' in the complex solution as it unfolds using the depth cue of the stereoscopic display and the near real-time nature of the computational steering system opens a whole new dimension to the scientists for interacting with their simulations.

Modi, A., Long, L. N. and Plassmann, P. E.

"REAL-TIME VISUALIZATION OF WAKE-VORTEX SIMULATIONS USING COMPUTATIONAL STEERING AND BEOWULF CLUSTERS"

5th International Meeting, High Performance Computing for Computational Science, Porto, Portugal, June 2002.

In this paper, we present the design and implementation of POSSE, a new, lightweight computational steering system based on a client/server programming model. We demonstrate the effectiveness of this software system by illustrating its use for a visualization client designed for a particularly demanding real-time application -- wake-vortex simulations for multiple aircraft running on a parallel Beowulf cluster. We describe how POSSE is implemented as an object-oriented, class-based software library and illustrate its ease of use from the perspective of both the server and client codes. We discuss how POSSE handles the issue of data coherency of distributed data structures, data transfer between different hardware representations, and several other implementation issues. Finally, we consider how this approach could be used to augment AVOSS (an air traffic control system currently being developed by the FAA) to significantly increase airport utilization while reducing the risks of accidents.

Modi, A., Long, L. N. and Plassmann, P. E.

"REAL-TIME VISUALIZATION OF WAKE-VORTEX SIMULATION USING COMPUTATIONAL STEERING AND BEOWULF CLUSTERS"

5th International Meeting, High Performance Computing for Computational Science, VEC PAR 2002, Lisbon, Portugal, June 2002

A general computational steering system has been developed to carry out simulations on parallel computers and visualize them remotely in real-time. The steering system is extremely lightweight, portable, robust and easy to use. As a demonstration of the capabilities of this system, a parallel wake-vortex simulation code has been written and integrated with our Virtual Reality setup via a separate graphics client. The coupling of computational steering of our parallel simulation with VR setup provides us with near real-time visualization of the wake-vortex data in stereoscopic mode. It opens a new way for the future Air-Traffic Control systems to help reduce the capacity constraint and safety problems resulting from the wake-vortex hazard that are plaguing the airports today. At a more basic level, the ability to get 'immersed' in the complex solution as it unfolds using the depth cue of the stereoscopic display and the real-time nature of the computational steering system opens a whole new dimension to the scientists for interacting with their simulations.

Moet, H.

"THE EFFECTS OF THE ATMOSPHERIC TURBULENCE ON WAKE VORTICES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Wake vortices are strongly affected by ambient atmospheric parameters such as wind shear, stratification, and turbulence as well as by the proximity of the ground. The lifespan of wake vortices may be short in presence of strong turbulence but may also be of the order of several minutes in case of weak turbulence. The vortex lifespan is an essential aspect in the issue of wake vortex encounters. In this study we focus on the effect of three-dimensional ambient atmospheric turbulence on vortex decay using temporal large eddy simulations. The effect of ambient atmospheric turbulence has been investigated by placing vortex systems in homogeneous isotropic turbulence, which is assumed to be either a good approximation of atmospheric turbulence as well as a suitable option for generic vortex/turbulence interaction studies. A large set of single vortex and vortex pair configurations has been considered in order to determine the quantitative and qualitative effects of ambient turbulence on the vortex dynamics. The different mechanisms that have been observed during the decay process are turbulent diffusion, the creation of azimuthal structures of vorticity, the concurrent exchange of vorticity between primary vortices and the surrounding turbulence, as well as occurrence of large deformation and the onset of instability processes. The circulation, which quantifies the strength of the vortex is significantly affected by the presence of turbulence, and an accompanying parameter study resulted in the identification of pertinent parameters governing the circulation decay. Based on the numerical simulations, a simple turbulence decay model is proposed as a function of the parameters characterizing the ambient turbulence. A second three-dimensional large eddy simulation code is used to simulate the behavior of aircraft wake vortices in a more realistic atmosphere. In this case, both weak turbulence and stratification effects are studied. Stable stratification is here a consequence of the earth's boundary layer activity. A system of vortices in post roll-up phase placed in a suitable meteorological background form the initial conditions of a temporal simulation. Mesh refinement techniques enable the use of a large computational domain to capture the different scales of motion present in the atmospheric boundary layer as well as a sufficient resolution in the region where the

vortices reside. Eventually, the decay processes identified in the homogeneous isotropic turbulence simulations and in the more realistic test case will be compared.

"INVESTIGATION OF AMBIENT TURBULENCE EFFECTS ON VORTEX EVOLUTION USING LES"

AIAA Paper No. 2000-0756, Reno, NV, January 2000

The effects of ambient turbulence on vortex dynamics are studied using a validated, three-dimensional, large-eddy simulation model. The objective of this study is to understand the mechanisms of interaction between vortices and turbulence and to obtain quantitative data about the aging process. Numerical simulations are performed in order to isolate the effects of ambient turbulence on a configuration consisting of a single vortex or vortex pair. A set of simulations has been conducted by placing vortices in a field of homogeneous isotropic turbulence for a range of turbulence intensities. The results reveal typical phenomena of vortex/turbulence interaction such as gradual, quasi-linear circulation decay due to turbulent diffusion, vortex deformation, appearance of azimuthal vortical structures and the occurrence of long- and short-wavelength instabilities. Several parameter studies have been performed to quantify a critical parameter which affects the strength of vortices and/or predicts the occurrences of instabilities.

Moet, H. L. C., Laporte, F., Darracq, D. and Corjon, A.

"LARGE-EDDY SIMULATIONS OF VORTEX/TURBULENCE INTERACTION"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

The issue of aircraft wake vortices is directly related to two different aspects, namely the structure of the wake vortices themselves and the characteristics of the atmospheric turbulence surrounding them. The present study has focused on the dynamics of vortices interacting with turbulence. For this purpose, a single vortex or vortex pair configuration has been placed in homogeneous isotropic turbulence. Large-eddy simulations at realistic Re-number have been performed to study vortex decay. This has been achieved by varying parameters that govern either the vortex configuration or the turbulence. It was observed that the turbulence intensity and the vortex spacing were the main parameters that affect the decay. Furthermore, the role of the turbulence can be separated into two effects - on the one hand, it causes gradual decay due to the diffusive property of turbulence solely having a significant effect near the vortex core; on the other hand, the turbulence may trigger instabilities that lead to the accelerated decay of vortices.

Moet, H., Darracq, D. and Corjon, A.

"DEVELOPMENT OF A DECAY MODEL FOR VORTICES INTERACTING WITH TURBULENCE"

AIAA Paper No. 2001-0545, Reno, NV, January 2001

The result of recent LES simulations of vortices interacting with turbulence are used to define a simple turbulence decay model. The observations made during the analysis of the results showed the appearance of several phenomena that dominate the vortex decay. An accompanying parameter study resulted in the quantification of pertinent parameters such as the turbulence intensity, the integral length scale of the turbulence and the vortex separation. These parameters are incorporated in a new turbulence decay model that is best matched to the numerical simulation results.

"WAVE PROPAGATION IN VORTICES AND VORTEX BURSTING"

Physics of Fluids, Vol. 17, May 2005, pp. 054109-1 to 054109-15

The propagation of pressure waves in a Lamb-Oseen vortex has been investigated both by three-dimensional direct numerical simulations as well as a set of large-eddy simulations. The pressure wave is initiated by locally increasing the core radius of a Lamb-Oseen vortex at its edge. This wave travels along the vortex axis towards the region with a thinner core radius. Behind the wave the axial velocity increases so that sufficient swirl may trigger the helical instability. An abrupt change of flow structure in the vortex core is observed in the case of intersecting pressure waves: this phenomenon is known as vortex bursting. A vortex system composed of two symmetric counter-rotating vortices, which is similar to that of an aircraft has also been investigated by means of large-eddy simulations. In the far-field region the system develops linear instabilities such as the Crow instability, which is characterized by a large-scale symmetric sinusoidal deformation resulting in the reconnection of the two vortices. It also demonstrates the occurrence of helical instability and vortex bursting.

Moffatt, H. K.

"THREE COINS IN A FOUNTAIN"

Journal of Fluid Mechanics, Vol. 720, 2013, pp. 1-4.

If, in a large expanse of fluid such as air or water, an object that is heavier than the fluid displaced is released from rest, it descends in a manner that can depend in a complex way on its geometry and density (relative to that of the fluid), and on the fluid viscosity, which, as in other fluid contexts, remains important no matter how small this viscosity may be. A major numerical attack on this problem for the case in which the object is a thin circular disc is presented by Auguste, Magnaudet, and Fabre.

Mohan, A. T., Agostini, L., Gaitonde, D. V. and Garmann, D. J.

"STATISTICAL ANALYSIS AND MODEL REDUCTION OF SURFACE PRESSURE IN THE INTERACTION OF A STREAMWISE-ORIENTED VORTEX WITH A WING"

AIAA Paper 2015-3412, June 2015, Dallas, TX.

A streamwise oriented vortex can interact with a wing in numerous applications such as formation flight, where it offers advantages of higher lift and reduced drag, and turbomachinery blade-row interactions. High-fidelity simulations of such interactions are becoming more common, a recent example being those presented by Garmann and Visbal, who use a very high-order approach to analyze the effect of vortex impingement location on a rectangular wing at 4-degree angle-of-attack and Reynolds number of 20,000. These 3-D unsteady simulations generate immensely large datasets, making the effort to understand the underlying physics very challenging. Model reduction techniques have gained immense popularity not only to manage the data but also as an analysis tool. In this paper, we combine two such tools, specifically Empirical Mode Decomposition (EMD) and Dynamic Mode Decomposition (DMD), to analyze the surface pressure data from the simulations of Garmann and Visbal. It is shown that EMD and DMD can be used in conjunction with each other to study the footprint of a given flow feature on the surface. The study also discusses the relationship between the transient response of surface pressure and the incident streamwise vortex with some interesting observations pertaining to non-uniform wing-loading. The effectiveness of DMD to extract a small subset of the data which can capture the key features of unsteady pressure interactions is also demonstrated. The flow structures associated with the key frequencies identified by DMD are discussed with implication on the engineering aspects of interest.

Mohring, W.

"ON VORTEX SOUND AT LOW MACH NUMBER"

Journal of Fluid Mechanics, Vol. 85, Part 4, 1978, pp. 685-691.

A transformation is described which relates the sound generated by low Mach number flow to the flow vorticity. For compact flow fields the apparent sound source is of quadrupole type and linear in the vorticity and therefore also linear in the flow velocity. This scheme is applied to the sound generated by the interaction of two identical thin vortex rings. Then a flow field with several compact vortices is discussed. It is found that each vortex can be replaced acoustically by a dipole related to the impulse of the vortex, plus the quadrupole just mentioned plus a spherically symmetric sound source related to the energy of the vortex. An application to low Mach number free-space turbulence shows that the generated sound is related to the vorticity correlation tensor.

Moin, P.

"REVISITING TAYLOR'S HYPOTHESIS"

Journal of Fluid Mechanics, Vol. 640, 2009, pp. 1-4.

Taylor's hypothesis, relating temporal to spatial fluctuations in turbulent flows is investigated using powerful numerical computations by del Alamo and Jimenez. Their results cast doubt on recent interpretations of bimodal spectra in relation to very large-scale turbulent structures in experimental measurements in turbulent shear flows.

Moisy, F. and Petitjeans, P.

"PRESSURE MEASUREMENTS IN A STRETCHED VORTEX"

Lecture Notes in Physics, Vol. 555, 2000, pp. 252-262

We report new results obtained with a strong laboratory vortex, generated between rotating disks with an axial stretching, providing a model of strong vortex structures present in turbulent flows. We first characterize the strength of the vortex in this geometry by means of a global pressure measurement, and give direct evidence of a mechanism of stretching saturation due to strong rotation. Pressure measurements are then performed with a miniature probe sensor close to the vortex, in order to study the relevance of bulk measurements with small but invasive sensors. We analyze the influence of some geometric characteristics of the probe (size, distance from the vortex) on the measured pressure, together with the influence of the presence of a probe on the vortex strength. We briefly discuss consequences of these observations on pressure measurements in the bulk of turbulent flows.

Mokry, M.

"INTENSIFICATION OF AIRCRAFT WAKE VORTICES IN CROSSWIND SHEAR"

Journal of Aircraft, Vol. 40, No. 2, March-April 2003, pp. 405-407.

Based on the convection of thin vortex sheets, it was shown that aircraft vortices can temporarily intensify in the presence of crosswind shear.

Mokry, M.

"NUMERICAL SIMULATION OF AIRCRAFT TRAILING VORTICES INTERACTING WITH AMBIENT SHEAR OR GROUND"

Journal of Aircraft, Vol. 38, No. 4, July-August, 2001, pp. 636-643

A two-dimensional algorithm, based on the continuous vortex sheet method, is proposed for modeling the evolution and propagation of aircraft trailing vortices in a sheared environment. Among the phenomena discussed are the generation of secondary vortices, shear-layer instabilities, and interactions of trailing vortices with atmospheric and ground shear layers. Numerical simulations are produced by a code written as an interactive-graphics application for the Windows platform.

Mokry, M.

"THE VORTEX MERGER FACTOR IN AIRCRAFT WAKE TURBULENCE"

The Aeronautical Journal, January 2005, pp. 13-22

Vortex merger is studied within the context of two-dimensional discrete vortex sheets and demonstrated on two equally oriented circular vortices and aircraft tip and flap vortices. It is confirmed

that, depending on the wing load distribution, the latter may or may not coalesce into a single counter-rotating pair. The interaction of a vortex with an equally oriented shear layer, governed by the same physical principle, suggests a possible intensification of an aircraft vortex in cross-wind shear.

Mokry, M.

"HAZARD OF WAKE VORTEX ENCOUNTERS IN CROSSWIND SHEAR"

AIAA Paper No. 2003-0378, Reno, NV, January 2003

An interaction of aircraft wake vortices with a shear layer is investigated using the convection of vortex sheets in two space dimensions. Based on the numerical simulation results it is suggested that, in the presence of crosswind shear, one aircraft following another may be subjected to a stronger vortex than expected in the wake of the leading aircraft in a quiescent atmosphere. Suggestions are given on how to prevent creation of such vortices and how to avoid encountering them.

Mokry, M.

"AUGMENTATION OF AIRCRAFT WAKE VORTICES IN CROSSWIND SHEAR"

The 10th International Symposium on Flow Visualization, August 2002, Kyoto, Japan

Interactions of aircraft trailing vortices with crosswind shear are investigated using the method of discrete vortex sheets. Computer visualization reveals that equally-signed vorticity may combine to produce a vortex larger than the original wingtip vortex.

Mokry, M.

"NUMERICAL SIMULATION OF AIRCRAFT TRAILING VORTICES IN AN INTERACTIVE GRAPHICS ENVIRONMENT"

AIAA Paper No. 1999-0827, Reno, NV, January 1999

The motion of aircraft trailing vortices is simulated in the Windows graphics environment, using the C++ object-oriented approach. A time-efficient, physically meaningful modeling is provided by the continuous sheet method. Among the phenomena discussed are the generation of secondary vortices, shear layer instability and the interactions of trailing vortices with atmospheric and ground shear layers.

Mokry, M.

"REAL-TIME SIMULATION OF AIRCRAFT WAKE VORTICES"

Proceedings of the Fifth Annual Conference of the CFD Society of Canada, CFD Society of Canada, Victoria, May 1997, pp. 9-15 - 9-20

This paper demonstrates the usefulness of a computer live simulation in uncovering and understanding various physical phenomena accompanying the roll-up of vortex sheets. Among the observed and analyzed features are the contraction of the vortex sheet prior to the formation of an inboard vortex, instability, and irreversibility. Supplied by an on-line measurement of atmospheric conditions, the method can be extended to be used as a real-time simulation of aircraft wake vortices near the ground. The demonstration code has been written using the Graphics Device Interface (GDI) and the Object Windows Library (OWL) of Borland C++, Version 5.01.

Mokry, M. and Rainbird, W. J.

"CALCULATION OF VORTEX SHEET ROLL-UP IN A RECTANGULAR WIND TUNNEL"

J. Aircraft, Vol. 12, No. 9, September 1975, pp. 750-752

The note utilizes the concept of Green's functions to calculate the roll-up of a vortex sheet wake in a rectangular wind tunnel with solid walls. The computations are performed by the discretization of the continuous vortex sheet model by finite length elements which show more stable behavior than Westwater's array of point vortices. The results show that the vorticity distribution has essentially a stationary center of gravity, in marked contrast with the free air case where the center of gravity moves downwards.

Mokry, M. and Yeung, A. F. K.

"ON THE EVOLUTION OF TRAILING VORTEX SHEETS"

Proceedings of Third International Workshop on Vortex Flows and Related Numerical Methods, ESAIM, Vol. 7, 1999, pp. 292-303

The initial phase of the evolution of trailing vortex sheets is modelled using the continuous sheet method, corresponding to $Re = \infty$. In the proposed 2D numerical scheme, vorticity is conserved. A qualitative comparison of the numerically simulated results and low-speed data obtained by particle image velocimetry is provided. Among the phenomena discussed are the interactions of the trailing vortices with atmospheric and ground shear layers.

Mokry, M., Xu, H. and Yeung, A. F. K.

"EXPERIMENTAL AND NUMERICAL VISUALIZATION OF WING TRAILING VORTICES"

Proceedings of 9th International Symposium on Flow Visualization, Edinburgh, Scotland, August 2000, pp. 213-1-213-10

Wing trailing vortices are visualized both experimentally and computationally. The particle image velocimetry is applied to a half-wing tested in a low-speed wind tunnel. A numerical simulation of the vortices generated by a two-component wing is implemented using an Euler's equation solver. The separate C-grid topologies of the wing and flap are coupled using the chimera overlapping grid strategy. Vortex-specific physical phenomena, such as the initial rollup at wing tips and sub-vortex orbiting, are observed using an animated motion of fluid particles. Finally, a simple vortex sheet method, modelling potential flow in the cross-flow plane, is employed to study the development of the vortices and their interactions with atmospheric and ground shear layers. Presented are live computer simulations, showing the birth of secondary vortices and their interactive motion in crosswind.

Moldoveanu, C., Giovannini, A., Boisson, H.-C. and Moraru, F.

"NUMERICAL SIMULATION OF A LONGITUDINAL COUNTER-ROTATING VORTEX PAIR IN INTERACTION WITH GROUND"

Proceedings of the 5th IASME/WSEAS International Conference on Fluid Mechanics and Aerodynamics, August 2007, Athens, Greece, pp. 220-229.

Any object moving in the air leaves behind it a more or less organized wake vortex. In case of the aircraft, this wake results in a rolling up of flow starting from the ends of the wings. It is due to the lift of each wing and the generated vortex will be as much more intense as the lift increases. It can constitute a danger to another aircraft that flies in this wake, especially during takeoff and landing. In this case the wake vortex trajectories and strengths are altered by ground interactions. This study presents the results of a Large Eddy Simulation of wake vortex in ground effect providing the vorticity flux behavior.

Moldoveanu, C., Giovannini, A., Boisson, H.-C. and Somoia, P.

"SIMULATION OF WAKE VORTEX AIRCRAFT IN GROUND EFFECT"

INCAS - Bulletin, Vol. 3, Issue 1, 2011, pp. 55-61.

The problem developed in this paper is encountered in airplane aerodynamics and concerns the influence of long-life longitudinal wake vortices generated by wing tips or by external obstacles such as reactors or landing gears. More generally it concerns 3D bodies of finite extension in cross flow. At the edge of such obstacles, longitudinal vortices are created by pressure differences inside the boundary layers and rotate in opposite senses. It can constitute a danger to another aircraft that flies in this wake, especially during takeoff and landing. In this case the wake vortex trajectories and strengths are altered by ground interactions. This study presents the results of a Large Eddy Simulation of wake vortex in ground effect providing the vorticity flux behavior.

"MATHEMATICAL MODELS USED TO STUDY THE AIRCRAFT WAKE VORTICES"

Proceedings of the Scientific Conference AFASES 2013, May 2013, Brasov, Romania, pp. 671-676.

Developing air traffic and introducing large aircraft in use in the group of transport aircrafts has led to the necessity to optimize separation distances between aircrafts, especially near airports. These distances are imposed by airport safety and security conditions, related to the action of the wake turbulence generated by an aircraft on another. At the edge of the aircraft wings, longitudinal vortices are created by pressure differences inside the boundary layers and rotated in opposite senses. It can constitute a danger to another aircraft that flies in this wake, especially during take-off and landing. This paper presents the mathematical models used to simulate the aircraft wake vortex behavior.

Moldoveanu, C.-E., Somoia, P., Vedinas, I. and Ferrier, P.

"RESEARCHES CONCERNING AIRCRAFT WAKE VORTEX"

1st International Conference, New Challenges in Aerospace Sciences (NCAS 2013), November 2013, Bucharest, Romania.

An aircraft flying leaves behind it a more or less organized wake composed of persistent vortices, which constitute a danger for the following aircraft. To avoid this, the distances between aircrafts are imposed by airport safety and security conditions, related to the action of the wake turbulence generated by an aircraft on another. At the edge of the aircraft wings, longitudinal vortices are created by pressure differences inside the boundary layers and rotated in opposite senses. This study presents the modelling methods of the turbulence using Large Eddy Simulation and some applications in the case of wake vortex.

"AUTOMATED METEOROLOGICAL REPORTS FROM COMMERCIAL AIRCRAFT"

Bulletin American Meteorological Society, Vol. 84, No. 2, February 2003, pp. 203-216.

Automated weather reports from commercial aircraft have been an important data source for numerical weather prediction (NWP) models for more than a decade, and have improved the forecasts from these models. More recently, direct access to these reports has become available to government weather forecasters and other researchers through a Web site operated by NOAA's Forecast Systems Laboratory (FSL). Direct access to these data has resulted in better quality control of the data, and more timely and accurate forecasts. We provide an overview of the kinds of aircraft data that are currently available, a brief history and overview of FSL's Web site and other data distribution mechanisms, a look at the use of the data in models, and examples of the use of these data in research and operational forecasting.

Monsch, S. C.

"A STUDY OF INDUCED DRAG AND SPANWISE LIFT DISTRIBUTION FOR THREE-DIMENSIONAL INVISCID FLOW OVER A WING"

MS Thesis, May 2007, Clemson University, Clemson, SC.

The purpose of this study was to validate an approach to estimating the induced drag on a finite wing by using a wake integral analysis. The long-term goal is related to developing an aerodynamic-structural systems integrated design methodology for wings using a transpiration boundary condition to control the spanwise lift distribution throughout a typical mission to minimize lift-induced drag. The short-term goal addressed by this study is to develop a methodology to extract accurate and robust calculations of the induced drag from second order numerical solutions. Numerical results for an untwisted, finite rectangular wing (NACA 0012, AR = 6.7) using no flap deflections are compared against theoretical lifting line predictions. The numerical approach used an Euler-based computational fluid dynamic (CFD) solver. An in-house lifting line code was used to predict the theoretical reference values. By dividing the wing into twenty span-wise sections and using a surface integral of pressure at each section, a span-wise lift distribution was extracted from the CFD solution. Under flow conditions representing subsonic and transonic flows (Mach 0.3 - 0.7) at small angles of attack, the comparison between the predicted numerical and lifting-line span-wise lift distributions show good agreement with a maximum deviation of only 2.4 percent over the wing span.

Montalvo, C. and Costello, M.

"META AIRCRAFT FLIGHT DYNAMICS"

Journal of Aircraft, Vol. 52, No. 1, January-February 2015, pp. 107-115.

A meta-aircraft is an air vehicle composed of a set of independent aircraft that are connected in flight to form a larger composite aircraft. This paper explores the dynamics of meta-aircraft systems with a focus on the changes in the aircraft flight dynamic modes and flexible modes of the system. Specifically, when aircraft are connected, basic flight dynamic modes such as the phugoid, short period, Dutch roll, spiral, and roll modes change as a function of the number of connected aircraft. For aircraft connected in a wing-tip-to-wing-tip configuration, the longitudinal modes remain largely invariant with respect to the number of aircraft, whereas lateral modes are variable for both tip-to-tail and wing-tip-to-wing-tip connection configurations. In addition, connected aircraft exhibit complex flexible modes that change based on the characteristics of the connection joint and the number of connected aircraft. These conclusions are reached using a rigid six-degree-of-freedom representation for a single aircraft, where aircraft are connected through a set of linear and rotational elastic elements modeling the connection mechanism. Aerodynamic loads from all lifting surfaces are computed using a nonlinear lifting-line approach to enable aerodynamic wake interactions between connected aircraft.

"NUMERICAL SIMULATION OF CONTRAIL FORMATION ON THE COMMON RESEARCH MODEL WING/BODY/ENGINE CONFIGURATION"

AIAA Paper 2018-3189, June 2018, Atlanta, GA.

Aircraft contrails may contribute to the global radiative forcing. In this context, the investigation of contrail formation in the near field of an aircraft may be helpful in developing strategies to reduce undesirable impacts. Contrail formation is also a complex topic, since several physical processes are involved, covering a large range of space and time scales, from the engine exit to the atmospheric global scale. In the near field of the aircraft, contrail formation is mainly dominated by microphysics and mixing processes between the propelling jets and the external flow (the so-called jet-vortex interaction). In this study, three-dimensional Reynolds-Averaged Navier-Stokes (RANS) simulations of contrails produced by the Common Research Model wing/body/engine configuration during cruise flights is performed. In the present work, a dedicated internal nozzle geometry has been designed to replace the through flow nacelle of the original CRM configuration. Thus, the engine core and bypass flows are computed in the simulations, which allows several parametrical studies and avoids using parameterizations to describe the plume's dilution. The objective is to simulate the early development of contrails in a fresh plume whose dilution is obtained with a spatial simulation of jet/vortex interaction. A coupling is carried out with a chemical and a microphysical model implemented in the unstructured Navier-Stokes CFD code CEDRE to simulate particle growth using an Eulerian approach. The implemented microphysics model can simulate water condensation onto soot particles, considering their adsorption of sulfur species. In this context, an adaptation grid mesh procedure has been used to generate an optimized unstructured mesh in the fluid zone of interest (i.e. vortex wake and jet exhaust).

"NUMERICAL SIMULATION OF THE UNSTEADY WAKE BEHIND AN AIRFOIL"

J. Aircraft, Vol. 26, No. 6, June 1989, pp. 509-514

The unsteady wake behind an airfoil is simulated numerically by a system of discrete vortex cores, also called point vortices. In common with previously developed procedures, at each time step a core is added to the wake at the trailing edge, and the cores already in the wake are convected at the local particle velocity. The innovation of the present method is that, as the cores begin to separate, more cores are added to the system and the circulations around the individual cores are reduced according to a linear interpolation routine. The spacing between cores is maintained approximately while the total circulation around the wake and airfoil is maintained exactly. In several examples, one finds qualitative agreement between computed wake shapes and flow visualization. The method shows promise as a means of simulating unsteady, closely coupled aerodynamic interference.

Moore, D. W.

"FINITE AMPLITUDE WAVES ON AIRCRAFT TRAILING VORTICES"

Aero. Quarterly, Vol. 23, November 1972, pp. 307-314

Numerical methods are used to study the growth of waves of finite amplitude on a pair of parallel infinite vortices. The vortices are treated as lines except in so far as the detailed structure of the core is needed to remove consistently the singularity in the line integrals for the velocities of the vortices. It is shown that the velocities eventually touch and the shape of the wake at this instant is calculated. The wave is quite distorted at this instant, but it is shown that its gross properties are given roughly by linear theory.

Moore, D. W.

"A NUMERICAL STUDY OF THE ROLL-UP OF A FINITE VORTEX SHEET"

J. Fluid Mech., Vol. 63, Part 2, April 1974, pp. 225-235

A point-vortex representation is used to study numerically the evolution of an initially plane vortex sheet. By introducing a tip vortex to represent the tightly rolled portion of the vortex sheet, the chaotic motion which was a feature of some earlier studies is eliminated and the details of the outer portion of the spiral are calculated. The rate of rolling up is calculated and is shown to be governed by the analytically predicted similarity law of Kaden during the initial stages of the rolling up. The calculations are continued until 99% of the vorticity has been rolled up, at which stage the spiral displays a marked ellipticity.

Moore, D. W.

"THE DISCRETE VORTEX APPROXIMATION OF A FINITE VORTEX SHEET"

AFOSR-TR-72-0034, October 1971, California Institute of Technology, Pasadena, CA

It is shown by examination of a special case of aircraft trailing vortices that the approximation of replacing a finite vortex sheet by an array of line vortices can be unreliable regardless of how many vortices are used.

"THE INSTABILITY OF A STRAIGHT VORTEX FILAMENT IN A STRAIN FIELD"

Proceedings of the Royal Society of London, Series A - Mathematical and Physical Sciences, Vol. 346, No. 1646, 1975, pp. 413-425

A straight infinite vortex of finite cross section is deformed by the action of weak irrotational plane strain. The deformed vortex is shown, in the absence of axial flow, to be unstable to disturbances whose axial wavelengths lie in a narrow band, whose width is proportional to the imposed strain. The band is centered on the wavelength of the helical wave which does not propagate on the unstrained circular vortex. Thus support is given to the instability mechanism proposed recently by Widnall, Bliss and Tsai. The argument depends, however, on the mirror image of the helical wave also being a possible non-propagating disturbance on the unstrained vortex.

Moore, D. W. and Saffman, P. G.

"AXIAL FLOW IN LAMINAR TRAILING VORTICES;"

Proc. Royal Soc. London, Vol. 333, Series A, June 1973, pp. 491-50.

The structure of laminar trailing vortices behind a lifting wing is considered. The inviscid roll up of the trailing vortex sheet is examined, and the nature of the singularity at the center of the spiral is determined. It is shown that viscosity removes the singularity and the structure of the viscous core is obtained. The pressure in the viscous core is found and used to calculate the axial velocities produced by streamwise pressure gradients. It is found that the perturbation of axial velocity can be either away from the wing or towards the wing depending on the distribution of tip loading on the wing. For elliptic loading, the perturbation is towards the wing. The axial flow deficit in the core due to the boundary layers on the wing is also estimated. A comparison with experiment is made and reasonable agreement is found.

Moore, D. W. and Saffman, P. G.

"STRUCTURE OF A LINE VORTEX IN AN IMPOSED STRAIN"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 339-354

The velocity of a vortex line depends on its structure, i.e., the shape of the cross-section and the detailed vorticity distribution. As a first step towards an understanding of how the structure depends on the motion and the construction of a valid approximation for the motion of vortex lines in general flow fields, the structure of straight-line vortices in a uniform two-dimensional straining field is considered. Two cases are considered in detail; irrotational strain and simple shear.

Moore, D. W. and Saffman, P. G.

"THE MOTION OF A VORTEX FILAMENT WITH AXIAL FLOW"

Phil. Trans. Royal Soc. London, Vol. 272, No. 1226, July 1972, pp. 403-429

Infinitesimal waves on a uniform vortex flow is studied. The equation for the frequency of helical waves is obtained, and solved for the case of long waves which leave the internal structure almost unaltered. A method is developed to obtain results for vortices of non-uniform structure and for displacements which are not necessarily small compared with the core radius. The approach consists of balancing the Kutta-Joukowski lift force, the momentum flux due to the axial motion, and the tension of the vortex line. A general equation for the motion of a vortex filament is obtained, valid for arbitrary shape and internal structure, and in the presence of an external irrotational velocity field. When the axial flow vanishes, the method is equivalent to using the Biot-Savart law for the self-induced velocity with a suitable cutoff.

Moore, M. D.

"WAKE VORTEX WINTIP-TURBINE POWERED CIRCULATION CONTROL HIGH-LIFT SYSTEM"

Circulation Control Workshop, Hampton, VA, March 2004, pp. 641-656

A synergistic technology set is proposed that would use Circulation Control (CC) trailing edge blowing coupled to a wake vortex powered wingtip-turbine air compressor. This technology would provide small aircraft with the ability to take off and land in shorter distances, while achieving greater efficiency at the cruise condition; or takeoff and land at equivalent speeds and distances as today with a smaller wing and higher wing loading. Circulation Control has been investigated for over 30 years and shown to be very effective in increasing the wing maximum lift coefficient in tests of commercial transport and fighter aircraft vehicles. However, one of the significant penalties associated with CC systems is the power required to supply the source blowing air. Another part of this problem is that the CC mass flow required per pound of aircraft, and therefore the pneumatic power required, is proportional to the square of the takeoff velocity. Applying CC systems to aircraft that takeoff and land at relatively high speeds, such as commercial transports and fighters that are on the order of 120 knots, requires significant blowing power. Applying a CC system to GA aircraft that takeoff and land at speeds of about 60 knots, would require lower mass flows and are potentially a better fit for this technology. GA aircraft currently suffer from poor cruise efficiencies because the wing areas are sized by the takeoff and landing condition, making the wing approximately twice as large as required for efficient cruise. In addition, over sizing the wing to meet takeoff and landing results in low wing loading which is much more susceptible to turbulence, resulting in poor ride quality compared to higher wing loadings.

Morales, F. and Squires, K. D.

"SIMULATION OF ROTOR VORTEX INTERACTIONS WITH A PARTICLE-LADEN TURBULENT BOUNDARY LAYER"

AIAA Paper No. 2011-4041, June 2011, Honolulu, Hawaii.

Rotorcraft operation in austere environments can result in difficult operating conditions, particularly in the vicinity of sandy areas. The uplift of sediment by rotorcraft downwash, a phenomenon known as brownout, hinders pilot visual cues and may result in potentially dangerous situations. Brownout is a complex multi-phase flow problem that is not unique and depends on both the characteristics of the rotorcraft and the sediment. The lack of fundamental understanding constrains models and limits development of technologies that could mitigate its adverse effects. This provides the over-arching motivation of the current work focusing on models of particle-laden sediment beds. The particular focus of the current contribution is numerical modeling of near-surface fluid-particle interactions in turbulent boundary layers. Simulations are performed with and without coherent vortices superimposed on the background flow to understand the influence of rotorcraft downwash. The objectives are to gain insight into the fluid-particle dynamics that influence transport near the bed by analyzing the competing effects of the vortices, inter-particle collisions, and gravity. The computations are performed using an Euler-Lagrange approach in which a fractional-step method is applied to the fluid and with the particulate phase modeled using Discrete Particle Simulation. Following the

introduction of coherent vortices into the domain, the structures substantially distort the boundary layer, increasing the wall shear stress and raising kinetic energy levels of the turbulence. The fluid phase then returns to equilibrium as the vortices dissipate further downstream.

Moreira, J. and Johari, H.

"DIRECT MEASUREMENT OF DELTA WING VORTEX CIRCULATION USING ULTRASOUND"

AIAA Paper No. 1997-0743, January 1997, Reno, NV.

The circulation around a closed path encompassing the primary vortex of stationary delta wings is investigated using ultrasound. Ultrasonic pulses were propagated clockwise and counterclockwise along a fixed, closed path which was positioned perpendicular to the delta wing root chord lines. Circulation in the plane of the closed path was then determined from the transit time difference between the clockwise and counterclockwise pulses. Half-delta wings of 60- and 70-deg sweep angle were tested over a range of angles of attack from 2 to 38 deg and from 2 to 52 deg, respectively, in 20 increments, and at distances of 35, 50, 65, and 80 percent root chord from the wing apexes. Circulation behavior was examined as it relates to these parameters and to primary vortex burst location. Circulation was measured to grow nonlinearly with angles of attack for which the burst point remained downstream of the wing planform; circulation then increased in an approximately linear manner with increasing angle of attack until the burst point reached the vicinity of the wing apex. Circulation was found also to increase approximately linearly with increasing chordwise location at constant angles of attack.

Morillo, J. A. and Peters, D. A.

"VELOCITY FIELD ABOVE A ROTOR DISK BY A NEW DYNAMIC INFLOW MODEL"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 731-738.

The potential flow equations are converted to ordinary differential equations through a Galerkin approach in which velocity and pressure potential functions are expanded in terms of closed-form solutions to Laplace's equation. Because the method gives differential equations for the flow in terms of a relatively few generalized coordinates that represent modes of the flowfield, the resultant equations can be used effectively in preliminary design, real-time simulations, and dynamic eigenvalue analysis for aeroelasticity. This new theory is more general than the Peters-He dynamic wake model because it has a more rigorous derivation and includes inflow modes previously neglected in the Peters-He model. Results are presented in the frequency domain for simple harmonic motion. The complete velocity field above the disk is obtained by this new methodology, for axial and skewed flows, for various skew angles, and for different pressure distributions and are compared with the Peters-He model and with an exact solution obtained by a convolution integral.

Morozov, V. V. and Kalyadina, T. V.

"GREEN'S MODEL OF CYLINDRICAL VORTEX DECAY"

Computational Math. And Modeling, Vol. 19, No. 2, 2008, pp. 186-194. [Translated from Prikladnaya Matematika I Informatika, No. 25, 2007, pp. 70-80.]

Modeling vortex decay is essential for estimating the risk that during landing an aircraft will hit the wake vortex from a preceding aircraft. The relevance of this problem has increased due to the growing traffic in airports and the development of vortex forecasting systems. Green's model, one of the models describing the decay of point vortices, is generalized in this article to cylindrical vortices.

"VALIDATION OF THE TIME BASED SEPARATION CONCEPT AT LONDON HEATHROW AIRPORT"

10th USA/Europe Air Traffic Management Research and Development Seminar (ATM2013), June 2013, Chicago, IL.

Headwind conditions on final approach cause a reduction in the landing rate which impacts not only the achieved capacity, but also the predictability of operations, time and fuel efficiency, and the environment (emissions). The ground speed reduction in headwind conditions results in an increase in the time spacing between each arrival pair for distance-based separations. The Time-Based Separation (TBS) concept changes the separation rules on final approach from distance based to time based to stabilize the time spacing between arrival pairs across headwind conditions to recover the lost landing rate currently experienced. This paper presents the key results of the final research phase of the validation of the TBS concept. This validation has been conducted in the framework of the SESAR Development phase project P6.8.1 Flexible and Dynamic Use of Wake Turbulence Separations. The work started in 2010 and is about to be finalized in February 2013 achieving pre-industrial development (V3) maturity level. The project has developed and assessed both the generic TBS concept and a local adaptation of the concept to the London Heathrow operating environment. The scope of the paper is focused on the validation of the concept for London Heathrow airport covering the real-time simulation results and the wake turbulence safety data analysis results.

"BASIC RESEARCH IN WAKE VORTEX ALLEVIATION USING A VARIABLE TWIST WING"

The 1980 Aircraft Safety and Operating Problem, Part 2, NASA Langley Research Center, March 1981, pp. 409-423

The variable twist wing concept was used to investigate the relative effects of lift and turbulence distribution on the rolled-up vortex wake. Several methods of reducing the vortex strength behind an aircraft were identified. These involve the redistribution of lift spanwise on the wing and drag distribution along the wing. Initial attempts to use the variable twist wing velocity data to validate the WAKE computer code have shown a strong correlation, although the vorticity levels were not exactly matched.

"NASA AERIAL APPLICATIONS WAKE INTERACTION RESEARCH"

Paper AA-82-005, American Society Agricultural Engineers and National Agricultural Aviation Association, Las Vegas, December 1982

A computer code has been developed for predicting trajectories of particles released in the wakes of airplanes or helicopters. The code accounts for effects of turbulence, crosswind, propeller slipstream, terrain variations, and plant canopy density on particle trajectories. Comparisons are given between experiments and theory. Applications of the code for spray pattern improvement are illustrated.

Morris, J. P.

"EFFECT OF ADDING VORTEX ATTENUATING SYSTEMS ON THE DESIGN, PERFORMANCE, AND OPERATIONS OF A HEAVY COMMERCIAL JET TRANSPORT"

Proceedings of the Aircraft Wake Vortices Conf., FAA-RD-77-68, June 1977, DOT Transportation Systems Center, Cambridge, MA, pp. 229-24.

Various trailing vortex attenuation concepts have been proposed for use on heavy jet transports. A preliminary investigation of the effects of several of these concepts on the design, performance, and operations of a model 747-200 airplane has been conducted. Three of these concepts that have been judged to be potentially feasible have been selected for this presentation: retractable splines, modified approach flaps (30 deg. inboard, 0 deg. outboard), and flight spoiler deflection. The effectiveness of these devices in alleviating the wake vortices is not addressed; the discussion is limited to the impact on airplane design requirements and resulting performance characteristics.

Morris, P. J., McLaughlin, D. K., Gabrielson, T. B. and Boluriaan, S.

"THE DEVELOPMENT OF A PLAN FOR THE ASSESSMENT, IMPROVEMENT AND DEPLOYMENT OF A RADAR ACOUSTIC SOUNDING SYSTEM (RASS) FOR WAKE VORTEX DETECTION"

Report 2005-0176054, September 2004, Penn State Univ., University Park, PA.

This report describes the activities completed under a grant from the NASA Langley Research Center to develop a plan for the assessment, improvement, and deployment of a Radar Acoustic Sounding System (RASS) for the detection of wake vortices. A brief review is provided of existing alternative instruments for wake vortex detection. This is followed by a review of previous implementations and assessment of a RASS. As a result of this review, it is concluded that the basic features of a RASS have several advantages over other commonly used wake vortex detection and measurement systems. Most important of these features are the good fidelity of the measurements and the potential for all weather operation. To realize the full potential of this remote sensing instrument, a plan for the development of a RASS designed specifically for wake vortex detection and measurement has been prepared. To keep costs to a minimum, this program would start with the development an inexpensive laboratory-scale version of a RASS system. The new instrument would be developed in several stages, each allowing for

a critical assessment of the instrument's potential and limitations. The instrument, in its initial stages of development, would be tested in a controlled laboratory environment. A jet vortex simulator, a prototype version of which has already been fabricated, would be interrogated by the RASS system. The details of the laboratory vortex would be measured using a Particle Image Velocimetry (PIV) system. In the early development stages, the scattered radar signal would be digitized and the signal post-processed to determine how extensively and accurately the RASS could measure properties of the wake vortex. If the initial tests prove to be successful, a real-time, digital signal processing system would be developed as a component of the RASS system. At each stage of the instrument development and testing, the implications of the scaling required for a full-scale instrument would be considered. It is concluded that a RASS system, developed for the specific application of wake vortex detection, could become part of a robust Aircraft Vortex Spacing System (AVOSS). This system, in turn, could contribute to Reduced Spacing Operations (RSO) in US airports and improvements in Terminal Area productivity (TAP).

"FORMATION OF MINI VORTEX RINGS ARISING FROM A VORTEX PAIR IMPINGING ON A WAVY WALL"

69th Annual Meeting of the APS Division of Fluid Mechanics, November 2016, Portland, OR.

In this work, we examine the impingement of a counter-rotating vortex pair onto a wavy wall. When a vortex pair with the long-wave 'Crow' instability interacts with a flat boundary, the topology of the pair changes. This results in rebounding vortical structures whose form is dependent on the extent of the instability prior to wall interaction. By considering the 'complementary' experiment of a straight vortex pair encountering a wavy wall (rather than a wavy vortex pair impinging on a flat wall), certain critical features of the two flows are found to be similar. Such research has applications in fundamental turbulence, and in flows such as wingtip vortices generated behind aircraft.

"GROUND JET BLAST HAZARD"

NASA ASRS Directline, Issue No. 6, August 1993.

A high-level description on the importance of jet blast is given herein. A summary of the incident reports related to jet blast was presented.

Morton, B. R.

"THE STRENGTH OF VORTEX AND SWIRLING CORE FLOW"

J. Fluid Mech., Vol. 38, Part 2, September 1969, pp. 315-333

This note presents a discussion of the roles of axial momentum flux, flow force, angular momentum flux and circulation in determining the strength and hence characterizing the structure of such narrow

rotating axisymmetric core flows as swirling jets, vortex jets, sink vortices and vortex wakes. The salient (though sometimes neglected) features of these core flows are that perturbation pressure plays an essential role both in the coupling of axial and azimuthal velocity fields and in the transmission of force along the core, and that flux of angular momentum is invariant only along cores with zero gross circulation. Several existing solutions are brought into relationship by the discussion, including Long's similarity solution for draining vortices and Reynolds' dimensional treatment of swirling wakes.

Morton, T. S.

"THE VELOCITY FIELD WITHIN A VORTEX RING WITH A LARGE ELLIPTICAL CROSS-SECTION"

J. Fluid Mech., Vol. 503, 2004, pp. 247-271

The velocity field within a steady toroidal vortex is found for arbitrary mean core radius and section ellipticity. The problem is solved by transforming to coordinates that define invariant sets. The method allows the properties of the coordinate system metric tensor to be exploited in the continuity equation to obtain the solution. The vorticity is found to decrease monotonically with distance from the symmetry axis. For a given outer radius and outer perimeter velocity, the circulation of the vortex ring can be either smaller or larger than that of Hill's spherical vortex.

Morvant, R., Badcock, K. J., Barakos, G. N. and Richards, B. E.

"AIRFOIL VORTEX INTERACTION USING THE COMPRESSIBLE VORTICITY CONFINEMENT METHOD"

AIAA Journal, Vol. 43, No. 1, January 2005, pp. 63-75

The phenomenon of blade-vortex interaction (BVI) is central to the study of rotorcraft aerodynamics and aeroacoustics. The numerical simulation of BVI is challenging because most numerical schemes tend to alter the characteristics of the vortex, which must be preserved until the interaction. The compressible vorticity confinement method (CVCM) can preserve vortices and requires minimal modifications to existing computational-fluid-dynamics codes. Inviscid and viscous calculations using a range of turbulence models have been carried out for a well-known, head-on BVI case. This is the first time CVCM is employed for turbulent flow calculations with an upwind solver. The results obtained using the CVCM show a good agreement with measurements.

Mosher, M. C.

"A METHOD FOR COMPUTING THREE-DIMENSIONAL VORTEX FLOWS"

Zeitschrift fur Flugwissenschaften und Weltraumforschung, Vol. 9, May-June 1985, pp. 125-133

A new vortex method is presented for computing incompressible, inviscid, three-dimensional fluid flows. It is pointed out that this method has the convenient numerical properties of the two-dimensional vortex method, and, for this reason, is ideally suited for computing fluid flows in many problems of aerodynamic and hydrodynamic interest. Thus, jets and concentrated wake vortices can

be studied, considering wing-tip, strake, nose, and horseshoe vortices. The bookkeeping efforts involved in extending this method to a consideration of viscous effects are not very great, and the discussed procedure has, therefore, an advantage over the vortex filament method. Another advantage is related to the absence of requirements for the tracking of a finite difference grid. The considered method was successfully tested with respect to three problems.

Moss, S. J.

"THE TESTING AND VERIFICATION OF CONTRAIL FORECASTS USING PILOT OBSERVATIONS FROM AIRCRAFT"

Meteorol. Appl., Vol. 6, 1999, pp. 193-200.

Contrail forecasting techniques used within the UK Meteorological Office have changed little since the early 1940s and there has been no formal verification of the results. Recent research has shown that old forecasting techniques may not be wholly applicable to modern aircraft that now use more efficient engines. To compare the performance of both the old and the new forecasting techniques a validation trial was carried out over a nine-month period in which RAF pilots reported when and where contrails did and did not occur. These observations were compared with the predicted contrail levels from both the old and newer forecasting techniques. The results indicate that both techniques give a similar performance and that neither significantly out-perform a simple persistence prediction.

"A PARAMETRIC INVESTIGATION OF NON-CIRCULAR SPIROID WINGLETS"

EPJ Web of Conferences, Vol. 67, 2014, pp. 02077-1 to 02077-6.

This paper will present the study about Spiroid winglets and will go through its theoretical significance as well as the processes involved in the selection of an optimum aerodynamic design (configuration) of the spiroid that produced efficient aerodynamic performance results in terms of mainly Lift to Drag ratio (L/D), Induced drag, Chordwise and Spanwise Pressure distributions, Vorticity formation and strength comparison (between a simple wing, simple winglet and the spiroid with the best performance results) by varying several parameters and by comparing detailed Computational Fluid Dynamics Analyses on every design under cruise conditions. Consequently, the research conducted in this paper concluded that the spiroid exhibit better performance numbers upon comparison with its other options in terms of vortex reduction and overall drag reduction.

Moulden, T. H. and Frost, W.

"EFFECTS OF FOG DROPLETS ON WAKE VORTEX DECAY RATE"

NASA CR-2758, October 1976, Univ. Tennessee Space Institute, Tullahoma, TN

A simple model for the motion of particles in a laminar line vortex is discussed. The energy required to accelerate a set of these particles was determined and shown to be only a small fraction of the energy content of the vortex flow. It is shown that this energy transfer is unlikely to be sufficient to significantly modify the vortex decay rate. It is further argued that the effect of the particle on the viscous properties of the resulting two-phase fluid leads to a slower decay rate than in single phase air flow. However, this conclusion may not necessarily follow for turbulence flows. Results show that the migration of particles to the outer flow results in a redistribution of the velocity profile in the vortex and in a non-uniform two phase viscosity across the core. It is suggested that these effects may accelerate vortex bursting.

Moussa, C. and Carley, M. J.

"A LAGRANGIAN VORTEX METHOD FOR UNBOUNDED FLOWS"

International J. Numerical Methods in Fluids, John Wiley and Sons Ltd., 2008

A technique is presented for velocity calculations on the highly distorted node distributions typical of those found in Lagrangian vortex methods. The method solves the partial differential equation for stream function directly on the nodes, via a sparse, symmetric system of equations that can be solved using standard iterative solvers. When implemented in a triangulated vortex method, the technique gives computation times which scale as N to power 1.23, where N is the number of nodes. The computation scheme is derived for two-dimensional problems and applied to the prediction of the evolution of perturbed multipole vortices.

Mowforth, E.

"DETAILS OF MEASUREMENTS IN A TURBULENT TRAILING VORTEX"

Aero. Quarterly, Vol. 10, May 1959, pp. 161-162

The vortex was produced by an untwisted rectangular wing, which was mounted as a half-model in the middle of the wall of the low-speed wind tunnel at Cambridge University. Measurements were made of total pressure, angle of upwash, and static pressure.

Mudkavi, V. Y.

"THE PHENOMENON OF VORTEX BREAKDOWN"

Proceedings of the Fluid Dynamics Symposium in Honour of Professor R. Narasimha on his 60th Birthday, July 1993, Sikkim, India, pp. 123-135.

Vortex breakdown is an abrupt change of flow structure that occurs in swirling flows. More than 3 decades of research in this area has not shed light upon this very basic fluid dynamical phenomenon. The mechanism that leads to vortex breakdown is very poorly understood despite numerous theoretical and experimental investigations. There is still a need for a coherent theory. In this paper

these issues are considered in the form of a review of current literature on the phenomenon of vortex breakdown. Some existing criteria to predict the breakdown are presented.

Mudukutore, A. S. and Marshall, R. E.

"SIMULATION OF RADAR OBSERVED WINGTIP GENERATED WAKE VORTICES IN FOG"

Proceedings 28th Conf. on Radar Meteorology, American Meteorology Society, Austin, TX, September 1997, pp. 161-162

The present radar simulation attempts to model aircraft wingtip wake vortex returns in the presence of ground clutter and noise. The reflectivity model used assumes backscattering from a rain and cloud-droplet Rayleigh target environment. A Ka-band pulsed Doppler radar is simulated for the wake generated by a C-5A airlifter.

Mueller, E. R.

"APPLICATION OF UAV TECHNOLOGY TO EVALUATION OF TIME-BASED TRAJECTORY NAVIGATION REQUIREMENTS"

AIAA Paper No. 2004-6535, Chicago, IL, September 2004.

A review of air traffic control procedures and studies suggests that if airport capacity is to increase substantially it will be necessary to precisely control the flight paths and times of arrival of aircraft in the airport vicinity. One such method of achieving this precision, termed the individual flight corridor concept, is being studied to determine if such a process is feasible. The benefits of the concept, which have been evaluated by other researchers, are presented, and are followed by an analysis of the obstacles to and requirements for its implementation. Using this previous research as a foundation, the longitudinal and lateral navigation requirements are defined that implement the individual flight corridor concept with an equivalent level of safety to current arrival operations. The primary obstacle to meeting the navigation requirements of the time-based trajectory is uncertainty in the wind field forecast around the airport, so a simulation was designed to quantify the relationship between wind uncertainty, navigation errors, and aircraft dynamics. The results of the simulation suggest that wind errors up to 15 meters per second in either the longitudinal or lateral directions may be compensated for within the required navigation performance that will produce an equivalent level of safety to current operations, evidence that the individual flight corridor concept will be a viable method of increasing arrival capacity at some airports. An Unmanned Aerial Vehicle (UAV) currently under development at the Unmanned Flight Operations Laboratory of NASA Ames will be used to flight test the concept and validate the results of the simulation. Flight testing with a UAV is projected to reduce cost and increase safety relative to the use of manned aircraft, and provide more flexibility in the mix of equipment and guidance and control capabilities.

Muirhead, V. U.

"COMPRESSIBLE VORTEX FLOW"

AIAA Paper No. 1973-0106, Washington, DC, January 1973

The key role that the axial core flow plays in the characteristics of an unconfined compressible vortex has been examined. Isentropic compressible flow equations have been developed to relate pressure, density, and velocity. An index was developed to indicate the strength of a vortex produced by induced circulation and induced core flow. Using the index and the compressible flow equations, the variation of vortex characteristics with change in circulation, core velocity, atmospheric pressure, kinematic viscosity and the speed of sound was determined. The unconfined vortex was modeled with selected boundary conditions. Experimental observations are discussed and related to the theory.

Mula, S. M., Stephenson, J. H., Tinney, C. E. and Sirohi, J.

"DYNAMICAL CHARACTERISTICS OF THE TIP VORTEX FROM A FOUR-BLADED ROTOR IN HOVER"

Experimental Fluids, Vol. 54, 2013, pp.1600-1613.

Dynamical characteristics of tip vortices shed from a 1 m diameter, four-bladed rotor in hover are investigated using various aperiodicity correction techniques. Data are acquired by way of stereo-particle image velocimetry and comprises measurements up to 260 degrees vortex age with 10-degree offsets. The nominal operating condition of the rotor corresponds to $Re = 248,000$ and $M = 0.23$ at the blade tip. With the collective pitch set to 7.2 degrees and a rotor solidity of 0.147, blade loading (coefficient of thrust divided by rotor solidity) is estimated from blade element momentum theory to be 0.042. The findings reveal a noticeable, anisotropic, aperiodic vortex wandering pattern over all vortex ages measured. These findings agree with recent observations of a full-scale, four-bladed rotor in hover operating under realistic blade loading. The principal axis of wander is found to align itself perpendicular to the slipstream boundary. Likewise, tip vortices trailing from different blades show a wandering motion that is in phase instantaneously with respect to one another, in every direction and at every wake age in the measurement envelope.

Mula, S. M., Stephenson, S., Tinney, C. E. and Sirohi, J.

"DYNAMICAL AND EVOLUTIONARY CHARACTERISTICS OF THE TIP VORTEX FROM A FOUR-BLADED ROTOR IN HOVER"

68th AHS Annual Forum, May 2012, Fort Worth, TX.

The dynamical and evolutionary characteristics of the tip vortices produced by a reduced-scale, 1-m diameter, four-bladed rotor in hover are investigated using the well-known Q criterion combined with the center of mass approach. The data is acquired by way of stereo PIV and focused on wake ages up to 360 degrees with 10-degree offsets during hover conditions. The nominal operating condition of the rotor is at a rotational speed of 1520 RPM, corresponding to $Re = 248,000$ and a blade loading of 0.0446, obtained from BEMT estimates. Previous investigations revealed a noticeable, anisotropic, aperiodic vortex jitter pattern over all vortex ages which was not previously observed. Furthermore, the

core radius appeared to be constant after the first blade passage, even up to a vortex age of 260 degrees and was also not previously observed. These findings are confirmed using other vortex methods: Centroid of Vorticity and Normalized Helicity.

Muller, B.

"HIGH ORDER DIFFERENCE METHOD FOR LOW MACH NUMBER AEROACOUSTICS"

European Congress on Computational Methods in Applied Sciences and Engineering ECCOMAS 2001, Swansea, Wales, UK, September 2001

The Euler equations are split into a conservative and a symmetric non-conservative portion to allow the derivation of a generalized energy estimate. Owing to the large disparity of acoustic and stagnation quantities in low Mach number aeroacoustics, the split Euler equations are formulated in perturbation form. While the conventional central sixth-order accurate stencil is employed in the interior, the difference method is third-order accurate at the boundary to satisfy the summation by parts property analogous to the integration by parts in the continuous energy estimate. Since thereby a discrete energy estimate is automatically satisfied, strict stability of the high order difference method is guaranteed. The boundary conditions are implemented by a penalty term. The classical Runge-Kutta method is used for time integration. Spurious oscillations are suppressed by a new characteristic-based filter. The method has been applied to simulate vortex sound at low Mach numbers. The computed acoustic pressure generated by an almost circular Kirchhoff vortex is in excellent agreement with the analytical solution.

Muller, B.

"ON SOUND GENERATION BY THE KIRCHHOFF VORTEX"

Report 209/1998, 1998, Uppsala University Dept. of Scientific Computing, Uppsala, Sweden

A 2D test case for low Mach number computational aeroacoustics is provided. The Kirchhoff vortex is an elliptical patch of constant vorticity rotating with constant angular frequency in irrotational flow. This 2D flow field constitutes an exact solution of the 2D incompressible Euler equations. Due to its unsteadiness in the inertial frame of reference, the Kirchhoff vortex generates sound. Here, the exact incompressible velocity and pressure distributions and a low Mach number approximation of the far field acoustic pressure are stated. Moreover, the Helmholtz equation is exactly solved to yield the complete acoustic pressure field of an almost circular Kirchhoff vortex.

Muller, B. and Yee, H. C.

"ENTROPY SPLITTING FOR HIGH ORDER NUMERICAL SIMULATION OF VORTEX SOUND AT LOW MACH NUMBERS"

Journal of Scientific Computing, Vol. 17, No. 1-4, December 2002, pp. 181-190

Several recent developments in efficient, stable, highly parallelizable high order non-dissipative spatial schemes with characteristic based filters that exhibit low dissipation for long time linear and nonlinear wave propagations are utilized for computational aeroacoustics (CAA). For stability consideration, the Euler equations are split into a conservative and a symmetric non-conservative portion. Due to the large disparity of acoustic and stagnation quantities in low Mach number aeroacoustics, the split Euler equations are formulated in perturbation form to minimize numerical cancellation errors. Spurious oscillations are suppressed by a characteristic-based filter. The method has been applied to accurately simulate the sound emitted by an almost circular Kirchhoff vortex at low Mach numbers.

Muller, B. and Yee, H. C.

"HIGH ORDER NUMERICAL SIMULATION OF SOUND GENERATED BY THE KIRCHHOFF VORTEX"

Proceedings of 2nd AMIF Conference, 12-14 October 2000, pp. 1-14

An improved high order finite difference method for low Mach number computational aeroacoustics (CAA) is described. The improvements involve the conditioning of the Euler equations to minimize numerical cancellation errors, and the use of a stable non-dissipative sixth-order central spatial interior scheme and a third-order boundary scheme. Spurious high frequency oscillations are damped by a third-order characteristic-based filter. The objective of this paper is to apply these improvements in the simulation of sound generated by the Kirchhoff vortex.

Muller, E. A. and Obermeier, F.

"THE SPINNING VORTICES AS A SOURCE OF SOUND"

Conference Proceedings No. 22, September 1967, Specialists' Meeting of the Fluid Dynamics Panel of AGARD, Gottingen, Germany.

Flow and sound field of a simple aerodynamic sound source - the two-dimensional spinning vortices - are calculated. In this calculation the method of matched asymptotic expansions is employed. This method for the solution of singular perturbation problems has been developed during the last years. It allows for the computation of an asymptotic solution of the differential equations of the flow, which is valid both in the near field and the far field. One obtains a seventh power law in a characteristic velocity U for the sound power radiated by unit length of the spinning vortices in contrast to the eighth power law obtained by M. J. Lighthill for three-dimensional flows. It is possible to generalize the above method to vortex flows and their radiation fields; results will be given.

Muller, E.-A. and Obermeier, F.

"VORTEX SOUND"

Fluid Dynamics Research, Vol. 3, 1988, pp. 43-51.

Vortex motion is the only source of aerodynamic sound production in low Mach number flow: the unsteady part of the vorticity distribution contributes linearly to the sound field. The following fundamental model flows, which illustrate the vorticity as the predominant sound source in unsteady flows, are discussed: An initially planar elliptic vortex; two identical coaxial initially elliptic vortex rings, where a special case is the leap-frogging of two identical circular rings. For head-on collision of two identical circular vortex rings and for several cases of vortex-body interaction good agreement between theory and experiment exists. If the Mach number is not low, other mechanisms have also to be considered. Here the theory is not yet fully developed. Experimental results for a vortex-airfoil interaction in transonic flow show that local flow separation and boundary layer as well as compressibility effects play a basic role. However, if the motion of vorticity would be known in subsonic flow, essential parts of the sound field could be calculated by the theory. In addition, it is shown that the general theory is well suited to provide a better understanding of the scattering of sound waves by vortex motion, at least for long wave lengths.

"VISUALIZATION AND MEASUREMENT OF HELICOPTER ROTOR FLOW WITH SWEEPED BACK TIP SHAPES AT HOVER FLIGHT USING 'FLOW VISUALIZATION GUN' TIME LINE TECHNIQUE"

Experiments in Fluids, Vol. 21, Issue 3, July 1996, pp. 161-169.

The Flow Visualization Gun (FVG), a novel time line visualization technique, has been used to investigate the flow field of a helicopter rotor with swept back tip shape in hover flight condition. After introducing the FVG-technique, the paper presents some visualization photographs of the rotor blade tip vortices and the rotor downwash. Using orthogonal sets of flow photographs and digital image analysis, the 3-dimensional time line displacement within the flow and the tip vortex structure are determined. The data of 16 time-line experiments are interpolated in space and time to obtain velocity data on an evenly spaced 3-dimensional grid. Vorticity contour plots of the flow field show the complex arrangement of the tip vortices of the blade itself and of the preceding blade and some additional vorticity in the direct wake which may form a secondary vortex. Understanding and control of this vorticity distribution is important for the design of new efficient tip shapes. While the FVG technique has been used so far for qualitative investigation of complex flow patterns at local velocities of up to 20 m/s, a good comparison to laser velocimetry data validates the technique as an interesting tool for both qualitative and quantitative investigation.

Muller, S. D.

"BIO-INSPIRED OPTIMIZATION ALGORITHMS FOR ENGINEERING APPLICATIONS"

PhD Thesis, 2002, Swiss Federal Institute of Technology, Zurich, Switzerland.

The optimization of physical processes in engineering applications poses different challenges to the optimization engineer such as: Which optimization algorithm do I choose for a particular application? How do I choose optimization parameters and functions in a practical problem? How do I optimize

highly dynamical, noisy, or expensive problems? This thesis answers these questions in the context of stochastic optimization methods and applications. It provides new developments of bio-inspired optimization algorithms with an emphasis on evolutionary algorithms and their applications to a wide range of problems in the areas of turbomachinery, aeronautics, and micro- and nanotechnology. The development of bio-inspired algorithms includes the coupling of evolutionary algorithms with machine learning techniques for generalization purposes, the enhancement of convergence speed of evolutionary algorithms for parallel computer architectures, and a novel optimization algorithm inspired by the food-searching behavior of bacteria. In the application part, we discuss the optimal design of airfoil profiles, the cooling of turbine blades, jet mixing, and aircraft trailing vortex destruction, as well as micromixers, design of microchannels, and molecular dynamics applications.

"DETERMINATION OF REAL-TIME PREDICTORS OF THE WIND TURBINE WAKE MEANDERING"

Experimental Fluids, Vol. 56, 2015, pp. 56-1 - 56-11.

The present work proposes an experimental methodology to characterize the unsteady properties of a wind turbine wake, called meandering, and particularly its ability to follow the large-scale motions induced by large turbulent eddies contained in the approach flow. The measurements were made in an atmospheric boundary layer wind tunnel. The wind turbine model is based on the actuator disc concept. One part of the work has been dedicated to the development of a methodology for horizontal wake tracking by means of a transverse hot wire rake, whose dynamic response is adequate for spectral analysis. Spectral coherence analysis shows that the horizontal position of the wake correlates well with the upstream transverse velocity, especially for wavelength larger than three times the diameter of the disc but less so for smaller scales. Therefore, it is concluded that the wake is a rather passive tracer of the large surrounding turbulent structures. The influence of the rotor size and downstream distance on the wake meandering is studied. The fluctuations of the lateral force and the yawing torque affecting the wind turbine model are also measured and correlated with the wake meandering. Two approach flow configurations are then tested: an undisturbed incoming flow (modelled atmospheric boundary layer) and a disturbed incoming flow, with a wind turbine model located upstream. Results showed that the meandering process is amplified by the presence of the upstream wake. It is shown that the coherence between the lateral force fluctuations and the horizontal wake position is significant up to length scales larger than twice the wind turbine model diameter. This leads to the conclusion that the lateral force is a better candidate than the upstream transverse velocity to predict in real time the meandering process, for either undisturbed (wake free) or disturbed incoming atmospheric flows.

Mullins, J.

"TRAILS OF DESTRUCTION"

New Scientist, Vol. 152, No. 2056, November 1996, pp. 28-31

The horizontal and violently spinning streams of air, called wake vortices, which trail behind large aircrafts are hazardous for the following aircrafts. The ferocious nature of wake vortices necessitates adequate spacing between aircrafts to avoid plane crashes. Aircraft designers and air traffic controllers focus their attention on understanding the formation, persistence, decay, and prediction of vortices. Understanding the influence of wing design and weather conditions on vortex formation are important for overcoming the problems posed by wake vortices.

"POTENTIAL BENEFITS OF A PAIRED APPROACH PROCEDURE TO CLOSELY SPACED PARALLEL RUNWAYS IN INSTRUMENT AND MARGINAL VISUAL CONDITIONS"

27th Digital Avionics Systems Conf., October 2008, St. Paul, Minnesota

This paper discusses a concept called 'Paired Approaches' which is designed to facilitate approaches to closely spaced parallel runways (CSPRs) -- i.e., runways separated by 700 feet to 2500 feet, in instrument meteorological conditions (IMC). This paper focuses on the potential benefits of the procedure. It first provides a brief review of the procedure and prior work. It discusses the variety of procedures currently available for parallel runways, and discusses the magnitude of the delay problem in the National Airspace System (NAS) not addressed by any of these existing procedures or procedures under development, but which the proposed paired approach procedure would address. It presents the potential capacity gain from the paired approach procedure at two representative major airports, and the percentage of time that the procedure could be available. The paper also presents a summary of potential infrastructure requirements for implementing the procedure, and concludes by providing an outline of the research and development needed to establish its deployment in the NAS.

Munk, M. M.

"NOTE ON VORTICES ON THEIR RELATION TO THE LIFT OF AIRFOILS"

NACA TN-184, March 1924, NACA Langley Aero. Lab., Langley Field, VA

This note, prepared for the NACA, contains a discussion of the meaning of vortices, so often mentioned in connection with the creation of lift by wings. The action of wings can be more easily understood without the use of vortices.

Munk, M. M.

"NOTE ON VORTICES AND ON THEIR RELATION TO THE LIFT OF AIRFOILS"

Technical Note No. 184, March 1924, National Advisory Committee for Aeronautics, Washington, DC

This note, prepared for the N. A. C. A., contains a discussion of the meaning of vortices, so often mentioned in connection with the creation of lift by wings. The action of wings can be more easily understood without the use of vortices.

"AUSWERTUNG VON WIRBELSCHLEPPENMELDUNGEN IM US AVIATION SAFETY REPORTING SYSTEM (ASRS)"

Report: IB 111-2010/33, DLR, German Aerospace Research Center, July 2010, Cologne, Germany.

An evaluation of the NASA Aviation Safety Reporting System (ASRS) database was attempted. The database listed 488 reported wake encounters and 58 incidents (physical or personal damage) between the years of 1999 and 2009, of which most occurred during approach and landing. Most of the encountering aircraft were medium sized behind a medium or heavy aircraft.

"NUMERICAL SIMULATION OF VORTICAL FLOWS USING VORTICITY CONFINEMENT COUPLED WITH UNSTRUCTURED GRID"

AIAA Paper No. 2001-0606, Reno, NV, January 2001

This paper discusses the use of the vorticity confinement method coupled with the unstructured grid approach to simulate vortical flows. The method is evaluated by several vortical flow computations of the leading-edge separation vortices on delta wings and the wing tip vortices of NACA0012 wing. It is shown that the vorticity confinement can keep the vorticity away from the numerical diffusion effectively. Although further study to reduce the dependency of the confinement coefficient on the grid density is required, the present results indicate the possibility of accurate vortical flow computations by the vorticity confinement method coupled with unstructured and adaptive refinement grids.

Murman, E. M. and Stremel, P. M.

"A VORTEX WAKE CAPTURING METHOD FOR POTENTIAL FLOW CALCULATIONS"

AIAA Paper No. 1982-0947, St. Louis, MO, June 1982

A method is presented for modifying finite difference solutions of the potential equation to include the calculation of non-planar vortex wake features. The approach is an adaptation of Baker's 'cloud in cell' algorithm developed for the stream function-vorticity equations. The vortex wake is tracked in a Lagrangian frame of reference as a group of discrete vortex filaments. These are distributed to the Eulerian mesh system on which the velocity is calculated by a finite difference solution of the potential equation. An artificial viscosity introduced by the finite difference equations removes the singular

nature of the vortex filaments. Computed examples are given for the two-dimensional time dependent roll-up of vortex wakes generated by wings with different spanwise loading distributions.

Mursch-Radlgruber, E., Bradley, S. and von Hunerbein, S.

"VORTEX DETECTION AND RANGING (VODAR)"

ISARS 2004, Cambridge, UK, July 2004

Case studies of wing-tip vortices from landing aircraft have previously been reported from a linear array of four SODARs that recorded only vertical velocities. Aircraft vortex structure is clear on the single-shot SODAR profiles. We develop a relatively simple potential flow vortex model, which includes the essential features of the aircraft and of the SODAR array, allowing visualization of the time evolution of the 3D vortex structure. Comparison between field results and the simple vortex model demonstrates the prospect of routinely monitoring wakes and developing of climatology of their interaction with the environment.

"DESIGN AND COMPUTATIONAL FLUID DYNAMIC ANALYSIS OF SPIROID WINGLET TO STUDY ITS EFFECTS ON AIRCRAFT PERFORMANCE"

International Research Journal of Engineering and Technology, Vol. 4, Issue 12, December 2017, pp. 1298-1306.

In aerodynamic applications usual demands are reduction in overall drag and increase in lift. This constitutes a major challenge in any aerodynamic application or study. The same is true for a typical aircraft application. The drag profile of most aircrafts has a major portion of its drag consisting of lift induced drag. This drag can be reduced by using wingtip devices such as winglets etc. One such winglet is bio-inspired and is known as spiroid winglet. Present study deals with the investigation of the effects of spiroid winglets geometric modifications on aerodynamic performance of aircraft. The study consists of modifying the design of existing spiroid winglet based on paper and carrying out numerical simulations using Computational Fluid Dynamic (CFD) methods to simulate a modified spiroid winglet design consisting of a 360 degree blended wingtip and having enhanced aerodynamic performance.

"ON EVOLUTION AND ACOUSTIC CHARACTERISTICS OF A COMPRESSIBLE VORTEX RING"

Aeroacoustics, Vol. 7, No. 3 & 4, 2008, pp. 199-222.

Sound generated during formation of a compressible vortex ring at the open end of a shock tube and during its propagation is studied experimentally for shock Mach numbers of 1.28 to 1.61. The occurrence of different events such as primary ring formation, growth of the primary ring, secondary

and tertiary vortices formation, and pinching-off are identified as predominant noise producing events. Wavelet analysis of the measured microphone signal identifies the time of occurrence of the above events which is verified using flow visualization pictures. The distributions of acoustic fluctuations are measured at a fixed distance from the exit center of the tube at different angular locations in horizontal diametrical plane and the directivity of the amplitude of sound pressure associated with the evolution of vortex ring is found. It is observed that the vortex ring's evolution sound is dominant between 25 to 50 degrees angle from the axis of the shock tube. Experiments with short driver section produce rings with small trailing jet. Sound generated during the initial formation of these rings, after the diffraction of the incident shock at the open end of the shock tube, is dominant than the vortex ring's evolution sound. In shock tubes with larger driver section, the primary vortex ring is followed by a relatively longer trailing jet. In these cases, sound generated during formation of subsequent shear-layer vortices and their interaction with the trailing jet is also significant.

"INSTRUMENTATION SYSTEM FOR ONBOARD DETECTION, WARNING AND AVOIDANCE OF WAKE VORTEX, WINDSHEAR AND CLEAR AIR TURBULENCE HAZARDS - FIRST RESULTS FROM I-WAKE TEST CAMPAIGNS"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

The European funded I-WAKE project is dedicated to the functional definition of a future Detection, Warning and Avoidance system for atmospheric hazards, the assessment of proper Human-Machine Interface (HMI), the demonstration of airborne detection of wake vortices and the development of laser technology for a future affordable system. One of the system requirements is its operation in all phases of flight and in all weather; to satisfy this request, the system must be multi-sensor, e.g. a combination of lidar, radar and uplinked data, and must compensate the 2.4km detection range of its lidar with a predictor. Early June, the project completed its flight simulator phase to assess with pilots HMI solutions for wake vortex hazard display on Navigation Display, Vertical Navigation Display and Primary Flight Display. For wake vortices, the predictor used is based on VFS degraded by the uncertainties on the model inputs. The flight simulator tests were conducted at AIRBUS facilities in Hamburg on the THOR simulator. The impact of weather on the wake prediction was compared in a robustness analysis to the other input parameters. End of June, the flight tests were successfully carried out in Toulouse to show the feasibility of airborne detection of wake vortices. The equipment was installed onboard the NLR Cessna Citation II test aircraft and detected invisible wake vortices generated by an A340-600 flying 2-3Nm ahead. Thanks to varied atmospheric conditions, how much weather impacts the lidar detection performance can be studied. The presentation will summarize the results of the wake predictor robustness analysis with respect to parameter uncertainties and present for the first time the successful results of the June flight test campaign. Recommendations for the system definition conclude the talk.

"ATM DECISION SUPPORT TOOL FOR WAKE VORTEX HAZARD MANAGEMENT COMBINING SENSORS AND MODELING"

AIAA Paper 2014-2332, June 2014, Atlanta, GA.

Capacity gains in the terminal area and on the airport surface can be achieved by integrating wake vortex hazard management more dynamically in the setting of separation minima. To define these more efficient intervals, smart planning techniques are integrated into a wake vortex decision support system. The system performs prediction, detection and monitoring of wake vortices based on wake vortex sensor suite and sensor simulations, wake predictor, weather sensors and weather nowcasting and forecasting. The architecture and system performance has been verified and validated during several trials. The results and recommendations have been used to define the trials to come and subsequent technology improvements.

Myers, T. J.

"DETERMINATION OF BRAGG SCATTER IN AN AIRCRAFT GENERATED WAKE VORTEX SYSTEM FOR RADAR DETECTION"

Ph.D. Thesis, August 1997, Virginia Polytechnic Institute, Department of Electrical Engineering, Blacksburg, VA

Remote detection and tracking of wingtip generated wake vortices is important for hazard avoidance especially near airports. Aircraft that fly through these hazardous vortices experience sudden induced roll. Experiments have demonstrated that there is sufficient radar cross section for remote detection at frequencies ranging from VHF to C band (100 MHz to 5 GHz). The mechanism that yields this radar cross section is Bragg scattering from the index of refraction variations due to the atmospheric water vapor and potential temperature fields being mixed by the wake vortex system. Refractive index variations of the size that correspond to half the operating radar wavelength produce the observed radar return. Previous analysis has postulated turbulence within the wake vortex to be the generator

of the index of refraction variations. In this work, a new mechanism is identified that does not assume turbulence within the wake vortex system. This 'laminar flow mechanism' causes refractive index structuring that stretches into successively smaller spirals over time as the wake vortex system swirls and descends through the stratified atmosphere. The results are quantitatively consistent with experimental data. Results indicate that this new mechanism has a sharply peaked doppler spectrum which is encouraging for coherent detection by doppler radar.

Myers, T. J., Scales, W. A. and Marshall, R. E.

"DETERMINATION OF AIRCRAFT WAKE VORTEX RADAR CROSS SECTION DUE TO COHERENT BRAGG SCATTER FROM MIXED ATMOSPHERIC WATER VAPOR"

Radio Science, Vol. 34, No. 1, January-February 1999, pp. 103-111

Remote detection and tracking of wing-tip generated wake vortices are important for hazard avoidance, especially near airports. Aircraft that fly through these hazardous vortices experience sudden induced roll. Experiments have demonstrated that there is sufficient radar cross section for remote detection at frequencies ranging from VHF to C band (100 MHz to 5 GHz). The mechanism that yields this radar cross section is Bragg scattering from the index of refraction variations due to the atmospheric water vapor being mixed by the wake vortex system. Refractive index variations of the size that correspond to half the operating radar wavelength produce the observed radar return. Previous analysis has postulated turbulence within the wake vortex to be the generator of the index of refraction variations. In this work, a new mechanism is identified that does not assume turbulence within the wake vortex system. This 'laminar flow mechanism' mixes the stratified atmosphere as the wake vortex system swirls and descends, which causes refractive index structure that stretches into successively smaller spirals over time. The results are quantitatively consistent with experimental data.

"AN EXPERIMENTAL STUDY OF THE INTERACTION OF LARGE THREE-DIMENSIONAL EDDIES AND SMALL STREAMWISE VORTICES"

AIAA Paper No. 1997-0442, Reno, NV, January 1997

The interactive effect of large three-dimensional eddies convecting above small near wall streamwise vortices was experimentally studied. Counter-rotating streamwise vortices emulating turbulent boundary layer near wall structure were generated by a Gortler instability mechanism. Large outer region eddies were generated and shed three-dimensionally by pitch oscillating a NACA 0009 airfoil with saw-tooth shape trailing edge extension. The structure of these large three-dimensional eddies included a high speed insweep toward the wall whose leading-edge front was skewed in the spanwise direction. The near wall streamwise vortices broke down when this high-speed front arrived overhead. This suggests that the large outer region eddies, and particularly the high speed insweep, plays a role in the bursting process of turbulent boundary layers.

"VORTEX SHEET MODELING WITH CURVED HIGHER-ORDER PANELS"

J. Aircraft, Vol. 24, No. 11, November 1987, pp. 776-782

A method is presented for predicting the geometry of a vortex sheet trailing a lift-generating wing. It differs from other methods in that it uses a continuous vorticity distribution and curved panels rather than discrete vortex filaments or flat panels. Although the original intent was to apply cyclic iterations to the computed results, it was found that the results of the initial cycle were already in good agreement with the experiment.

Nagid, G.

"WAKE TURBULENCE - THE INVISIBLE ENEMY"

ICAO Bulletin, Vol. 43, April 1988, pp. 14-15

Studies to reduce the danger of wake turbulence, especially to following aircraft, and guidelines for wake turbulence classification of aircraft are discussed. An ICAO conference created three categories of aircraft based on maximum certified take-off mass, with heavy craft being those over 136,000 kg, light craft being less than 7,000 kg and medium craft being those in between. The radar separation minima for light aircraft following medium aircraft has been increased from 7.4 km to 9.3 km. Further guidance material is being developed based on wake turbulence research.

Nagid, G.

"ICAO WAKE TURBULENCE PROVISIONS"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 10-1 - 10-12.

The ICAO wake turbulence provisions have been implemented by most of the Contracting States. Considerable efforts have been made by ICAO to standardize these provisions world-wide. Nevertheless, some States, including the US and UK, still have provisions which are different from those of ICAO in terms of designation and number of wake turbulence aircraft categories. Additional research and development programs, to detect and track wake vortices with a view to determining their dynamics and decay mechanism, are essential to determine the feasibility of reduced separation between aircraft, which would alleviate congestion and reduce delays at major airports.

Naguib, A. M. and Koochesfahani, M. M.

"ON WALL-PRESSURE SOURCES ASSOCIATED WITH THE UNSTEADY SEPARATION IN A VORTEX-RING/WALL INTERACTION"

Physics of Fluids, Vol. 16, No. 7, July 2004, pp. 2613-2622

Molecular tagging velocimetry measurements from an earlier investigation are used to study the wall-pressure and the flow structures responsible for its generation in the flow field resulting from the impingement of an axisymmetric vortex ring on a flat wall. The velocity-field data are used to obtain the spatial distribution of the pressure sources, and the result is employed in conjunction with the solution to Poisson's equation to yield the wall-pressure information. The outcome reveals a characteristic wall-pressure signature that is produced repeatedly whenever the primary vortex ring interacts with the wall to form vortex rings with opposite sense of vorticity. The details of the signature are analyzed and related to specific flow features and their mutual interaction at different phases of the generation/evolution cycle of the new rings. Finally, the flow mechanisms leading to the generation of substantial positive and negative wall pressure in the characteristic signature are clarified.

"LARGE EDDY SIMULATIONS OF PERSISTENT AIRCRAFT CONTRAILS"

AIAA Paper No. 2011-0993, January 2010, Orlando, FL.

A three-dimensional large eddy simulation (LES) model has been used to study the development of persistent aircraft condensation trails (contrails) under a variety of atmospheric and initial conditions. The LES solves the incompressible Navier-Stokes equations with a Boussinesq approximation for buoyancy forces. Contrail ice particles are modeled using a Lagrangian tracking approach, with water mass and heat exchange coupled between the vapor and solid phases. Three sets of simulations vary the atmospheric turbulence environment, initial aircraft wake flow field, and ambient humidity to investigate the sensitivity of contrail properties to these parameters. Higher levels of turbulence and vertical shear, larger aircraft, and higher ambient humidity are all found to increase the ice mass present in the contrail to some extent. Each of these parameters also affects the optical properties and area coverage of the resulting contrail. These simulations provide sensitivity data that are used to improve a model of aircraft exhaust plume dynamics implemented in a global scale climate model.

Nakagawa, T.

"ON UNSTEADY AIRFOIL-VORTEX INTERACTION"

Acta Mechanica, Vol. 75, 1988, pp. 1-13.

An experimental investigation on unsteady airfoil-vortex interaction has been done. The incident vortex, to interact with a downstream airfoil (NACA 0018, chord length 20 mm), is generated by a square cylinder (side length $D=20$ mm). The square cylinder and airfoil are arranged in tandem and the spacing ratio L/D of the central distance to the side length is set a constant value of 4.625. The free stream Mach numbers are varied between 0.153 and 0.750, whereas the free stream Reynolds numbers (based on the side length D) are varied between 71300 and 344000. It is found that as the incident vortex approaches the airfoil, the circulation and scale are decreased until it arrives at a position near the leading edge of the airfoil. During this stage, some circulation of the incident vortex is

transferred to the secondary vortex generated on the airfoil opposite to the surface that the incident vortex approaches. Thus, circulation and scale of the secondary vortex is increased. However, after the incident vortex goes further downstream, no circulation of the incident vortex is transferred to the secondary vortex effectively. As the result, both the incident vortex and secondary vortex decay due to the viscous dissipation through the interaction with the boundary layer of the airfoil. The locus of the incident vortex is deviated in such a way that it goes away from the airfoil. The streamwise position of the secondary vortex is adjusted by the incident vortex, or vice versa, to meet each other just behind the trailing edge of the airfoil.

Nakamura, Y. and Uchida, S.

"BREAKDOWN CONDITION OF AN AXISYMMETRIC SWIRLING FLOW"

AIAA Journal, Vol. 19, No. 8, August 1981, pp. 1083-1085

A method for prediction and explanation of vortex breakdown using a simple axial velocity profile is proposed. The principle underlying the method is to find solutions which approximately satisfy the Navier-Stokes equations, thus leading to the critical condition of breakdown.

Nakazono, Y.

"FLOW STRUCTURE OF ANNULAR JETS AND EFFECT OF ACOUSTIC EXCITATION ON THEIR MIXING"

AIAA-Paper No. 1996-0640, Reno, NV, January 1996

The effect of inner-to-outer nozzle diameter ratio on the flow structure of the wake and jets vortex speed have been studied by using a flow visualization method and a conditional sampling technique. As a result, convection velocity of wake vortex is faster than that of jet vortex. When inner-to-outer nozzle diameter is small, the wake has a helical mode. But, for large inner-to-outer diameter ratio, this mode changes, and large energetic wake vortex is generated periodically and moves downstream. Next, the effects of sound wave on their mixing were studied. Sound waves related to the shear layer were mainly selected. Mean velocity, fluctuation velocity and its spectra were measured, and jet flow was investigated by using a Schlieren photography and a smoke wire method.

Nangia, R. K. and Palmer, M. E.

"FORMATION FLYING OF COMMERCIAL AIRCRAFT - ASSESSMENT USING A NEW APPROACH - WING SPAN LOAD & CAMBER CONTROL"

AIAA Paper No. 2007-250, Reno, NV, January 2007

The idea of flying commercial aircraft in formation to reduce fuel usage, has been around for some time. There are many results available using idealized approaches e.g. vortex lattice formulations. In view of the greater importance being attached to environmental aspects, the need has arisen to evaluate the possible advantages and disadvantages. This paper steps up the analysis level exploiting a

recently developed design method that allows span loading and camber control on wings with without winglets. The method has been adapted to assess the aerodynamics of wings in formation and then to redesign them to eliminate induced roll effects. From a limited number of flight formation configurations assessed so far, the method predicts induced drag reductions of near 30%, affording overall drag reductions of the order of 15%. The benefits may well be larger, using other formation spacing parameters. Limited results using an Euler solver reflect benefits of the same order.

Narain, J. P. and Uberoi, M. S.

"THE MOTION OF A TRAILING VORTEX-WAKE IN A STRATIFIED MEDIUM"

Atmospheric Environment, Vol. 8, No. 5, May 1974, pp. 459-473

An analytical study of a trailing vortex-wake in a uniform and a stratified environment is presented. A turbulent entrainment velocity is postulated based on the assumption of similarity of the wake surface and consistent with several averaged conservation equations. In a homogenous density environment, the descending wake is brought to rest due to its buoyancy in the initial phase of wake motion. It is then accelerated upwards. The lifetimes of the wakes are found to be in excellent agreement with previous experimental results. In the absence of mutual interaction of vortices in the wake, the final ascending phase is a decelerating phase. The effect of weak linear stratification is to damp the movement of the vortex wake. The wake oscillates with decreasing amplitude and wavelengths with increasing magnitudes of linear stratification.

"TRAILING VORTEX-PAIR INSTABILITY"

Phys. Fluids, Vol. 16, No. 6, June 1973, pp. 761-768

The instability of a vortex-pair to infinitesimal disturbances is studied in the inviscid and incompressible fluid approximations. The cores of the vortices contain uniform axial-velocity jets of fluid density different from that of the surrounding medium. In one model a nonrotating core with surrounding potential vortex is assumed, and in the other a uniformly rotating core. In the lowest order of a perturbation parameter, denoting the ratio of vortex core radius to the distance between the vortices, the long-wavelength symmetric amplification factor of a vortex-pair decreases with increasing jet axial-velocity in either model, with decreasing core density in a rotating core model, and with increasing core density in nonrotating core model. The vortex-pair is more unstable to negative mode of deformation than to the positive mode in the presence of an axial jet in both models considered. The surface tension has a destabilizing effect on the vortex pair in the long-wavelength approximations. The effect of core density and jet axial velocity on long-wavelength symmetric amplification factors of the vortex pair in higher orders of perturbation parameters have also been outlined.

Narain, J. P. and Uberoi, M. S.

"NONLINEAR STABILITY OF CYLINDRICAL VORTEX ENCLOSING A CENTRAL JET OF LIGHT OR DENSE FLUID"

Phys. Fluids, Vol. 16, No. 9, September 1973, pp. 1406-1417

A nonlinear analysis of the inviscid stability of a cylindrical vortex enclosing a central jet of light or dense fluid is presented. A uniformly valid second-order expansion is obtained using the method of multiple time scales. For a stagnant core surrounded by a potential vortex, the axisymmetric mode remains stable to various scales of disturbances independent of core density. For asymmetric modes, the nonlinear effects make the stagnant core vortex sheet more unstable in second order for a given value of the core density. A central jet of any finite density always has a destabilizing effect on the jet-vortex system undergoing any mode of deformation. A jet of any velocity tends to increase the unstable growth rates with increasing order of perturbations. The surface tension has a stabilizing effect with increasing order of perturbations. The frequency of oscillation becomes amplitude dependent in various orders of perturbations. The cylindrical surface departs significantly from its initially perturbed sinusoidal form and assumes a sinusoidal form.

Narducci, R.

"COMPARISON OF BLADE TIP VORTEX CALCULATIONS TO WIND TUNNEL MEASUREMENTS"

Proceedings of the ARO Rotorcraft Wake Prediction Basic Research Workshop, March 2009, Georgia Institute of Technology, Atlanta, GA, p. 185.

Accurate calculations of blade tip vortices by computational fluid dynamics methods is of ever-increasing importance to the rotorcraft community. Increasing demand for rotor performance requires design and evaluation of rotor systems with high-fidelity methods for helicopter manufacturers to remain competitive. Generally, CFD can provide accurate near-field solutions that capture key physical elements since they are based on first principles. However, CFD methods are notorious for premature dissipation when it comes to far field wakes. The implication is that in the rotor environment blade tip vortices are weakened or washed out completely prior to the arrival of the proceeding blade. The result is improper prediction of blade loads on the outboard section and ultimately poor rotor performance prediction. Calculations are made on a stationary rotor blade in Mach 0.15 flow for the purpose of benchmarking the ability of steady Reynolds Average Navier Stokes methods to compute blade tip vortices. Several spatial discretization schemes and gridding strategies are investigated. Computed results are compared against measurements made by the quantitative wake survey system in the Boeing-Vertol Wind Tunnel.

Nash, J. F.

"SOME CALCULATIONS EXTENDING THE WILLIAMS' MODEL OF THE DECAY OF TRAILING VORTICES"

LG73ER0191, October 1973, Lockheed-Georgia Company, Marietta, GA

Part I gives the results of calculations presented for any given span load distribution, relevant to the 'second stage' of trailing-vortex decay (where roll-up is complete but before the interaction between the two vortices becomes dominant). The problem of relating equivalent wake 'age' to distance downstream of the wing is addressed, for the case of a turbulent vortex. It is shown that a variable eddy viscosity is physically more realistic than a constant one, and the decay of the vortices with distance is calculated on this basis, for three simple spanwise-loading distributions. Some exploratory calculations have been performed to investigate the influence on vortex decay of the displacement effect associated with core injection. It is shown that the main effect is to limit the maximum circumferential velocities, present in the vortex, during the early phases of decay. In Part II, the vorticity equations, expressed in cylindrical polar coordinates, are solved for a semi-infinite rotationally-symmetric viscous vortex, in an incompressible, non-uniform axial flow. An advanced implicit numerical scheme is used, based on the extended Choleski method. The scheme is unconditionally stable, resulting in an economical, highly efficient computation tool. Input to the calculations consists of the vector vorticity profiles, at some initial axial station, together with the longitudinal variation of the far-field axial velocity. Output consists of the vector vorticity and velocity profiles at successive stations downstream.

"THE FLOW AROUND A MODEL HELICOPTER MAIN ROTOR IN GROUND EFFECT"

Experimental Fluids, Vol. 52, 2012, pp. 151-166.

Wind tunnel measurements of the wake below and ahead of a model helicopter main rotor in simulated forward flight in ground effect are presented. The wind tunnel used was equipped with a rolling road, and the ground speed was matched to the wind tunnel speed for a representative simulation in the wind tunnel of forward flight over the ground. Particle image velocimetry was used to investigate the structure of the wake, and it was observed that the moving ground had a remarkable effect on the flow; the wake is closer to the rotor and its size is reduced compared with the stationary ground case. The detailed distribution of vorticity within the wake is affected by the moving ground, and the mechanism for this is discussed in the paper.

Nathan, N. D. and Green, R. B.

"FLOW VISUALISATION OF THE HELICOPTER BROWN-OUT PHENOMENON"

The Aeronautical Journal, Vol. 113, No. 1145, July 2009, pp. 467-478.

Quantitative and qualitative results of a series of experiments conducted on a rotor in ground effect at low forward speeds are presented. The velocity over a wide area of the ground effect wake was measured using particle image velocimetry, and the evolution of the flow is described as the forward speed increases. The formation of a dust cloud leading to so-called helicopter brown-out was simulated through a series of flow visualization experiments. The technique involved sprinkling a fine dust on the ground below and ahead of the rotor. Larger dust clouds were observed at lower forward

speed, and the dust cloud penetrated the areas of the flow including those where vorticity levels were of low magnitude and occasional velocity fluctuations from the mean were large.

Naughton, J. W. and Settles, G. S.

"EXPERIMENTS ON THE ENHANCEMENT OF COMPRESSIBLE MIXING VIA STREAMWISE VORTICITY, PART I -- OPTICAL MEASUREMENTS"

AIAA Paper No. 1992-3549, July 1992, Nashville, TN.

In recent years, compressible turbulent mixing flows have been studied in detail to understand and control the physics governing them. Although much has been learned from these studies, attempts to significantly increase the mixing of two streams have been largely unsuccessful. Based upon promising results in subsonic flow, the present study was initiated to increase the compressible mixing rate of a supersonic jet injected into a co-flowing supersonic stream by adding streamwise vorticity to the injected flow. This flowfield was imaged using the Planar Laser Scattering (PLS) technique, and mixing rates were derived entirely from captured images. The results of this image analysis indicate that increases in mixing rate of up to 60 percent are possible through the addition of streamwise vorticity. Furthermore, the degree of mixing enhancement appears to be dependent on the amount of swirl added. Analysis of the instantaneous turbulent structure suggests that this increase in mixing is due to a modification of the largest turbulent structures in the mixing layers.

Naughton, J. W. and Settles, G. S.

"A THEORETICAL FRAMEWORK FOR MIXING LAYERS SURROUNDING COMPRESSIBLE TURBULENT SWIRLING JETS"

AIAA Paper No. 94-2245, June 1994, Colorado Springs, CO.

Recently, there has been some success in increasing the growth rates of compressible jets by adding swirl to the flow. Although some explanations for this phenomenon have been proposed, no definitive theory has been presented. In this paper, a framework for analyzing these flows is developed, and its results are compared with experimental data. The results indicate that the theoretical model can predict the enhanced growth rates associated with compressible swirling jets relative to their nonswirling counterparts. Furthermore, a convective Mach number for these swirling flows is discussed. Including compressibility effects determined by this parameter in the current analysis shows that there is an optimal amount of swirl that maximizes the mixing enhancement. Thereafter, any additional swirl actually decreases the enhancement effect.

Naughton, J. W., Cattafesta III, L. N. and Settles, G. S.

"AN EXPERIMENTAL STUDY OF COMPRESSIBLE TURBULENT MIXING ENHANCEMENT IN SWIRLING JETS"

Journal of Fluid Mechanics, Vol. 330, 1997, pp. 271-305.

Compressible jets with various amounts of swirl and compressibility are investigated experimentally. The mixing-layer growth rate is obtained from time-averaged images of the mixing layer using the planar laser scattering (PLS) technique, and the swirl is quantified with laser Doppler velocimetry and intrusive probes. The results conclusively demonstrate that the addition of swirl to the jet increases entrainment by up to 60 percent compared to a corresponding non-swirling case. Instantaneous PLS images reveal modified turbulent structure in the mixing layer of the swirling-jet cases. In particular, analysis of these images indicates that both the spatial extent and amplitude of the largest turbulent fluctuations are increased when swirl is added. Based on these results, a parameter B that correlates the observed growth-rate enhancement is proposed. This parameter is derived assuming that the streamwise vorticity, generated in the mixing layer by the addition of small amounts of swirl, causes additional turbulent mixing that increases the growth rate. When the available growth-rate data for swirling jets are plotted against this parameter, they collapse to a single curve with increased enhancement for higher values of B. This result implies that the degree of enhancement increases with compressibility, although the dimensional growth rates for the present compressible swirling-jet cases are still less than those of their incompressible counterparts.

Naughton, J. W., Cattafesta, L. N. and Settles, G. S.

"EXPERIMENTS ON THE ENHANCEMENT OF COMPRESSIBLE MIXING VIA STREAMWISE VORTICITY, PART II -- VORTEX STRENGTH ASSESSMENT AND SEED PARTICLE DYNAMICS"

AIAA Paper No. 1993-0742, January 1993, Reno, NV.

In recent years, compressible turbulent mixing has been studied in detail to understand and control the physics governing it. Although much has been learned from these studies, attempts to significantly increase the mixing of two streams have been largely unsuccessful. Based on promising results in subsonic flow, the present study was initiated to increase the mixing of co-flowing supersonic streams by way of streamwise vorticity. Part I of this study measured the mixing-layer growth rates of these swirling flows using Planar Laser Scattering (PLS). In this second part of the study, the strengths of the vortices are quantified using intrusive probes and Laser Doppler Velocimetry (LDV). In addition, the seed particles used for the PLS imaging are measured with a two-color light-transmission technique. An analysis of these experimental results indicates that the particles faithfully represent the dynamics of the turbulent swirling flow. Comparing the previously-determined mixing-layer growth rates with the present vortex strength data reveals that the increase of turbulent mixing, up to 60 percent for the cases studied, scales with the degree of swirl. Furthermore, this mixing enhancement appears to be independent of the level of compressibility of the mixing layer.

"PIV AND LDA MEASUREMENTS OF THE WAKE BEHIND A WIND TURBINE MODEL"

The Science of Making Torque from Wind, published in IOP Journal of Physics: Conference Series, Vol. 524, 2014, pp. 012168-1 to 012168-10.

In the present work we review the results of a series of measurements of the flow behind a model scale of a horizontal axis wind turbine rotor carried out at the water flume at Technical University of Denmark (DTU). The rotor is three-bladed and designed using Glauert theory for the tip speed ratio of 5 with a constant design lift coefficient along the span of 0.8. The measurements include dye visualization, Particle Image Velocimetry and Laser Doppler Anemometry. The wake instability has been studied in the range of tip speed ratio of 3 - 9 at different cross sections from the very near wake up to 10 rotor diameters downstream from the rotor. The initial flume flow was subject to a very low turbulence level with a uniform velocity profile, limiting the influence of external disturbances of the inherent vortex instability. Using PIV measurements and visualization, special attention was paid to detect and categorize different types of wake instabilities and the development of the flow in the near and the far wake. In parallel to PIV, LDA measurements provided data for various rotor regimes, revealing the existence of three main regular frequencies governing the development of different processes and instabilities in the rotor wake. In the far wake a constant frequency corresponding to the Strouhal number was found for the long-scale instabilities. This Strouhal number is in good agreement with the well-known constant that usually characterizes the oscillation in wakes behind bluff bodies. From associated visualizations and reconstructions of the flow field, it was found that the dynamics of the far wake is associated with the precession (rotation) of a helical vortex core. The data indicate that Strouhal number of this precession is independent of the rotor angular speed.

"EXPERIMENTAL STUDY OF VORTEX SHAPES BEHIND A WING EQUIPPED WITH DIFFERENT WINGLETS"

Journal of Aerospace Science and Technology, Vol. 3, No. 1, 2006, pp. 1-15.

An extensive experimental study is conducted to examine the effects of different winglet shapes and orientations on the vortex behind a wing, static surface pressure over the wing, and wake of a swept wing at various angles of attack. Four types of winglets, spiroid (forward and aft), blended, and wing grid are used in this investigation. Wing static surface pressure measurements are obtained for both chordwise and spanwise as well as the wake profiles at various angles of attack using the winglets. The data are compared with those without winglet -- that is, bare wing. The results show that integration of winglets change the flowfield over and around the wing significantly. Further, it is found that certain winglet configurations improve both the wake and the wing pressure distribution. The total pressure in the wake of the model varies drastically when the wing is equipped with winglets.

"COMPUTATIONAL STUDY OF THREE-DIMENSIONAL OBLIQUE SHOCK WAVE/VORTEX INTERACTION"

AIAA Paper No. 1995-2770, July 1995, San Diego, CA.

A numerical study has been conducted to study the three-dimensional oblique shock wave/vortex interaction (OSVI) to investigate the effects of Mach number, vortex strength, and ratio of the vortex axial to freestream velocity. The three-dimensional, unsteady, compressible Euler equations are solved

to simulate the OSVI. An analytical vortex model is prescribed at the inflow and allowed to interact with an existing oblique shock. The axial velocity through the vortex core has a deficit which is characteristic of supersonic stream-wise vortices. Three distinct flowfield structures are obtained depending on vortex strength and ratio of the vortex axial to freestream velocity. Weak interaction was characterized by minimal change in vortex strength and shock structure while a moderate interaction results in regions of subsonic flow. The strong interaction results in vortex breakdown, dramatic change in shock structure, and region of reversed flow. Streamwise redistribution of vorticity was also calculated and was found to be largest for the strong interaction while the weak interaction resulted in very small changes of vorticity levels.

Nedungadi, A. and Lewis, M. J.

"COMPUTATIONAL STUDY OF THE FLOWFIELDS ASSOCIATED WITH OBLIQUE SHOCK/VORTEX INTERACTIONS"

AIAA Journal, Vol. 34, No. 12, December 1996, pp. 2545-2553

The interaction between a supersonic streamwise vortex and an oblique shock is solved numerically using unsteady, three-dimensional Euler equations. The parametric study ascertains the effects of vortex strength, streamwise velocity deficit, and Mach number on the oblique shock/vortex interaction. The vortex, whose tangential and streamwise velocities are analytically modeled, is introduced upstream of the shock and allowed to interact with the shock. The interaction is examined at freestream Mach numbers of 3 and 5, using vortices of varying strength and possessing various velocity deficits. Three distinct types of interactions -- weak, moderate, and strong -- are observed, depending very strongly on the streamwise velocity deficit and, to a lesser degree, on the strength of the vortex. The weak interaction is characterized by a slight distortion of the shock and vortex with the resulting flowfield being supersonic everywhere. The moderate interaction, however, results in a more pronounced distortion of the shock, creating a small pocket of subsonic flow downstream of the interaction. In addition, the incident vortex is highly distorted by the shock and eventually splits up into two counter-rotating vortices. In the strong interaction, due to the formation of a large subsonic region, a dramatic reorganization of the original shock occurs, accompanied by a region of reversed subsonic flow, a stagnation point, and a drastic expansion of the vortex core, all of which are characteristics of vortex breakdown.

Nedungadi, A. and Lewis, M. J.

"NUMERICAL SIMULATIONS OF OBLIQUE SHOCK/VORTEX INTERACTIONS RESULTING IN VORTEX BREAKDOWN"

AIAA Paper No. 1997-0068, January 1997, Reno, NV.

The interaction between a supersonic streamwise vortex and an oblique shock is solved numerically using the unsteady, three-dimensional, Euler equations. In particular, the strength of the incident vortex and oblique shock are chosen such that the oblique shock/vortex interaction results in vortex

breakdown. The flowfield associated with vortex breakdown is analyzed and the effects of Mach number on vortex breakdown are presented. Due to the deficit in Mach number through the vortex core, the incident vortex breaks down, creating a large subsonic, reversed flow region. This subsonic region acts as if it were a bluff body in a supersonic stream, and the outer flow responds by creating a three-dimensional shock around it. It is observed that the static pressure within the recirculating bubble approaches stagnation pressure and that the axial velocity approaches zero. These two observations seem to indicate the possibility of vortex breakdown. It is also observed that when the vortex and shock strength are maintained, the axial extent of the breakdown region remains the same in the Mach number range examined; though the shape is dependent on the Mach number.

Nedungadi, A. and Lewis, M. J.

"NUMERICAL STUDY OF FUEL MIXING ENHANCEMENT USING AN OBLIQUE SHOCK/VORTEX INTERACTION"

Journal of Propulsion and Power, Vol. 16, No. 6, Nov.-Dec. 2000, pp. 946-955.

The effects of swirl and jet-to-freestream pressure ratio on the mixing performance of a swirling helium jet interacting with an oblique shock are investigated. The three-dimensional parabolized Navier-Stokes equations are solved to simulate the parallel injection of a swirling helium jet at Mach 3 into a coflowing stream of air at Mach 4. The effects of swirl and jet-to-freestream pressure ratios on the mixing performance are studied by considering various strengths for the swirling jet and various jet exit pressures, respectively. The mixing performance is based on several parameters that include the maximum helium mass fraction decay, the fraction of total helium mass flux present at various concentrations, and the total entropy rise. It is shown that the fraction of total helium mass flux that is present at a helium mass fraction of less than or equal to 0.05 increases from 8 to 16 percent and that the point at which pure helium ceases to exist occurs farther upstream with the addition of swirl. Furthermore, it is shown that the jet with the lower pressure and momentum provides better mixing performance than the higher pressure jet.

Neece, R. T.

"WAKE VORTEX RADAR SYSTEM DEVELOPMENT"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 299-308

An investigation of radar sensors for aircraft wake vortices is being conducted by NASA. The stated objective is to investigate microwave and millimeter wave sensors to locate, track, and observe the wake vortex hazard. Initially all-weather capability was the objective and early studies concentrated on the clear air detection problem. These studies included scattering and reflectivity studies, radar systems investigations, and clear air field experiments at X and C band. Bragg scattering from refractive index variations over small eddies was determined to be the most reliable natural reflectivity mechanism, and Bragg scattering by acoustic waves was also investigated. Clear air field

measurements were conducted at Wallops Flight Facility, White Sands Missile Range, with Lockheed Martin, and at Baltimore Washington International Airport, with the Applied Physics Laboratory. Results in clear air were marginal, indicating that developing a clear air detection system would be problematic. The focus has now changed to developing a low-visibility radar that will compliment a lidar wake vortex sensor. A 35 GHz pulsed Doppler radar is currently being assembled for field testing in 1998.

Neece, R. T., Britt, C. L., White, J. H., Mudukutore, A., Nguyen, C. and Hooper, B.

"WAKE VORTEX TRACKING USING A 35 GHz PULSED DOPPLER RADAR"

5th NASA Integrated CNS Conference and Workshop, Fairfax, VA, May 2005

A 35 GHz, pulsed-Doppler radar system has been designed and assembled for wake vortex detection and tracking in low visibility conditions. There is a potential for significant airport efficiency improvement, if a system can be employed to aid regulators and pilots in setting safe and efficient following distances based on airport conditions. To fill the need for detection capability in low-visibility conditions, a 35 GHz, pulsed-Doppler radar system is being investigated for use as a complimentary, low-visibility sensor for wake vortices. The radar sensor provides spatial and temporal information like that provided by Lidar, but under weather conditions that a Lidar cannot penetrate. Currently, we are analyzing the radar design based upon the data and experience gained during the wake vortex Lidar deployment with AVOSS at Dallas/Fort Worth International Airport. As part of this study, two numerical models were utilized in system simulations. The results of this study improve our understanding of the method of detection, resolution requirements for range and azimuth, pulse compression, and performance prediction. Simulations, applying pulse compression techniques show that detection is good in heavy fog to greater than 2000 m. Both compressed and uncompressed short pulses show the vortex structure. To explore operational challenges, siting and scanning strategies were also analyzed. Simulation results indicate that excellent wake vortex detection, tracking and classification is possible in drizzle (+15 dBZ) and heavy fog (-13 dBZ) using short pulse techniques (<99 ns) at ranges on the order of 900 m, with a modest power of 500 W output. At 1600 m, detection can be expected at reflectivities as low as -13 dBZ (heavy fog). The radar system, as designed and built, has the potential to support field studies of a wake vortex spacing system in low-visibility conditions ranging from heavy fog to rain, when sited within 2000 m of the flight path.

Nelkin, M.

"IN WHAT SENSE IS TURBULENCE AN UNSOLVED PROBLEM?"

Science, Vol. 255, January 1992, pp. 566-570.

Turbulence can be narrowly defined as a property of incompressible fluid flow at very high Reynolds number, and thus an attempt can be made to specify what is and what is not understood about it. The applicability of the Navier-Stokes equations of hydrodynamics to real turbulent flows and the success and limitations of direct numerical simulation are considered. A discussion is presented of universality,

and mention is made of the remarkable success of Kolmogorov's 1941 scaling ideas despite uncertainties about basic underlying assumptions such as local isotropy. Extensions of this scaling to the multifractal picture of dissipation fluctuations are discussed, but this picture remains phenomenological. Turbulence as defined above remains 'unsolved' in the sense that a clear physical understanding of the observed phenomena does not exist.

"SAFETY STUDY OF CLOSELY SPACED PARALLEL OPERATIONS UTILIZING PAIRED APPROACH"

DOT-FAA-AFS-400-2019-R-25, April 2019, FAA Flight Technologies and Procedures Division, Washington, DC.

This is an FAA report entitled 'Safety Study of Closely Spaced Parallel Operations Utilizing Paired Approach.' This study analyzed collision risk in the event of a course deviation by the lead aircraft in a Paired Approach operation. The closest in-trail distances deemed acceptable for the operation, referred to as collision safety limits, are identified. The study utilized fast-time simulations to assess collision risk for various in-trail starting distances at select locations along the approach. Major factors contributing to the collision safety limit include the difference in speed between the lead and trailing aircraft, runway centerline spacing, and the type of runway approach alignment (i.e., straight-in or offset).

Nelson, C. C., Cain, A. B. and Morris, P. J.

"SIMULATIONS OF HIGH SPEED IMPINGING JETS"

AIAA Paper No. 2012-0831, January 2012, Nashville, TN.

Time accurate simulation of a high-speed impinging jet configuration was performed using both the RANS-based Wind-US production flow solver and the CHOPA computational aeroacoustics solver. Qualitatively, the Wind-US solution predicted many of the major features observed experimentally for this flow. Though direct comparison with experiment was not possible, the predicted peak sound pressure level and frequency appears reasonable considering the published observations. The observed helical character of the jet plume was also predicted, at least in part. Our initial efforts to model this flow with the CHOPA solver, while not complete, are beginning to produce reasonable-looking results, though a full assessment is not possible until the simulation is complete.

Nelson, R. C.

"THE TRAILING VORTEX WAKE HAZARD: BEYOND THE TAKEOFF AND LANDING CORRIDORS"

AIAA Paper No. 2004-5171, Providence, RI, August 2004

This paper focuses on issues related to the trailing vortex wake hazard beyond the takeoff and landing corridors. The operational procedures adopted by the FAA in the 1970s for avoiding wake turbulence encounters in the take-off and landing corridors have been very successful in providing commercial

aviation with a high degree of safety. However, there is a growing body of evidence that encounters well beyond the immediate airport area could also prove to be hazardous. A review of commercial airline accidents for which a wake vortex encounter was a contributing factor in the accident are reviewed. Another problem that is addressed is wake encounters at cruise altitude. In the current study the vortex induced loads created by wake vortices at cruise altitude are examined.

Nelson, R. C.

"TRAILING VORTEX WAKE ENCOUNTERS AT ALTITUDE - A POTENTIAL FLIGHT SAFETY ISSUE?"

AIAA Paper No. 2006-6268, Keystone, CO, August 200.

The potential hazard of one aircraft encountering the trailing vortex wake of another aircraft during either take-off or landing is well known. The wake vortex hazard in the terminal area has been virtually eliminated using the operational procedures and aircraft separation criteria mandated by the air traffic authorities. This paper presents arguments that wake encounters at cruise altitude are a potential safety issue that needs to be examined. Wake vortex encounters at cruise altitudes are likely to increase due to three factors. These factors include; the reduction of the minimum vertical separation distances between aircraft, the increased air traffic allowed by the reduced vertical separations, and the large difference in the size of aircraft operating at the cruise altitudes. The arguments are supported by simple analysis and a review of simulation and flight test results obtained from earlier studies of wake encounters at low altitudes. Simple analysis techniques show that the rolling moment induced on a following aircraft is comparable in magnitude to that which could occur during take-off or landing. In addition, reported wake encounters at cruise altitude are discussed.

Nelson, R. C.

"TRAILING VORTEX WAKE DISTORTION AND ITS INFLUENCE ON AIRCRAFT SAFETY"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

This presentation examines the response of an airplane to an encounter with the trailing vortex wake generated by another airplane. Using simplified analysis techniques, key factors that affect the vortex-induced rolling moment on a penetrating airplane wing are presented. Simple strip theory and lifting line theory were used to estimate the rolling moment induced on the wing penetrating a trailing vortex wake. To test the validity of using simple strip theory or lifting theory to predict the vortex induced rolling moments, the methods were evaluated by comparing the predictions with experimental measurements. Experimental data obtained by NASA was used to evaluate the prediction methods. The data included measurements of the vortex velocity field and the roll moment induced on a wing located in the trailing vortex wake. The predictions were found to give good estimates of the vortex induced loads.

Nelson, R. C.

"THE DYNAMIC RESPONSE OF AIRCRAFT ENCOUNTERING AIRCRAFT WAKE TURBULENCE"

Ph.D. Thesis, June 1974, Penn. State Univ., University Park, PA

This investigation deals with the dynamic behavior of an airplane encountering aircraft wake turbulence. A digital computer simulation was developed to study the response of an aircraft flying into a trailing vortex wake. The simulation includes the complete six degree of freedom equations of motion, a description of the vortex velocity field, unsteady aerodynamics, and pilot control input. The parameters, varied in this simulation, include the penetration angle, separation distance, aircraft size (for both the penetrating and generating aircraft), and pilot control input (single- or multi-axes). Predicted vortex induced motions are presented for a variety of probe aircraft. The probe aircraft selected are representative of general aviation, business, and light jet transport type aircraft. The aircraft used to generate the vortex wakes are representative of the commercial transport fleet. The computer predictions indicate that relatively large aircraft (light jet transport) can experience unacceptable vortex-induced roll excursions.

Nelson, R. C.

"THE RESPONSE OF AIRCRAFT ENCOUNTERING AIRCRAFT WAKE TURBULENCE"

AFFDL-TR-74-29, June 1974, Air Force Flight Dynamics Lab., Wright-Patterson AFB, OH

The investigation deals with the dynamic behavior of an airplane encountering aircraft wake turbulence. A digital computer simulation was developed to study the response of an aircraft flying into a trailing vortex wake. The simulation includes the complete six degrees of freedom equations of motion, a description of the vortex velocity field, unsteady aerodynamics, and pilot control input. The parameters varied in this simulation include the penetration angle, separation distance, aircraft size, and pilot control input.

Nelson, R. C.

"DYNAMIC BEHAVIOR OF AN AIRCRAFT ENCOUNTERING AIRCRAFT WAKE TURBULENCE"

J. Aircraft, Vol. 13, No. 9, September 1976, pp. 704-708

This paper deals with the dynamic behavior of an airplane encountering aircraft wake turbulence. A digital computer simulation was developed to study the response of an aircraft flying into a trailing vortex wake. The simulation includes the complete six degree-of-freedom equations of motion, a description of the vortex velocity field, unsteady aerodynamics, and pilot control input. The parameters, varied in this simulation, include the penetration angle, separation distance, aircraft size (for both the penetrating and generating aircraft), and pilot control input (single or multi-axes). It was found that pilot control input could be momentarily out of phase with the vortex induced disturbance. Thus, in certain cases, the pilot's control input would tend to aggravate the vortex-induced upset.

Nelson, R. C. and Babie, B. M.

"AN EXPERIMENTAL STUDY OF THE STABILITY OF A FOUR-VORTEX SYTEM"

AIAA Paper No. 2005-4852, Toronto, Canada, June 2005

An experiment is currently being conducted at the University of Notre Dame to investigate the interactions, and ultimately the instabilities, that persist in a four-vortex wake. A wake consisting of four trailing vortices was created in Notre Dame's atmospheric boundary layer wind tunnel. The advantage of this tunnel is the long test section, which permits the observation of wake interactions at distances up to thirty wake-spans downstream of the point of generation. The wake was created by four high aspect ratio wing models such that the circulation strength and the spacing between each vortex in the wake may be controlled. The principal aim of this study is to experimentally determine the optimal configurations, based on circulation strength and spacing, that are consistent with the rapid amplification of certain wake vortex instability modes. The primary method for evaluating the experimental facility has been flow visualization. Helium bubbles were introduced into the core region of individual vortices to visualize these wake structures. This paper presents some early results from the visualization of the four-vortex wake. These results suggest that the use of helium bubbles is a suitable method for visualizing wake vortices for the full length of the test section.

Nelson, R. C. and Jumper, E. J.

"AIRCRAFT WAKE VORTICES AND THEIR EFFECT ON FOLLOWING AIRCRAFT"

AIAA Paper No. 2001-4073, Montreal, Canada, August 2001

This paper discusses the response of an airplane to an encounter with the trailing vortex wake generated by another airplane. A simplified analysis is used to identify key factors that affect the vortex-induced rolling moment. This is followed by selected simulation results that show how sensitive the upset response is to how the aircraft enters the vortex wake. Entry angle and pilot input were important factors in determining the maximum upset angle. Finally, the idea of wing design features to reduce the vortex hazard is reviewed.

Nelson, R. C. and McCormick, B. W.

"THE DYNAMIC BEHAVIOR OF AN AIRCRAFT ENCOUNTERING AIRCRAFT WAKE TURBULENCE"

AIAA Paper No. 1974-0774, Anaheim, CA, 1974

This paper deals with the dynamic behavior of an airplane encountering aircraft wake turbulence. A simplified analysis is presented in which the various factors influencing the vortex-induced rolling moment are examined. Based upon this simplified analysis, a method is developed which allows a rapid estimate of the vortex induced rolling moment to be made. Also, results from a digital computer simulation of the aircraft vortex penetration are presented. The computer predictions indicate that relatively large aircraft (80,000 lb. jet transport) can experience unacceptable vortex-induced roll excursions. Also, the results from the simulation were found to compare favorably with flight test

results. In addition to evaluating the vortex-induced responses, the effect of pilot control input was assessed. It was found that pilot control inputs were momentarily out of phase with the vortex-induced disturbance. Thus, the pilot's control inputs tended to aggravate the vortex-induced upsets.

"AIRCRAFT-VORTEX PENETRATION"

SAE Paper No. 730296, Wichita, KS, 1973

As a result of research programs, the hazard of wake turbulence to light aircraft has been well documented. In this paper it is emphasized that relatively large aircraft can also be susceptible to vortices generated by large jet transports. This conclusion is based upon a review of accident records and the results from a computer simulation of the aircraft-vortex interaction. The computer simulation consists of the equations of motion with six degrees of freedom as well as control input by the pilot.

"CORRELATION OF TRAILING VORTEX DATA OBTAINED FROM FLIGHT TEST MEASUREMENTS"

AIAA General Aviation Technologyfest, November 1977, Wichita, KS.

There are several theories which can be used to predict the rate of decay of the velocities within a trailing vortex wake. Iversen proposed a method of correlating trailing vortex data based upon a variable eddy viscosity vortex decay model. Flight test data collected using the tower fly-by technique is used to show that Iversen's technique can be used to successfully collapse the data to a single curve, despite the differences in aircraft size and operating conditions.

Nelson, W. C.

"AIRFOIL TIP VORTEX CONTROL"

US Patent 4,017,041, April 1977

Device for diminishing tip vortices in an aircraft. For the purpose of diminishing the tip vortices generated by aircraft there are provided retractable foils at or near the airfoil, as wing, tips in question and projecting upwardly and/or downwardly therefrom. The operation of the retractable foils is satisfactory if such foils are parallel to the centerline of the aircraft but it is preferable if such foils are angled slightly with respect thereto, such as if the leading edge of the upper foil is angled approximately 10 degrees inwardly toward the fuselage of the aircraft and the bottom foil is oppositely angled also approximately 10 degrees. The retractable foils, in addition to diminishing wing tip vortices, also when used on wing tips improve the rate of climb of an aircraft at a given engine setting and appear to diminish the area over which the major amounts of noise generated by the aircraft will be dispersed. The foils may be fully retractable into the aircraft wing, but if not fully retracted, they will each provide a small streamlined ridge projecting upwardly and/or downwardly adjacent the tip of the

aircraft wings which will improve the lift characteristics of the wings by diminishing air flow around the end of the wings sufficiently to move than compensate for the drag otherwise created. The foils are also advantageously applicable to other aircraft components, such as flaps, stabilizers or elevators.

"EVOLUTION AND BREAKDOWN OF HELICAL VORTEX WAKES BEHIND A WIND TURBINE"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012077-1 - 012077-11.

The wake behind a three-bladed Glauert model rotor in a water channel was investigated. Planar particle image velocimetry was used to measure the velocity fields on the wake center-line, with snapshots phase-locked to blade position of the rotor. Phase-locked averages of the velocity and vorticity fields are shown, with tip vortex interaction and entanglement of the helical filaments elucidated. Proper orthogonal decomposition and topology-based vortex identification are used to filter the PIV images for coherent structures and locate vortex cores. Application of these methods to the instantaneous data reveals unsteady behavior of the helical filaments that is statistically quantifiable.

Nespor, J. D., Hudson, B., Stegall, R. L. and Freedman, J. E.

"DOPPLER RADAR DETECTION OF VORTEX HAZARD INDICATORS"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 37-1 - 37-43

Wake vortex experiments were conducted at White Sands Missile Range, NM using the AN/MPS-39 Multiple Object Tracking Radar (MOTR). The purpose of these experiments was twofold. The first objective was to verify that radar returns from wake vortex are observed for some time after the passage of an aircraft. The second objective was to verify that other vortex hazard indicators such as ambient wind speed and direction could also be detected. The present study addresses the Doppler characteristics of wake vortex and clear air returns based upon measurements employing MOTR, a very sensitive C-Band phased array radar. In this regard, the experiment was conducted so that the spectral characteristics could be determined on a dwell-to-dwell basis. Results are presented from measurements of the backscattered power, velocity, and spectral width when the aircraft flies transverse and axial to the radar beam. The statistics of the backscattered power and spectral width for each case are given. In addition, the scan strategy, experimental test procedure and radar parameters are presented.

Neubert Jr., D. E.

"TRAILING VORTEX / FREE-SURFACE INTERACTION"

MS Thesis, December 1992, Naval Postgraduate School, Monterey, CA.

An investigation of the interaction of a trailing vortex with a free surface has been undertaken for the purpose of understanding the origin of scars and striations. Velocity and turbulence measurements have been carried out using a Laser-Doppler Velocimeter (LDV) for various positions of the vortex relative to the free surface. The results have shown that the vortex motion affects the free surface and is affected by it. This mutual interaction leads to the development of surface scars comprised primarily of heterotrophic vortices normal to the free surface. Furthermore, the velocity and turbulence characteristics are affected such that the vertical components of turbulence decay rapidly and the horizontal components stretch in the horizontal plane. The experiments have provided sufficient understanding of the physics of the phenomenon for the subsequent undertaking of the development of a predictive numerical model.

"DENSITY STRATIFICATION EFFECTS ON WAKE VORTEX DECAY"

J. Aircraft, Vol. 23, No. 11, November 1986, pp. 820-824

Results of an experimental study to determine the effects of density stratification on wake vortex decay are presented. The range of stratification commonly encountered in the atmosphere was simulated in the Vortex Research Facility at NASA Langley Research Center by variations in the vertical temperature gradient. Wake measurements were made for low and high aspect ratio, swept and unswept wings at chord Reynolds numbers of about 2×10^5 to 6×10^5 . The results indicate that, in the absence of turbulence, density stratification can determine wake descent distance and lifetime. A comparison of laboratory and flight-test measurements with a vortex decay model suggests a significant Reynolds number effect on wake vortex decay.

Nevill, R. G.

"DOPPLER SONAR IN DETECTION OF AIRCRAFT WAKES"

AT-2027-098-ASA, November 1974, Univ. of Birmingham, Birmingham, England

Doppler sonar remote velocity probes have been proposed as means of detecting and locating the hazardous wingtip vortices shed by heavy aircraft. A theoretical model is discussed in which the target strength is related to the energy dissipation in the vortex core and to the angle of scatter. This model includes a modification of existing scattering theory to account for the refraction expected in a real aircraft wake. An experiment designed to evaluate the acoustic target strength in a vortex core and assess the range of frequencies suitable for acoustic probing, is described. A brief trial of a doppler sonar equipment in conjunction with independent wake monitors at an airport is also reported.

"SOME OBSERVATIONS ON VORTEX-RING COLLISIONS UPON INCLINED SURFACES"

Experiments in Fluids, Vol. 57, 2016, pp. 109-1 to 109-18.

This paper reports upon a laser-induced fluorescence visualization and time-resolved particle image velocimetry study to resolve the detailed dynamics associated with $Re = 2000$ and 4000 circular vortex rings colliding with 30 – 77 -degree inclined surfaces. Two-dimensional visualization results show that larger inclination angles lead to increasingly rapid size reduction in the primary vortex-ring core closer to the surface, faster formation of the secondary vortex-ring core, and subsequent ingestion by the former. In contrast, primary vortex-ring core further away from the surface becomes physically larger and incoherent more rapidly, with slower formation and entrainment of the secondary vortex-ring core. Interestingly, a vortex dipole and small vortex-ring-like structure are produced for the largest inclination angle of 75 degrees, possibly due to vortex disconnection and reconnection processes. Results taken along the non-inclined plane show significant bulging of the primary vortex-ring cores when the inclination angle increases from 30 degrees onwards. More importantly, additional vortex cores are observed to entwine with the primary vortex-ring core and provide strong direct evidence for the bi-helical vortex line flow mechanism put forward by Lim Exp Fluids 7:453-463, 1989). Lastly, the behavior of the primary and secondary vortex-ring cores further away from the surface is highly sensitive towards the state of the bi-helical lines compressed at that region. Strong compression driven by circumferential flows due to large inclination angles may explain the unique flow structures and behavior observed for 75 degree inclination angle here.

Newman, B. G.

"FLOW IN A VISCOUS TRAILING VORTEX"

Aero. Quarterly, Vol. 10, May 1959, pp. 149-162

The equations of motion for an isolated laminar viscous vortex at moderate to large Reynolds numbers are linearized, by assuming that both the rotational velocity and the deficit of longitudinal velocity are small compared with that in the free stream. The rotational motion and the longitudinal motion may then be superimposed and solutions are readily obtained for each. If the vortex is generated by a body with profile drag it is predicted that the deficit of longitudinal velocity will be positive, which is in agreement with experimental observation. Further details of the solution and its relation to the flow in real vortices are discussed; and the theory is compared with some measurements in a turbulent vortex.

Newman, S., Brown, R., Perry, J., Lewis, S., Orchard, M. and Modha, A.

"COMPARATIVE NUMERICAL AND EXPERIMENTAL INVESTIGATIONS OF THE VORTEX RING PHENOMENON IN ROTORCRAFT"

57th Annual Forum of the American Helicopter Society, Washington, DC, May 2001

The boundary for the onset of vortex ring flow breakdown in low-speed flight is derived from a physical hypothesis expressed as an extension of simple momentum theory. Predictions are adjusted to accord with measurements found in the literature and with some further deductions made regarding the nature of the flow in the vortex ring state. The opportunity is taken to investigate the details of the flow using a new numerical analysis of the unsteady rotor wake. By maintaining diffusion of vorticity at very low levels, the numerical approach fulfils an essential requirement for modelling the vortex ring condition, since vortices can persist for a long time in the vicinity of the rotor disk. The numerical analysis is compared with test data in the literature as well as with recently generated model rotor data. The numerical analysis supports the assumptions made in deducing the boundary for the onset of vortex ring. The complexity of the flow within the vortex ring/turbulent wake flow states is also revealed. The work has shown that it is possible to calculate and understand the details of the flow in the vortex ring and turbulent wake regimes. The numerical analysis suggests that apparently minor variables can affect the flow, and that variations in these variables may account for some of the contradictions in past results that have made these regimes somewhat mysterious.

Ng, T. T. and Oliver, D. R.

"LEADING EDGE VORTEX AND SHEAR LAYER INSTABILITIES"

AIAA Paper No. 98-0313, Reno, NV, January 1998

The stability of a leading-edge vortex was studied using available flow visualization and velocity data. The development of a vortex can be envisioned to compose of three possible stages. During the initial stage, the shear layer and its associated vorticity immediately downstream from the apex coalesce to form a primary vortex core. During this stage the vortex flow resembles a forced vortex. When the primary core is sufficiently developed, the secondary vortex becomes a prominent perturbation along the leading edge. The induced cross flow instability leads to the formation of stable, co-rotating, streamwise vortex filaments in the separated shear layer. A second stage of development occurs where the straining field of the main vortex amplifies the secondary instability near the saddle point in-between a co-rotating shear layer vortex pair. This leads eventually to the formation of a secondary vortex core consisting of a series of vortices with an opposite sense of rotation to the primary core. A vortex system as such violates the circulation distribution criterion for helical flow stability, and the vortex becomes centrifugally unstable. If the growth rate of the instability is sufficiently fast compared with the convection rate, a third stage of development occurs over the wing. The expected result is an expansion of the vortex cross-section or vortex breakdown, with the circulation eventually re-establishing a stable distribution.

Nguyen, D. P. C.

"MAY 26 - JUNE 6, 1997 JFK2 DEPLOYMENT: WAKE VORTEX MEASUREMENTS AT JOHN F. KENNEDY INTERNATIONAL AIRPORT FOR A 2.02 MICRON PULSED COHERENT LIDAR, A 10.6 MICRON CW LIDAR, AND A GROUND WIND VORTEX SENSING SYSTEM"

RTI/4903-032-03S, August 1998, Center for Aerospace Technology, Research Triangle Institute, Hampton, V.

From May 26 through June 6, 1997, the Wake Vortex Lidar Project from NASA Langley Research Center deployed a 2.02-micron pulsed lidar to John F. Kennedy (JFK) International Airport to assess its performance capabilities with other previously field-tested wake measurement sensors. In November 1996, tests were simultaneously conducted with several other wake vortex and meteorological sensors in the middle marker region of Runway 31R. The latest deployment to JFK included the same 10-micron continuous wave (CW) lidar from MIT/LL and the ground-based anemometer array from the Volpe Center. Correlating wake vortex data was gathered and compared for all three participating wake vortex measurement sensors.

"NUMERICAL SIMULATION OF TRAJECTORY AND DEFORMATION OF BUBBLE IN TIP VORTEX"

Applied Mathematics and Mechanics, Vol. 33, No. 6, 2012, pp. 701-716.

According to the behaviors of a bubble in the ship wake flow, the numerical simulation is divided into two stages, quasi-spherical motion and non-spherical motion, based on whether the bubble is captured by the vortex or not. The one-way coupled particle tracking method and the boundary element method are adopted to simulate these two stages, respectively. Meanwhile, the initial condition of the second stage is taken as the output of the first one, and the entire simulation is connected and completed. Based on the numerical results and the published experimental data, the cavitation inception is studied, and the bubble is tracked. Besides, the split of the bubble captured by the vortex and the following sub-bubbles are simulated, including motion, deformation, and collapse. The results provide some insight into the control on wake bubbles and optimization of the wake flow.

Nichols, R. H.

"ALGORITHM AND TURBULENCE MODEL REQUIREMENTS FOR SIMULATING VORTICAL FLOWS"

AIAA Paper No. 2008-337, Reno, NV, January 2008

Navier-Stokes computational results using a 3rd order spatial upwind flux algorithm and two 5th order spatial WENO algorithms are compared for a wing tip vortex configuration and for a forebody at angle-of-attack. Rotational and curvature corrections and Detached Eddy Simulation (DES) variations of the Spalart-Allmaras (SA) and Shear Stress Transport (SST) turbulence models are also investigated. The results for these two test cases demonstrate that higher order fluxes improve the prediction of the vortex significantly as it is convected downstream from the body. The rotationally corrected SA model reduced the eddy viscosity in the vortex core region and provided a much-improved solution of the vortex over the baseline SA model. The SST DES model solution was also more accurate in the vortex core region than the baseline SST model.

Nichols, T., Argrow, B. and Kingston, D.

"ERROR SENSITIVITY ANALYSIS OF SMALL UAS WIND-SENSING SYSTEMS"

AIAA Paper 2017-0647, January 2017, Grapevine, TX.

A mathematical investigation is made into sources of error in inertial wind measurements made from small unmanned aircraft systems with the objective of broadly determining the nature and significance of errors in the relative wind; state estimation; and pressure, temperature and humidity subsystems as well as errors that result from physical and temporal alignment errors between these systems. Errors in inertial vehicle velocity, relative wind measurement and angular alignment of state estimation and relative wind sensing systems are shown to have the greatest impact. A new approach to identifying possible error sources based on periodicity of errors in the aircraft yaw angle, that flows from the error mathematics, is also presented and demonstrated in a simple flight test case.

Nicks, O. W.

"EXPERIMENTAL COMPARISON OF TWO WING TIPS"

Technical Soaring, Vol. XIV, No. 3, 1990, pp. 81-88.

Systematic tests of six wing tip configurations chosen for a general aviation application had shown a sharp-edged tip to be best for a range of conditions. A full-sized model was made from the outer five feet of a 15-meter glider wing having a drooped tip. The model was made to allow tips to be interchanged, and a sharp-edged tip like that developed for the general aviation application was tested on a direct comparison basis with the original glider tip. At full scale Reynolds numbers, the model tests showed the new sharp-edged tip to be superior for all values of lift coefficient above 0.4. In addition to gains in L/D of up to 6%, the climb parameter was significantly improved by as much as 6%, and the increase in maximum lift coefficient of 4% could offer a reduced stall speed. From earlier tests of a general aviation application, an increase in effective dihedral at high angles of attack can also be expected. Flow field surveys were made of the wake downstream of the tip, to determine the nature and location of the vortices. These showed a distinct effect on the location and strength of the vortices and appear to corroborate the higher lift of the new tip.

Nicolaon, J. P.

"OPTIMISED WAKE VORTEX SEPARATION STANDARDS IN THE NEAR- AND FAR-TERM"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

Eurocontrol has launched a high-level project, WakeSep, which attempts to federate research currently ongoing in Europe, as well as identifying gaps where new projects are needed, to support the operational implementation of Wake Vortex-based separations. WakeSep takes as far-term objective the concept described by ATC_Wake in Europe and like that of WakeVAS in the USA. It also identifies the set of enablers that need to be in place for such a concept to be implemented. In this presentation

we describe for certain of these enablers the issues that must be addressed to reach the far term solution. In particular, the impact on detection and prediction of wake-vortices of uncertainty in the forecasting of weather is considered. Meteorological conditions will have a major impact on the possibility of capacity gains in two areas. Firstly, current WV detection equipment will not support operational usage in heavy rain or under low visibility conditions. Secondly, the difficulty to accurately accommodate real weather conditions in WV prediction models will influence the confidence that can be placed in the predictions and thus in the separations that can be applied. This problem is exacerbated by variations due to the local topology which would require a detailed validation of the model at each airport. It seems likely that deterministic predictive models will not be able to produce sufficiently reliable results so that there is a need to adopt a more probabilistic approach. Eurocontrol will launch an action next year to identify the main European airports which are capacity-constrained by WV. For the high potential airports, it is intended to undertake a meteorological and WV data collection over a full year. The notion of weather classes introduced in SWake will be used to create a statistical model of WV behavior specific to that airport.

Nicolosi, F., De Marco, A., Sabetta, V. and Vecchia, P. D.

"ROLL PERFORMANCE ASSESSMENT OF A LIGHT AIRCRAFT: FLIGHT TESTS AND FLIGHT SIMULATION"

AIAA Paper 2015-2238, June 2015, Dallas, TX.

This paper deals with the assessment of roll performance of a light aircraft through several flight tests and flight simulations. The general problem of a reliable evaluation of aircraft roll performance is first discussed, including the estimation of the aerodynamic derivatives that mainly influence the airplane rolling characteristics. Next, the results of extensive flight test activities on a two-seat Tecnam P92 light aircraft are presented. The attentive analysis of many roll maneuvers performed at different flight speeds and with various aileron maximum deflections has shown unexpected good roll performance for this non-aerobatic aircraft and has been extremely useful to derive the aileron efficiency factor in non-linear conditions (high aileron deflections). Flight data have been used to extract the main aerodynamic derivatives involved and to implement an accurate flight simulation model of the aircraft. Both 1-DoF and 6-DoF Flight simulations have been used in the first part of this research to select an appropriate matrix of test conditions. Finally, when the key lateral aerodynamic derivatives were estimated from flight experiments, the resulting flight simulations have shown a very good agreement with measured time histories.

Nicolosi, F., De Marco, A., Sabetta, V. and Vecchia, P. D.

"ROLL PERFORMANCE ASSESSMENT OF A LIGHT AIRCRAFT: FLIGHT SIMULATIONS AND FLIGHT TESTS"

Aerospace Science and Technology, Vol. 76, 2018, pp. 471-483.

A methodology is presented for the roll performance assessment of a light aircraft. The study is based both on flight simulations and flight tests, focusing on the accurate determination of the lateral control power. The chosen test airplane was a Tecnam P92, a two-seat ultralight aircraft which was

specifically equipped with a lightweight and accurate instrumentation for the planned set of flight data measurements. A matrix of flight experiments for the test campaign was established with the support of 6-degree-of-freedom simulations, implementing a carefully constructed baseline dynamic model of the aircraft. The article discusses first the general problem of a reliable evaluation of aircraft roll performance indicators, i.e. the estimation of the aerodynamic derivatives that mainly influence the airplane ability to roll. Next, the results of extensive flight test activities are presented. The analysis of several roll maneuvers performed at different flight speeds and with different aileron maximum deflections showed interesting rolling characteristics for this non-aerobatic aircraft. One notable finding was a clear nonlinear dependency of the aileron efficiency index on aileron deflection amplitude. A control power derivative extracted from flight data in the form of lookup table was used to correct the baseline flight dynamics model. Flight simulations outputs based on the updated model showed a satisfactory agreement with experimental time histories. According to this, the present effort proposes a new method to estimate the aileron control derivative in whole the flight envelope for light aircraft.

Nielsen, J. N. and Schwind, R. G.

"DECAY OF A VORTEX PAIR BEHIND AN AIRCRAFT"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 413-454

A model of a trailing vortex pair behind an aircraft is presented which is thought to represent a case of extreme vortex persistency. Three stages are considered in the analysis: a rolling-up stage directly behind the aircraft, a second stage in which the vortices act independently as constant strength equilibrium turbulent vortices, and a third stage where the vortices physically interact and decay in strength. An overall theory is presented encompassing all three stages and aimed at obtaining equilibrium solutions. Calculative examples are presented for all stages.

Nielsen, J. N. and Sweberg, H. H.

"NOTE OF COMPRESSIBILITY EFFECTS ON DOWNWASH AT THE TAIL AT SUBCRITICAL SPEEDS"

NACA L-19 (originally issued as Confidential Bulletin L5009), March 1945, Langley Memorial Aeronautical Laboratory, Langley Field, VA.

Calculations have been made to show the magnitude of compressibility effects on the downwash at the tail at subcritical speeds. Experimental results of tests of two airplane models are included to give some verification of the theory. The calculations showed that the effects of compressibility on the span load distribution along the wing and on the downwash angle at the tail are small for constant values of the lift coefficient. The experimental results confirmed these calculations.

Nielsen, J. N., Stahara, S. C. and Woolley, J. P.

"INGESTION AND DISPERSION OF ENGINE EXHAUST PRODUCTS BY TRAILING VORTICES FOR SUPERSONIC FLIGHT IN THE STRATOSPHERE"

AIAA Paper No. 1974-0042, Washington, DC, 1974

Detailed analysis has been made of the ingestion and dispersion of engine exhaust products into the trailing-vortex system of a supersonic aircraft flying in the stratosphere. The rate of mixing between the supersonic jet and the co-flowing supersonic stream was found to be an order of magnitude less than would be expected on the basis of subsonic eddy-viscosity results. Ingestion started at the end of the potential core and all hot gas from the engine was ingested into the trailing vortex within two core lengths. The temperature rise in the wake of the supersonic aircraft was found to be much greater than that for a subsonic transport since temperature rise varies directly as speed squared and inversely as aspect ratio.

Nielsen, J. N., Stahara, S. S. and Woolley, J. P.

"A STUDY OF INGESTION AND DISPERSION OF ENGINE EXHAUST PRODUCTS IN TRAILING VORTEX SYSTEMS"

NASA-CR-114721, Nov, 1973, Nielsen Engineering and Research Inc., Mountain View, CA

Detailed analysis has been made of the ingestion and dispersion of engine exhaust products into the trailing vortex system of supersonic aircraft flying in the stratosphere. The rate of mixing between the supersonic jet and the co-flowing supersonic stream was found to be an order of magnitude less than would be expected based on subsonic eddy-viscosity results. The length of the potential core was 66 nozzle exit radii so that the exhaust gases remain at elevated temperatures and concentrations over much longer distances than previously estimated. Ingestion started at the end of the potential core and all hot gas from the engine was ingested into the trailing vortex within two core lengths. The vortex inhibits entrainment and thermally insulates the hot gases in the core from the stratosphere. The final buoyancy phase started only ten seconds after leaving the trailing edge. The temperature rise in the wake of the supersonic aircraft is much greater than that for a subsonic transport since temperature rise was found to vary directly as speed squared and inversely as aspect ratio. The buoyancy theory incorporates an entrainment coefficient which is a function of local turbulence conditions. Comparison between the buoyancy calculations for the supersonic case with nondimensionalized subsonic aircraft contrail data on wake spreading showed good agreement. Velocity and temperature profiles have been specified at various stages of the wake, and the analysis in this report can be used to predict variations of concentrations of species such as NO under conditions of chemical reaction.

Nightingale, A. M., Rennie, R. M., Gordeyev, S., Kelly, R., Cavalieri, D. and Jumper, E. J.

"FLIGHT-TEST MEASUREMENT OF THE AERO-OPTICAL ENVIRONMENT OF A HELICOPTER IN HOVER"

AIAA Journal, Vol. 54, No. 9, September 2016, pp. 2782-2790.

Methods and results are described for flight-test measurements of the aero-optical effect of the near-field flow surrounding a medium-sized helicopter in hover. The data were acquired using a novel, passive measurement approach in which optical wave-front aberrations were computed from the displacements of light-emitting diodes attached to a target array mounted under the helicopter fuselage. The resulting aero-optical data are shown through the rotor downwash and through the engine exhaust of the helicopter, and they are compared to estimates computed using parametric models for the helicopter wake structure and rotor-vortex diffusion. The experimental data provide additional information on the magnitude and frequency content of the aero-optical aberrations, as well as vibration data, that will be valuable for future beam-control and modeling studies.

Nikolic, V.

"A STUDY OF THE DEVELOPMENT AND ATTENUATION OF WING GENERATED, VORTICAL WAKES"

Ph.D. Thesis, June 1997, University of Notre Dame, South Bend, I.

An inviscid three-dimensional model for calculation of the roll up of wing vortex wakes was developed to address the problem of wake-vortex alleviation in a systematic way. The code was extensively tested and validated using a large body of theoretical, computational, and experimental results. During the validation, it was shown that the second moment of vorticity, heretofore assumed to be constant, not only changes as the wake evolves, but must do so to conserve energy. Further, the second moment of vorticity has been shown to be a reliable measure of the completeness of the wake roll-up process. It was demonstrated that tailoring the wing spanwise load distribution by use of flaps modifies the resulting wake in terms of making it both more diffuse and, by moving the primary vortices closer together, renders it more susceptible to the Crow far-field instability. Injection of co-rotating discrete mid-span vortices both changes the roll-up pattern and hastens the far-field instability, but causes induced drag penalties. Excitation of the far-field instability of the main wing-vortex pair by injecting relatively-weak intermediate-span discrete vortices was investigated. A new method of determining the character of vortex entrainment was developed and shown to be viable. Additionally, in an unrelated investigation performed as part of this dissertation research, it was confirmed that the wake roll up can be disorganized by implementation positive bound-circulating gradients near wing tips; however, this benefit was offset by high drag and weight penalties. Finally, some new avenues for research are suggested.

Nikolic, V. R.

"INVESTIGATION OF POSSIBLE MERIT OF GURNEY FLAP AS WAKE VORTEX-ATTENUATION DEVICE"

AIAA Paper No. 2005-4979, Toronto, Canada, June 2005

An exploratory wind tunnel investigation into the effects of two Gurney flap configurations on the formation of wake vortices, as well as on the lift and drag characteristics of a rectangular wing model, has been conducted. As expected, the Gurney flaps significantly changed the wing lift and drag, with the effects increasing with the flap size. As a new observation, the flaps brought about noticeable

changes into the near-field trailing vortex wake pattern. The differences in the rollup patterns between the baseline wing and the flapped configurations have been observed using flow visualization tufts. This simple yet effective technique has been used to gain valuable insight into the flowfield characteristics. Based on the disposition of the tufts, a new measure of the strength of the wake vortex, the rollup tightness factor has been defined and used to effectively quantitatively characterize the vortices.

Nikolic, V. R.

"PRELIMINARY STUDY OF EFFECTS OF MOVABLE TIP STRAKES ON PERFORMANCE OF RECTANGULAR WING"

AIAA Paper No. 2004-4840, Providence, RI, August 2004

A preliminary study of the effects of movable tip strakes on the aerodynamic characteristics of a rectangular wing model has been conducted in a wind tunnel. This is a new concept for controlling the flow field around wings. The addition of sharp-edged slender-delta-shaped strakes significantly modified the wing's lift and drag. When deflected symmetrically, the strakes improved the lift-to-drag ratio of the baseline wing to a large extent. The concept also seems to have potential for lateral control. There are some indications that the strakes might favorably influence the near-field rollup of the trailing vortices. This concept warrants additional more detailed investigations using various flow visualization and measurement techniques.

Nikolic, V. R.

"EFFECT OF FULL-SPAN GURNEY FLAP HEIGHT ON WING WAKE VORTEX ALLEVIATION"

Journal of Aircraft, Vol. 43, No. 5, September-October 2006, pp. 1555-1558

A series of three Gurney flaps of varying height have been studied experimentally, in combination with a baseline rectangular wing model, to examine the effects of the flap height on the wing wake vortex strength and aerodynamic efficiency. Flow visualization tufts have been used to study the vortex patterns, both qualitatively and quantitatively. It has been found that the addition of the Gurney flaps markedly altered the vortex roll-up pattern, producing weaker vortices in the near-field studied, as measured by the roll-up tightness factor. This desirable effect increased with the flap height. At the same time, the addition of the flaps caused the wing's lift-to-drag ratio to decrease, although to a degree which has been much lower than the advantageous effect on vortex strength; for example, a 10% decrease in lift-to-drag vs a 28% decrease in vortex strength for a 1.5%-chord Gurney flap at a high angle of attack. It appears noticeable vortex alleviation can be attained even with relatively low height Gurney flaps. Therefore it seems justified to investigate Gurney flaps having heights in the range 0.5-1% of the wing chord in the future. The present study clearly confirmed the usefulness of the roll-up tightness factor for quantifying vortex strengths.

Nikolic, V. R.

"ADDITIONAL AERODYNAMIC FEATURES OF WING-GURNEY FLAP FLOWS"

Journal of Aircraft, Vol. 43, No. 5, September-October 2006, pp. 1325-1333

An extension of the existing explanation of the flow mechanisms characteristic of the wing-Gurney flap flow has been proposed. Based on the Helmholtz vortex theory, it has been postulated at the onset of the present study that, in addition to the spanwise vortices, as predicted by a commonly accepted flow hypothesis one or more pairs of streamwise trailing vortices ought to exist. A series of wind-tunnel models, including a clean wing and one full-span and two partial-span Gurney flaps, have been tested in a low-speed wind tunnel. Several techniques, including two methods of flow visualization of trailing vortices and measurements of rotational speeds produced by these vortices, have been employed. All of these methods have consistently and clearly indicated the presence of additional vortices. As such, these vortices are important for accurate prediction of the aerodynamic characteristics of wing-Gurney flap configurations.

"MOVABLE TIP STRAKES AND WING AERODYNAMICS"

Journal of Aircraft, Vol. 42, No. 6, Nov.-Dec. 2005, pp. 1418-1426

A wind-tunnel study of the effects of the addition of movable tip strakes on the aerodynamic characteristics of a rectangular wing model has been conducted. This is a new application of the strake concept for modifying the flowfield around a wing. The addition of sharp-edged slender delta-wing-shaped strakes significantly modified the flow pattern in the vicinity of the wing through generation of vortex lift. The strakes improved the lift-to-drag ratio of the baseline wing by as much as 23%. The method can have potential for lateral control too. Based on limited flow-visualization results, it appears that the strakes favorably influence the near-field roll up of the wing trailing vortices. The approach warrants additional investigation using more advanced measurement and flow-visualization techniques.

Nikolic, V. R.

"EFFECT OF GURNEY FLAP RELATIVE SPAN ON LIFT, DRAG, AND TRAILING VORTEX OF A RECTANGULAR WING"

AIAA Paper No. 2007-4177, Miami, FL, June 200.

An experimental study has been conducted to examine the effects that Gurney flap span has on the lift and drag of the wing-flap configuration and the near-field trailing vortex strength. The configurations tested included a rectangular wing, a full-span Gurney flap and two Gurney flaps having spans equal to one half the wing span, one positioned outboard, and the other inboard. All three flaps had a height equaling six percent of the wing chord. As expected, all three flaps significantly changed the wing lift and drag characteristics. While the flapped configurations developed much higher both lift

and drag coefficients, the overall effect on the wing lift-to-drag ratio has been found to be detrimental for all three flap configurations as compared to the baseline wing, the negative effect increasing with the flap span. Also, significant flattening of the lift-to-drag vs. lift coefficient curve has been observed. As expected, the addition of the flaps led to additional trailing vortices which affect the overall trailing vortex rollup and strength. The effect of the flaps on the trailing vortex strength in the near field has been quantified using a rollup tightness factor. This measure has indicated that while the configurations employing the full-span Gurney flap and the 50-percent-span flap located over the outboard wing sections exhibited trailing vortex strength reductions over most of the range of angles of attack tested, the configuration involving the inboard 50-percent flap developed stronger trailing vortices in the near field. These results have indicated that an effective means for trailing vortex reduction via Gurney flap use should be sought within the design space incorporating flaps located outboard. Future studies should include outboard Gurney flaps of varying relative span, other wing planforms and higher Reynolds numbers. Also, far field effects need to be examined.

"PLANFORM VARIATIONS AND AERODYNAMIC EFFICIENCY OF MOVABLE TIP STRAKES"

Journal of Aircraft, Vol. 44, No. 1, January-February 2007, pp. 340-343

The movable tip strake represents a novel use of the renowned concept believed to be important to the design of future airplanes. An experimental study has been conducted to explore the effects of varying strake planform on the performance of a rectangular wing. Four strake configurations, including two delta types, then one modified delta having a portion of the leading edge curved, and one cropped double delta, have been tested in a low-speed wind tunnel. The strakes were held at a constant setting relative to the main wing. The results showed noticeable advantages of the configurations employing strakes over the baseline wing. All strakes produced higher lift and drag coefficients than the clean wing. Future plans include extensive use of flow visualization to aid in better understanding the flow phenomena associated with these types of configurations. Effects on wake vortex attenuation and possible use in roll control should also be addressed.

Nikolic, V. R.

"EXAMINING A FAMILY OF MOVABLE WING TIP STRAKES INVOLVING VARYING LEADING EDGE FORMS AND SWEEP ANGLES"

AIAA Paper No. 2007-1270, Reno, NV, January 2007

The study constitutes an attempt to expand the understanding of an innovative use of a famous concept -- the use of movable wing tip strakes -- beyond the limited results of a previous exploratory investigation. It is believed that this novel method is significant to the design of airplanes in the future in several areas. Nine different configurations of movable wing tip strakes have been studied in a low-speed wind tunnel in combination with a rectangular wing model. The strakes varied in planform shape and they included four half-delta planforms, one planform whose leading edge combined a swept

straight line and a curved profile, and four configurations involving cropped double-delta planforms. All nine strakes featured sharp leading edges. The addition of the tip strakes significantly and consistently altered the aerodynamic characteristics of the wing. It has been found that one among the cropped double-delta tip strakes is most effective, in terms of lift-to-drag ratios at constant lift, to the other eight configurations, all of them being superior to the baseline wing over significant ranges of angle of attack. The cropped double-delta strake improved the aerodynamic efficiency of the baseline wing over a substantial range of moderate angles of attack by as much as 26 percent at the neutral setting. When deflected relative to the main wing, in the negative or positive sense, the strake improved the wing aerodynamic efficiency at higher or lower angles of attack, respectively.

"FIRST LOOK INTO EFFECTS OF DISCRETE MIDSPAN VORTEX INJECTION ON WING PERFORMANCE"

Journal of Aircraft, Vol. 41, No. 5, September-October 2004, pp. 1177-1182

The effects of midspan discrete vortex injection on the performance of a rectangular wing model were studied in a wind tunnel. Based on this preliminary study, discrete vortex injection, while affecting the wing lift and drag, does not degrade its overall performance to any significant degree. This is particularly so in the high-angle-of-attack range where use of vortex injection for wake turbulence alleviation had been proposed. The investigation confirms and expands previously reported, computationally determined results. This study was of a limited scope; additional aspects of discrete vortex injection warrant investigation.

Nikolic, V. R. and Jumper, E. J.

"ATTENUATION OF AIRPLANE WAKE VORTICES BY EXCITATION OF FAR-FIELD INSTABILITY"

AIAA Paper 1993-3511, Monterey, CA, August 1993

This paper presents the results of a computational study of the injection of discrete vortices at a wake-generating wing and their effect on the development and dynamics of the wing's wake. The study was motivated by the results of an experimental study by Rossow showing that injection of vortices at approximately the mid semispan of an airplane wing greatly reduced the potential hazard to an aircraft penetrating the wake. Our study suggests that the reduction in wake hazard is due to the excitation of the Crow instability in the primary 'wing-tip' vortices due to their interaction with secondary vortices formed around the injected vortices.

"MODIFIED, DISCRETE-VORTEX METHOD FOR STUDYING WING-LOADING EFFECTS ON WAKE DYNAMICS"

J. Aircraft, Vol. 33, No. 1, January-February 1996, pp. 155-16.

An inviscid model for calculating the roll up of wing-generated, vortical wakes has been developed. The model is shown to be an efficient means of studying the dynamics of the wake in the region from just behind the wing to the pre-viscous-dissipation far field. The model is based on a modified discrete-vortex method that includes the near-wing effects of the wing-bound vorticity and the fact that the wake originates at the wing, rather than at minus infinity. Three-dimensional wakes are produced by connecting the two-dimensional wake contours at successive Trefftz planes. The inclusion of the near-wing effects is shown to have a relatively large influence on the wake's dynamics and final disposition. The inclusion of rotational cores is shown to aid in smoothing the wake roll up, but appears to have little effect on the wake's final dispersion radii.

Ning, S. A.

"AIRCRAFT DRAG REDUCTION THROUGH EXTENDED FORMATION FLIGHT"

PhD Thesis, August 2011, Stanford University, Stanford, CA.

While the early pioneers of flight looked to birds to learn how to fly, the early aerodynamicists looked to birds to learn how to fly more efficiently. Among the many insights gleaned from nature, was the observation that migratory birds often flew together in formation. As aerodynamic theory developed, it was shown that formation flight could be used to increase range. Despite an understanding of the physics, technological challenges have prevented aviation from benefitting from the energy left behind in an aircraft's wake. However, advances in precision navigation and control over the last few decades have brought renewed attention to formation flight of aircraft. Past published studies have focused on close formation flight, but the hazards of flying in close proximity are unacceptable in commercial aviation. This research explores a more practical approach, which we term extended formation flight. Extended formations take advantage of the persistence of cruise wakes and extend the streamwise spacing between the aircraft by at least five wingspans. Classical aerodynamic theory suggests that the total induced drag of the formation should not change as the streamwise separation is increased, but the large separation distances of extended formation flight violate the simple assumptions of these theorems. At large distances, considerations such as wake rollup, atmospheric effects on circulation decay, and vortex motion become important. This dissertation first examines the wake rollup process in the context of extended formations and develops appropriate physics-based models. These simple models compare well with higher-fidelity Navier-Stokes solutions, as well as with experimental data. The wake model is then used to investigate the induced drag savings of formations of aircraft in the presence of uncertainty in model parameters, variation in atmospheric properties, and limitations of positioning accuracy. Extended formation flight is found to only be practical in low to moderately low turbulence conditions with streamwise separation distances less than about 40 to 50 wingspans. Tracking error is found to be the largest source of variation in the induced drag savings. At typical conditions, a 2-aircraft formation achieves a maximum reduction in induced drag of approximately 30 +/- 3%, while a 3-aircraft formation achieves a maximum reduction of 40 +/- 6% (95% confidence intervals). High-fidelity analyses are utilized to help understand the impact of compressibility while flying in formation. An Euler solver is modified to allow the use of the wake vortex model. This solver is then used to analyze the inviscid aerodynamic forces and moments of transonic wing/body configurations flying in a 2-aircraft extended formation. By slowing down by about 2%, a formation can

achieve large induced drag reductions with little compressibility penalties. Flying further from the center of the vortex can allow for slightly higher cruise speeds in exchange for higher induced drag. Finally, the methodology is applied to studying formations of non-identical aircraft. Fundamental considerations in optimally arranging the formations are identified. Choosing a proper formation arrangement can have a significant impact on the fuel burn. Simple guidelines for choosing the arrangement of the formation are found to often coincide with the optimal arrangement. Re-arranging the formation enroute, to minimize fuel burn, is shown to be generally unnecessary, and even in the best cases can only provide fuel savings on the order of half a percent.

Ning, S. A. and Kroo, I.

"COMPRESSIBILITY EFFECTS OF EXTENDED FORMATION FLIGHT"

AIAA Paper No. 2011-3812, June 2011, Honolulu, Hawaii.

Aircraft flown in formations may realize significant reductions in induced drag by flying in regions of wake upwash. However, most transports fly at transonic speeds and compressibility effects in formation flight are not well understood. This study uses an Euler solver to analyze the inviscid aerodynamic forces and moments of transonic wing/body configurations flying in a 2-aircraft formation. We consider formations with large streamwise separation distances (10-50 wingspans) in an arrangement we term extended formation flight. Compressibility-related drag penalties in formation flight may be eliminated by slowing 2-3 percent below the normal out-of-formation drag divergence Mach number, at fixed lift coefficient or fixed altitude. The latter option has the additional benefit that the aerodynamic performance of the formation improves slightly at higher lift coefficients. Optimal in-formation lift coefficients are not nearly as high as those estimated by incompressible analyses, but if not limited by engine performance, modest increases in altitude can yield further improvements in aerodynamic efficiency. Increasing the lateral separation of the aircraft can allow for slightly higher cruise speeds in exchange for higher induced drag. For the configurations examined here, a 1-2 percent reduction in Mach number combined with a lateral spacing increase of 5 percent span achieves a total formation drag savings of about 10 percent.

Ning, S. A. and Kroo, I.

"MULTIDISCIPLINARY CONSIDERATIONS IN THE DESIGN OF WINGS AND WING TIP DEVICES"

Journal of Aircraft, Vol. 47, No. 2, March-April 2010, pp. 534-543.

Conceptual wing design analysis methods are combined with numerical optimization to find minimum-drag wings subject to constraints of lift, weight, pitching moment, and stall speed. Tip extensions and winglets designed for minimum drag achieve similar performance, with the optimal solution depending on the ratio of the maneuver lift coefficient to the cruise lift coefficient. The results highlight the importance of accounting for the depth of the wing structural box in the weight model and including constraints on stall speed. For tailless aircraft, C-wings show a slight performance advantage over wings with winglets when longitudinal trim and stability constraints are considered.

This performance advantage is more significant for span-constrained or low-sweep designs. Finally, to demonstrate other possible applications of the method, planer wings with active load alleviation are optimized, showing drag savings on the order of 15 percent.

Ning, S. A., Flanzer, T. C. and Kroo, I. M.

"AERODYNAMIC PERFORMANCE OF EXTENDED FORMATION FLIGHT"

Journal of Aircraft, Vol. 48, No. 3, May-June 2011, pp. 855-865.

The aerodynamic benefits of formation flight have been known for nearly a century. However, these benefits have yet to be realized in a commercial environment in part due to the hazards associated with close formation flight. This paper explores a more practical approach to formation flight called extended formation flight, which takes advantage of the persistence of cruise wakes and extends the streamwise spacing between the aircraft by at least 10 spans. Induced-drag savings are estimated in an incompressible analysis considering the effects of wake rollup, vortex decay, vortex instabilities, vortex motion, atmospheric turbulence and stratification, and stochastic behavior. Extended formations are found to be unpractical for streamwise spacings larger than about 40 spans between each aircraft. For spacings around 10 to 40 spans, with low to moderately low atmospheric turbulence, a two-aircraft formation has a maximum induced-drag reduction of 30 +/- 3%, while a three-aircraft formation has a maximum induced-drag reduction of 40 +/- 6%. At these distances, aircraft tracking error is the most significant contribution to the variation in drag savings. Studies of transonic effects, ride quality concerns, and control and sensing strategies are necessary to further evaluate the potential of extended formation flight.

Ning, S. A., Flanzer, T. C. and Kroo, I. M.

"AERODYNAMIC PERFORMANCE OF EXTENDED FORMATION FLIGHT"

AIAA Paper No. 2010-1240, January 2010, Orlando, FL.

Close formation flight is of limited practicality for commercial aviation. Our concept of extended formation flight takes advantage of the persistence of cruise wakes by extending the streamwise spacing between aircraft in a formation. This allows the aircraft to fly at safe separation distances from each other, while still benefiting from the upwash of the upstream wake(s). In this paper we are interested in estimating the performance of these extended formations, and estimating some of the effects that limit the longitudinal extent of the formation. We consider the effects of wake rollup, vortex decay, vortex instabilities, vortex motion, and atmospheric turbulence and stratification in an incompressible analysis. Formations consisting of two and three aircraft are examined. For each we evaluate the mean formation induced drag savings and associated uncertainties. At separation distances less than 20 spans, a two aircraft formation saves 26-31 percent in induced drag, while a three aircraft formation saves 38-45 percent in induced drag. Aircraft tracking error, and vortex motion due to turbulent gusts are the greatest contributors to the variation in drag savings. Extended

formations are likely only practical in low to moderately low turbulence levels and for streamwise spacings less than about 50 spans.

Ning, S. A., Kroo, I., Aftosmis, M. J., Nemec, M. and Kless, J. E.

"EXTENDED FORMATION FLIGHT AT TRANSONIC SPEEDS"

Journal of Aircraft, Vol. 51, No. 5, September-October 2014, pp. 1501-1510.

Aircraft flown in formations can realize significant reductions in drag by flying in regions of wake upwash. However, most transports fly at transonic speeds where the impact of compressibility on formation flight is not well understood. This study uses an Euler solver to analyze the inviscid aerodynamic forces and moments of transonic wing/body configurations flying in a two-aircraft formation. Formations with large streamwise separation distances (10-50 wingspans) are considered. This work indicates that compressibility-related drag penalties in formation flight may be eliminated by slowing 2-3 percent below the nominal out-of-formation cruise Mach number, either at fixed lift coefficient or fixed altitude. The latter option has the additional benefit that the aerodynamic performance of the formation improves slightly at higher lift coefficients. Although optimal information lift coefficients are not as high as those estimated by incompressible analyses, modest increases in altitude can yield further improvements in aerodynamic efficiency. Increasing the lateral separation of the aircraft allows for slightly higher cruise speeds in exchange for higher induced drag. For the configurations examined here, a 1-2 percent reduction in Mach number combined with a lateral spacing increase of 5 percent span (vertical spacing aligned with the vortex) achieves a total formation drag savings of about 10 percent.

"AN EXPERIMENTAL INVESTIGATION ON THE CONTROL OF TIP VORTICES FROM WIND TURBINE BLADE"

AIAA Paper 2013-1104, January 2013, Grapevine, TX.

Wind turbine dynamics, wake effects and environmental impacts have been identified the most significant research topics needed for wind resource characterization and wind power generation. Among these issues, tip vortices generated from the blade tip have been recognized as a substantial resource for the turbulent wake flow as well as the aerodynamic noise emission from a wind turbine. An experimental study is conducted to characterize the evolution of the tip vortices downstream a well-designed horizontal axis wind turbine (HAWT) model. In addition to measuring dynamic wind loads (both aerodynamic forces and moments) and power output from the wind turbine model, a Particle Image Velocimetry (PIV) system is used to make phase-locked flow field measurements to quantify the time-evolution of the wake vortex and turbulence flow structures downstream of the wind turbine model. The objective of this study is to find an effective way to restrict the development of tip vortices and thus the consequential noise emission. By altering the blade tip design, unwanted tip vortices and vibration of blade is suppressed considerably. The detailed flow measurements at several cross sections of the blade are also conducted to illuminate the mechanism of vorticity reduction. The detailed flow

field measurements are correlated with the wind load and power output measurements to elucidate the underlying physics associated with power generation and environmental impacts from wind turbines.

Nixon, D.

"FAR FIELD EFFECTS OF WING WAKES"

AIAA Paper No. 2007-1268, Reno, NV, January 2007

This paper is concerned with the derivation of the equation for vehicle drag in terms of information available in the wake. Although the classic result for drag can be obtained by the analysis if the far field pressure is assumed to return to freestream values there is some doubt as to its validity. Also, the general assumption that drag represented by entropy production is not related to drag due to lift seems to be untrue. Furthermore, it was found that there is a residual effect of the aircraft left in the atmosphere that can cause disturbances to following aircraft. It is also found that the boundary condition for the Navier Stokes equations far downstream of the aircraft is that the shear stresses are zero.

Nolan, D. S.

"THE STABILIZING EFFECTS OF AXIAL STRETCHING ON TURBULENT VORTEX DYNAMICS"

Physics of Fluids, Vol. 13, No. 6, June 2001, pp. 1724-1738.

The evolution and dynamics of vortices in inviscid, incompressible flow under the influence of a deformation field which causes stretching in the axial direction are studied. These vortices are simulated using three-dimensional vortex methods which offer the advantages of having no inherent numerical dissipation and great computational efficiency for short to intermediate times. Two cases are studied: The evolution of a stable, but strongly perturbed vortex, and the evolution of an unstable vortex. In both types of vortices, it is found that the stretching and radial inflow associated with the surrounding deformation field can suppress the growth of disturbances and slow the development of turbulence. This stabilization is even greater than what one would expect from the purely kinematic effects of the deformation field alone, indicating there is negative feedback on the nonlinear vortex dynamics. The physical mechanisms for stabilization by stretching are discussed, along with potential applications for understanding the stability of intense geophysical vortices maintained by convection.

"SHORT-WAVELENGTH INSTABILITY AND DECAY OF A VORTEX PAIR IN A STRATIFIED FIELD"

J. Fluid Mech., Vol. 553, 2006, pp. 283-322

The evolution of a counter-rotating vortex pair in a stably stratified fluid is investigated using direct numerical simulations. The study focuses on the short-wavelength elliptic instability occurring in this

flow and the subsequent decay of the vortices. Depending on the level of stratification, as characterized by the Froude number which indicates the time scale of buoyancy to that of the instability, and the stage of evolution, stratification effects may significantly alter the behavior of the flow. In the case of weak to moderate stratification, the elliptic instability develops qualitatively in the same manner as in unstratified fluid. The primary effect of stratification is to reduce the vortex separation distance which enhances the mutually induced strain. Consequently, the instability has an earlier onset and higher growth rate with increasing stratification. The behavior is essentially described by linear stability theory for unstratified flow if the varying separation distance is taken into account. On the other hand, the final breakdown and decay of the flow may be greatly modified by stratification since buoyancy effects eventually emerge after sufficient time has elapsed. The decay is enhanced owing to additional mechanisms not present in unstratified flow. Secondary vertical vortex structures form between the primary vortices promoting fluid exchange in the transverse direction. Detrainment of fluid from the primary vortices by the generated baroclinic torque also contributes to the more rapid breakdown of the flow. In the case of strong stratification, in which the time scale of buoyancy is comparable to that of the instability, the flow is significantly altered. As a result of strong baroclinic torque, the primary vortices are brought together and detrainment occurs earlier. The associated reduction in radii of the vortices results in a higher axial wave mode and a more complex radial structure of the instability. Detrainment and mixing accelerate their decay. Late time evolution is dominated by the successive generation of alternate signed baroclinic torque which results in an oscillation of the total flow circulation at the buoyancy frequency.

"UNIQUE ECHOES OBSERVED BY FM-CW RADAR AT A JET AIRPORT"

TN 2787, September 1974, Naval Electronics Lab. Center, San Diego, CA

The capability of the recently developed FM-CW radar to detect detailed low-level small-scale humidity structure suggested the possibility that the radar may be capable of detecting wing-tip vortices. This report presents examples and describes statistical features of a unique echo observed by the FM-CW radar at the west end of runway 9-27 at the International Airport, Lindbergh Field, in San Diego. The data strongly indicate that the unique echo is created by departing aircraft. The source and nature of the echo is undetermined, however.

"ENERGY DECAY OF VORTICES IN VISCOUS FLUIDS: AN APPLIED MATHEMATICS VIEW"

Journal of Fluid Mechanics, Vol. 709, 2012, pp. 593-609.

The energy decay of vortices in viscous fluids governed by the compressible Navier-Stokes equations is investigated. It is shown that the main reason for the slow decay is that zero eigenvalues exist in the matrix related to the dissipative terms. The theoretical analysis is purely mathematical and based on the energy method. To check the validity of the theoretical result in practice, numerical solutions to

the Navier-Stokes equations are computed using a stable high-order finite difference method. The numerical computations corroborate the theoretical conclusion.

Nore, C., Bruno, A., Douady, S. and Abid, M.

"ON THE FEEDBACK OF VORTICITY ON STRETCHING"

Lecture Notes in Physics, Issue 555, 2000, pp. 275-282

In this paper, we have experimentally and numerically investigated the evolution of a vortex submitted to a non-uniform stretching. But it turns out that the vortex reacts by inducing secondary tori shaped structures which screen the effect of the primary stretching. This basically comes from the fact that there exists a differential rotation along the vortex axis which leads to a variation of the centrifugal force. The pressure gradient cannot balance this inhomogeneous centrifugal force anymore, the latter having a solenoidal part. Consequently, a secondary toroidal flow is induced which stretches the vortex in the regions where it was slowly rotating and compresses it where it was rapidly rotating.

Norman, T. R. and Light, J. S.

"ROTOR TIP VORTEX GEOMETRY MEASUREMENTS USING THE WIDE-FIELD SHADOWGRAPH TECHNIQUE"

AIAA Paper No. 1986-1780, June 1986, San Diego, CA.

Rotor tip vortex geometry data have been acquired using the wide-field shadowgraph technique. Shadowgraphs were taken of the wakes of two model main-rotor systems in hover. These shadowgraphs provided detailed tip vortex trajectories from which axial and radial vortex coordinates were measured. Another result of the experimental work was the development of a method to predict the degree of visibility of rotor tip vortices on shadowgraphs. Using this method, the ability of the shadowgraph technique to visualize tip vortices in the rotor wake was quantified.

Nosenchuck, D. M. and Brown, G. L.

"LIFTING BODY WITH REDUCED-STRENGTH TRAILING VORTICES"

US Patent 5,492,289, February 1996

A lifting body moves relative to a fluid, thereby creating a vortex field in the fluid downstream of the lifting body. The lifting body has a predetermined lift distribution along the length thereof which enhances the velocity component of the fluid flow directed outwardly from the centroid of the vortex field to reduce the strength of trailing vortices. In a preferred embodiment, the lifting body is a wing with a perturbation proximate to the tip end of the wing planform trailing edge.

"CONTROL OF WING-TIP VORTICES"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 18-1 - 18-20

Experiments have been carried out which demonstrate the potential of using a redistribution of vorticity (through small changes in wing geometry) to affect significantly the core size of a wing-tip vortex. Prior to the experiments, the change in geometry which produced the increased core area was predicted using a numerical simulation and an optimization procedure.

Novak, F. and Sarpkaya, T.

"TURBULENT VORTEX BREAKDOWN AT HIGH REYNOLDS NUMBERS"

AIAA Journal, Vol. 38, No. 5, May 2000, pp. 825-834

This paper deals with vortex breakdown in noncavitating swirling flows in tubes at high Reynolds numbers. Breakdown in slender vortices of high intensity begins with a rapidly spinning spiral at a point dictated by the prevailing flow and boundary conditions. The nascent spiral bursts into turbulence shortly after its inception, i.e., the breakdowns occurring at relatively low gamma or Reynolds numbers are bypassed at sufficiently high Reynolds numbers. Additional findings concern the core bifurcation, the random reversals in the sense of the spiral windings, and the absence of a reversed-flow region. The core meandering and stagnation-point darting are quantified and discussed considering extensive velocity, turbulence, and spectrum measurements.

Novak, F. G.

"AN EXPERIMENTAL INVESTIGATION OF VORTEX BREAKDOWN IN TUBES AT HIGH REYNOLDS NUMBERS"

PhD Thesis, September 1998, Naval Postgraduate School, Monterey, CA.

This thesis deals with non-cavitating swirling flows with vortex breakdown in various tubes. Phenomenological and quantitative investigations were carried out at Reynolds numbers (Re) as high as 300,000. It was shown that a high Re vortex transitions to its new state (breaks down) via a rapidly spinning spiral form, as demonstrated with 4,000 frames per second video, short exposure time (6 ns) imaging, and Digital Particle Image Velocimetry. Of the known types, the spiral emerges as the fundamental breakdown form and the axisymmetric bubble may now be regarded as a relatively low Re occurrence that is bypassed at sufficiently high Re. Some new phenomena were observed at high Re: Extremely rapid spiral rotation (over 1,000 revolutions per second), core bifurcation, and changes in the sense of the spiral windings. Familiar features of breakdowns, such as the transition from a jet-like to wake-like axial velocity profile and the rapidly expanding vortex core, were observed in extensive time averaged velocity and turbulence results ascertained with Laser Doppler Velocimetry. However, a mean stagnation point and recirculation were absent in the highest Re flow. The core meandering and stagnation point darting in the turbulent flow field were quantified and discussed in detail.

"ADVANCED AIRCRAFT PERFORMANCE MODELING FOR ATM: ENHANCEMENTS TO THE BADA MODEL"

24th Digital Avionics Systems Conference, Washington, DC, Oct-Nov 2005

An efficient Air Traffic Management (ATM) system requires planning of traffic flows that rely on accurate estimation of aircraft performances. New operational concepts, that will ensure seamless management of the forecasted growth of air traffic and provide increased capacity, are based on aircraft trajectory prediction. An aircraft performance model is the core of trajectory computation and therefore plays a central role in the development and evaluation of the future ATM systems.

"SPATIAL SIMULATION OF A CO-ROTATING VORTEX MERGING PROCESS IN UNSTABLE CONDITIONS"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

The present numerical study is motivated by the challenge to simulate the three-dimensional spatial dynamics of a co-rotating vortex pair, through the development of an elliptic instability, using a high order solver of the compressible Navier-Stokes equations. This phenomenon was studied previously only by temporal simulations. The interest of spatial simulation is first to analyze the effect of the axial velocity on the merging process which are neglected with the temporal approach, and to study interaction with jet flows. The numerical problem is the choice of boundary conditions: for the inflow and outflow conditions as well as for the lateral boundary conditions to represent a fluid at rest. Indeed, for these boundary conditions the problem comes from the no-zero circulation of the vortex system considered. The classic boundary conditions of Poinot and Lele based on the characteristics wave approach have been modified to be more adapted to the physics considered here. This new boundary condition assumes an irrotational flow close to the borders (to determine the magnitude of the waves), as the vorticity field is concentrated on the computational domain center where the vortex system is initially placed. After a validation of these improved boundary conditions and of all numerical tools used such as selective artificial dissipation, two spatial simulations of the vortex breakdown phenomenon have allowed validating our solver for a three-dimensional case by comparison to the results of Ruith et al. Thus, the merging process of equal co-rotating vortices through the development of elliptic instability with axial velocity were simulated by 3D spatial simulations.

Nybelen, L., Moet, H. and Paoli, R.

"SIMULATIONS OF MERGING IN A TWO CO-ROTATING VORTEX SYSTEM"

European Conference on Computational Fluid Dynamics, TU Delft, The Netherlands, 2006

All aircraft shed, because of lift, a wake ('vorticity sheet') which rapidly rolls up into several concentrated vortices at a distance of a few chords behind the trailing edge of the wing. A simplified configuration has been adopted to understand the physical mechanisms characterizing the merging process in the extended near-field. This consists in two co-rotating and symmetric (i.e. same core size and circulation) vortices, corresponding to the two vortices generated at wing and flap tip, respectively. Both the Lamb-Oseen and the Jacquin VM2 vortex models were used as numerical initial conditions. Two dimensional direct Numerical Simulations (DNS) were first conducted at low Reynolds numbers to study the merging in stable conditions. A so-called convective stage is identified which is critical in the stable merging process. It starts when the ratio between the vortex core size and the separation distance of the two vortices reaches the critical value for the Reynolds numbers considered. It is known that the vortex system might experience an elliptic short wavelength instability during the merging process at high Reynolds numbers. A second set of three-dimensional simulations (DNS/LES) was then carried out to analyze the development of such a short wavelength instability. The development of the instability was analyzed by either looking at the flow topology or by tracking the energy spectrum of the system. The resulting (unstable) vortex has a two-scale tangential velocity profile as in the case of two-dimensional (stable) merging. However, the unstable merging is faster than the stable merging.

"PREVIOUS WORK AND PRESENT KNOWLEDGE ON VORTEX INTERACTIONS WITH JETS AND WAKES"

AST4-CT-2005-012238, CERFACS, Toulouse, France, July 2005

Previous test campaigns (e.g., C-Wake and Airbus measurements) have demonstrated that jets can modify the wake structure significantly. In addition, the precise influence of the fuselage wake and the wakes of different wing elements (e.g., engine nacelle, landing gear) is still not well understood and the present knowledge is not systematic. Two types of strategies are pursued in this work. On the one hand, progressively more and more realistic flow fields are treated, while on the other hand continuing to use a fundamental approach, e.g., single vortex/cold jet, vortex pairs/cold jet, single vortex/hot jet. The motivation for the fundamental approach is to identify the main effects and relevant parameters associated with the interactions of vortices with wake flows and with cold or hot jets. On the other hand, fluctuating jets or wakes may also represent means to act on the flow. A further goal is therefore to evaluate the impact of such perturbations on wake vortices, and to determine whether pulsating jets or small devices, such as bluff bodies, could become an efficient way to act on the evolution of aircraft wakes and have an influence on vortex decay.

"A FLIGHT TESTED WAKE TURBULENCE AWARE ALTIMETER"

ISVC 2011, Part II, 2011, pp. 219-228.

A flying aircraft disturbs the local atmosphere through which it flies creating a turbulent vortex at each wing tip known as a wake vortex. These vortices can persist for several minutes and endanger

other aircraft traversing that turbulent airspace; large vortices are essentially invisible horizontal tornadoes and are a grave threat to smaller aircraft, especially during landing and take-off. Accidents related to wake turbulence have resulted in both loss of life and aircraft destruction in the United States and around the world. Currently no cockpit instrumentation exists that tracks wake vortices and enables a pilot to sense and avoid wake turbulence in real-time. This paper presents a prototype of a novel, flight tested instrument that tracks wake vortices and presents this information to a pilot in real time using a synthetic virtual world augmented with wake turbulence information.

"NAVIER-STOKES SOLUTIONS OF UNSTEADY SEPARATION INDUCED BY A VORTEX"

J. Fluid Mech., Vol. 465, 2002, pp. 99-130

Numerical solutions of the unsteady Navier-Stokes equations are considered for the flow induced by a thick-core vortex convecting along a surface in a two-dimensional incompressible flow. The presence of the vortex induces an adverse streamwise pressure gradient along the surface that leads to the formation of a secondary recirculation region followed by a narrow eruption of near-wall fluid in solutions of the unsteady boundary-layer equations. The locally thickening boundary layer in the vicinity of the eruption provokes an interaction between the viscous boundary layer and the outer inviscid flow. Numerical solutions of the Navier-Stokes equations show that the interaction occurs on two distinct streamwise length scales depending upon which of three Reynolds-number regimes is being considered. At high Reynolds numbers, the spike leads to a small-scale interaction; at moderate Reynolds numbers, the flow experiences a large-scale interaction followed by the small-scale interaction due to the spike; at low Reynolds numbers, large-scale interaction occurs, but there is no spike or subsequent small-scale interaction. The large-scale interaction is found to play an essential role in determining the overall evolution of unsteady separation in the moderate-Reynolds-number regime; it accelerates the spike formation process and leads to formation of secondary recirculation regions, splitting of the primary recirculation region into multiple corotating eddies and ejections of near-wall vorticity. These eddies later merge prior to being lifted away from the surface and causing detachment of the thick-core vortex.

"FORMATION OF TURBULENT VORTEX BREAKDOWN: INTERMITTENCY, CRITICALITY, AND GLOBAL INSTABILITY"

AIAA Journal, Vol. 50, No. 7, July 2012, pp. 1437-1452.

This study provides quantitative insight into the formation of vortex breakdown and the onset of global instability in a turbulent swirling jet. A water jet is guided through a rotating honeycomb that imparts the rotational motion passed through a contraction, and discharged into a large water tank. The flow states evolving at increasing swirl are mapped out via time-resolved particle image velocimetry. The experimental results scale properly with the swirl number based on the axial

momentum flux when the commonly used boundary-layer approximations are omitted. The instantaneous velocity field reveals that vortex breakdown occurs intermittently at a wide range of swirl numbers before it appears in the mean flow. At this intermittent state, the evolving breakdown bubble oscillates heavily between two streamwise locations where the vortex core is subcritical. Upon further increasing the swirl, the breakdown oscillations decay and a region of reversed flow appears in the mean flowfield. The formation of this so-called axisymmetric breakdown state is accompanied by a supercritical-to-supercritical transition of the inflowing vortex core. The reversed flow region is found to grow linearly with increasing swirl until the flow undergoes a supercritical Hopf bifurcation to a global single-helical mode, and vortex breakdown adopts a spiral shape. The global mode shape is extracted from the particle image velocimetry snapshots by means of proper orthogonal decomposition and Fourier analysis. The present experiment reveals that, at gradually increasing swirl, the jet first transitions to an axisymmetric breakdown state that remains globally stable until a critical swirl number is exceeded. This sequence of flow states agrees well with the transient formation of vortex breakdown observed in laminar flows.

"THREE-DIMENSIONAL COHERENT STRUCTURES IN A SWIRLING JET UNDERGOING VORTEX BREAKDOWN: STABILITY ANALYSIS AND EMPIRICAL MODE CONSTRUCTION"

Journal of Fluid Mechanics, Vol. 679, 2011, pp. 383-414.

The spatio-temporal evolution of a turbulent swirling jet undergoing vortex breakdown has been investigated. Experiments suggest the existence of a self-excited global mode having a single dominant frequency. This oscillatory mode is shown to be absolutely unstable and leads to a rotating counter-winding helical structure that is located at the periphery of the recirculation zone. The resulting time-periodic 3D velocity field is predicted theoretically as being the most unstable mode determined by parabolized stability analysis employing the mean flow data from experiments. The 3D oscillatory flow is constructed from uncorrelated 2D snapshots of particle image velocimetry data, using proper orthogonal decomposition, a phase-averaging technique and an azimuthal symmetry associated with helical structures. Stability-derived modes and empirically derived modes correspond remarkably well, yielding prototypical coherent structures that dominate the investigated flow region. The proposed method of constructing 3D time-periodic velocity fields from uncorrelated 2D data is applicable to a large class of turbulent shear flows.

"HORIZONTAL AXIS WIND TURBINE RESEARCH: A REVIEW OF COMMERCIAL CFD, FE CODES AND EXPERIMENTAL PRACTICES"

Progress in Aerospace Sciences, Vol. 92, 2017, pp. 1-24.

A review of wind turbine aerodynamics research is presented. The review is limited to Horizontal Axis Wind Turbine (HAWT) investigations. The focus is on recent near wake experiments, wake predictions by commercial CFD codes and current FSI and structural modelling attempts. For the near wake, the review considers experiments carried out in controlled conditions whereby the incoming freestream is perpendicular to the rotor plane. Additional anomalies such as wind shear, gusts and yaw transition are not considered. The survey of 3D commercial codes is also focused on HAWT models in parallel flow conditions. Finally, the structural models reviewed are divided into two separate categories: 1) blade deflection and performance under aerodynamic loads, and 2) the vibrational response of blades under aerodynamic loading. The aim is to highlight common trends within near wake experiments and investigate both CFD and FE modeling strategies -- to identify current limitations and future opportunities within the sector.

O'Bryan, T. C.

"AN EXPERIMENTAL STUDY OF THE EFFECT OF DOWNWASH FROM A TWIN-PROPELLER VTOL AIRCRAFT ON SEVERAL TYPES OF GROUND SURFACES"

NASA TN D-1239, NASA Langley, Langley Air Force Base, VA, January 1962

A full-scale, twin propeller VTOL aircraft with a maximum gross weight of 3,400 pounds has been operated on the ground to study the effect of downwash on several types of ground surfaces. Static operation over loose snow indicated a zone of obliterated vision ahead of the pilot in an arc of approximately 10 degrees on each side of the plane of symmetry. Static operation in the presence of loose surface material indicated that the downwash cleared the area near the aircraft of these particles without recirculation or damage to any components. Short-time operation at moderate forward speed over loose gravel, with the thrust axis at an angle of 70 degrees from the horizontal, resulted in propeller-blade erosion and numerous small dents and fabric punctures in the sides of the fuselage.

O'Bryan, T. C.

"AN INVESTIGATION OF THE EFFECT OF DOWNWASH FROM A VTOL AIRCRAFT AND A HELICOPTER"

NASA TN D-977, NASA Langley, Langley Air Force Base, VA, August 1961

Dynamic-pressure measurements, in ground effect, have been obtained about a single-rotor helicopter and a dual-propeller VTOL aircraft. The results indicate that the slipstream dynamic pressure along the ground, some distance from the center of rotation, is not a function of disk loading but merely a function of the gross weight or thrust of the aircraft. Furthermore, for a given gross weight the thickness of this outward flowing sheet of air is less for a small-diameter propeller (higher disk loading propeller).

O'Callaghan, J. J.

"FLIGHT CONTROL AND WAKE TURBULENCE EFFECTS ON AMERICAN AIRLINES FLIGHT 587"

AIAA Paper 2005-6110, August 2005, San Francisco, CA.

On November 12, 2001, American Airlines flight 587, an Airbus Industrie A300-600, was destroyed when it crashed into a residential area of Belle Harbor, New York, shortly after takeoff from runway 31L at John F. Kennedy International Airport. Before impact, the vertical stabilizer, rudder, and left and right engines departed the airplane. The 2 pilots, 7 flight attendants, 251 passengers, and 5 persons on the ground were killed. The NTSB determined that the probable cause of the accident was the in-flight separation of the vertical stabilizer as a result of the loads beyond ultimate design that were created by the first officer's unnecessary and excessive rudder pedal inputs, and that contributing to these rudder pedal inputs were characteristics of the Airbus A300-600 rudder system design and elements of the American Airlines Advanced Aircraft Maneuvering Program. During the investigation, it was determined that the airplane had encountered wake turbulence from a Boeing 747 at the time the first officer made his rudder pedal inputs. An objective of the investigation was to determine the significance of both the first officer's rudder inputs and the wake turbulence to the subsequent airplane dynamics and buildup of aerodynamic loads on the vertical tail. Simulations of the airplane motion, driven by the thrust and flight control inputs recorded on the Flight Data Recorder (FDR), as well as external wind gusts and pitch, roll, and yaw moments required to match the airplane dynamics recorded by the FDR, were used to determine the relative contribution of the wake turbulence (represented by the external wind gusts and moments) and flight control inputs to the overall airplane motion. The results of the simulations indicate that the first officer's flight control inputs produced the buildup of the sideslip angle and aerodynamic loads on the vertical tail that caused it to separate from the airplane. The effect of the wake turbulence on the airplane motion was minor.

"FLIGHT CONTROL FOR AUTOMATIC AERIAL REFUELING IN VORTEX WAKE BY TANKER"

Proceedings of the SICE Conference, 2005, pp. 1963-1966

This paper provides two design methods of a flight control system for aerial refueling. One is based on the proportional navigation guidance with acceleration control systems. The other employs the LOS (line-of-sight) angle control. Both control systems are designed using the model following servo controller. Computer simulation of aerial refueling in the presence of vortex wake by the tanker was conducted.

"ENHANCED CAPACITY THROUGH REDUCTIONS IN SEPARATION: NASA'S AVOSS"

Journal of ATC, October-December 2001, pp. 4-10

An aspect of airport terminal operations that holds potential for efficiency improvements is the separation criteria applied to aircraft for wake vortex avoidance. These criteria evolved to represent safe spacing under weather conditions conducive to the longest wake hazards, and consequently are overly conservative during a significant portion of operations. Under many ambient conditions, such as

moderate crosswinds or turbulence, wake hazard durations are substantially reduced. To realize this reduction NASA has developed a proof-of-concept Aircraft VORtex Spacing System (AVOSS). Successfully operated in a real-time field demonstration during July 2000 at the Dallas Ft. Worth International Airport, AVOSS is a novel integration of weather sensors, wake sensors, and analytical wake prediction algorithms. Gains in airport throughput using AVOSS spacing as compared to the current criteria averaged 6%, with peak values approaching the theoretical maximum of 16%. The average throughput gain translates to 15-40% reductions in delay when applied to realistic capacity ratios at major airports.

"A METHOD FOR ESTIMATING THE TURBULENT KINETIC ENERGY DISSIPATION RATE FROM A VERTICALLY POINTING DOPPLER LIDAR, AND INDEPENDENT EVALUATION FROM BALLOON-BORNE IN SITU MEASUREMENTS"

Journal of Atmospheric and Oceanic Technology, Vol. 27, October 2010, pp. 1652-1664.

A method of estimating dissipation rates from a vertically pointing Doppler lidar with high temporal and spatial resolution has been evaluated by comparison with independent measurements derived from a balloon-borne sonic anemometer. This method utilizes the variance of the mean Doppler velocity from several sequential samples and requires an estimate of the horizontal wind speed. The noise contribution to the variance can be estimated from the observed signal-to-noise ratio and removed where appropriate. The relative size of the noise variance to the observed variance provides a measure of the confidence in the retrieval. Comparison with in situ dissipation rates derived from the

balloon-borne sonic anemometer reveal that this particular Doppler lidar can retrieve dissipation rates over a range of at least three orders of magnitude. This method is most suitable for retrieval of dissipation rates within the convective well-mixed boundary layer where the scales of motion that the Doppler lidar probes remain well within the inertial subrange. Caution must be applied when estimating dissipation rates in more quiescent conditions. For the particular Doppler lidar described here, the selection of suitably short integration times will permit this method to be applicable in such situations but at the expense of accuracy in the Doppler velocity estimates. The two case studies presented here suggest that, with profiles every 4 s, reliable estimates of ϵ can be derived to within at least an order of magnitude throughout almost all of the lower 2 km and, in the convective boundary layer, to within 50 percent. Increasing the integration time for individual profiles to 30 s can improve the accuracy substantially but potentially confines retrievals to within the convective boundary layer. Therefore, optimization of certain instrument parameters may be required for specific implementation.

O'Connor, N.

"AIRCRAFT VORTEX SPACING SYSTEM (AVOSS) OVERVIEW AND FUTURE DIRECTION"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Several factors lead to a reduction in airport capacity in weather conditions that prevent the use of visual approach procedures. These factors include a reduction in the number of available runways and the longitudinal wake turbulence separation constraints used by Air Traffic Control (ATC). These wake constraints evolved over time to prevent wake encounters in weather conditions most conducive to long-lived wakes, and are unnecessarily large in weather domains that lead to rapid wake decay or drift away from the flight path. During visual conditions aircraft separation responsibility belongs to the pilots, who use their knowledge of weather conditions, lead aircraft type, and lead aircraft flight path to effectively self-separate from wake encounters. In many situations the resulting spacing is less than would be required in instrument operations. The AVOSS is designed to structure this process and minimize the difference in aircraft spacing between visual and instrument operations. The operational concept of AVOSS is to determine the spacing required to prevent wake vortex encounters, given the ambient weather conditions in existence at the airport. The AVOSS system uses sensed weather information to predict wake vortex behavior and develop safe spacing criteria. The meteorological subsystem uses sensors and modeling techniques to describe the vertical profiles of the wind, turbulence, and temperature from the surface to the glide slope intercept altitude. The wake predictor uses this weather profile and descriptions of the aircraft fleet at the airport to predict wake drift rate, sink rate, and decay rate for each modeled aircraft type. Runway throughput estimates are generated using the wake predictions. Wake sensors are used to check the predicted behavior. No ATC interface was included in the AVOSS demonstration. The AVOSS system was demonstrated at the Dallas Ft. Worth International airport in July of 2000. This paper will present an overview of the AVOSS as demonstrated. Included will be discussion of the system's potential impact on capacity and delays along with thoughts on the overall maturity of a Wake Vortex Advisory System (WVAS). A first generation WVAS is envisioned building on the success of the AVOSS. Such a system would offer

limited capability while allowing operational development. For example, an initial WVAS might be restricted to certain weather conditions. Development of a research effort leading to such a system is currently underway.

"THE STABILITY AND DEVELOPMENT OF TIP AND ROOT VORTICES BEHIND A MODEL WIND TURBINE"

Experiments in Fluids, Vol. 54, 2013, pp. 1591-1 - 1591-16.

When designing new wind farms, one has to rely on models describing the flow field around and inside the farm, since direct numerical simulation is far too computationally expensive. To develop better models for power prediction of wind farms, knowledge about the flow field around turbines, the stability of the wakes and the interaction between them is essential. Since the conditions during field measurements are difficult to control, wind tunnel measurements play an important role when studying wakes behind wind turbines. Within the present work, an experimental methodology has been developed to study the evolution and stability of the tip vortices shed from the rotor blades of a small-scale turbine model. The stability of the tip vortices was studied by introducing a periodic disturbance to the flow, which is shown to have a clear effect on the development of the vortices. Prior to the vortex breakdown, clear signs of vortex pairing were also observed. A parameter study was performed by varying the amplitude and frequency of the forced disturbance, and the effect on the tip vortices was evaluated. This experiment is one of the first where the influence of a periodic disturbance on a wind turbine wake is studied, something that previously has been performed in several numerical studies.

"MANIPULATION OF WING TIP VORTICES ON LOW ASPECT RATIO WINGS USING WINGLET CONTROL SURFACES"

AIAA Paper 2017-1270, January 2017, Grapevine, TX.

The aerodynamic forces generated by a wing tip mounted articulated winglet control surface on a low aspect ratio wing in steady flight are investigated. The wings experimentally tested constitute two categories, traditional trailing edge mounted aileron flaps, and wing tip mounted articulated winglets which hinge chordwise. Low-aspect-ratio (LAR) wings at low-Reynolds numbers were chosen because these parameters are common to micro aerial vehicle (MAV) flight. Control authority developed by the control surface configurations were directly compared by measuring lateral forces and specifically the roll moment in wind tunnel testing. Flat plate wing models were studied to isolate the low aspect ratio aerodynamics from more complicated wing geometry effects. The manipulation of wing tip vortices' (TV) by articulated winglets is found to be an effective method of generating roll, especially in sideslip situations. We see conventional flaps generate a predictable roll moment varying slightly with angle of attack while articulated winglets rely on altering the span-wise distribution of lift. It is seen that in the

delayed stall region, unique to LAR and delta wing flight, winglets generate the same authority as traditional flaps and develop greater authority in sideslip situations.

"DISPERSION OF AERIAL AGRICULTURAL SPRAYS; MODEL AND VALIDATION"

Agricultural and Forest Meteorology, Vol. 53, Issue 3, January 1991, pp. 223-255

A model that has developed to calculate the dosages of airborne pesticides in the downwind area during aerial crop spraying. The model is valid for crosswind flying, small flying heights (~ 2m) and formulations consisting of an involatile pesticide or a combination of an involatile pesticide and a volatile carrier liquid (e.g. water). The model consists of two submodels: a model which describes the development of a pair of initial clouds, mainly owing to the action of the aircraft induced vortices, and a model which describes the atmospheric dispersion of this pair of initial clouds. The model was validated by means of the results of field experiments carried out by R. S. Crabbe and M. McMooye.

Oetzel, K. G. and Vallis, G. K.

"STRAIN, VORTICES, AND THE ENSTROPY INERTIAL RANGE IN TWO-DIMENSIONAL TURBULENCE"

Physics of Fluids, Vol. 9, No. 10, October 1997, pp. 2991-3004.

The properties of vortices in a strain field are used to construct a phenomenological theory of the enstrophy inertial range in two-dimensional incompressible turbulence. The theory, based in part on the results and behavior of numerical simulations, attempts to combine spectral inertial range theories of the Kolmogorov type with the dynamics of vortex interactions in physical space. It is based on the assumptions that coherent vortices can survive in a turbulent flow if of sufficient strength compared to the background straining field, and that coherent structures feel a mean strain field, independent of their scale. The first assumption is suggested by a result in the theory of uniform elliptic vortices, while the second comes from numerical simulations. The theory employs a single non-dimensional parameter, essentially the ratio between the enstrophy flux and the mean strain, which then characterizes flows from extremely intermittent decaying turbulence to nearly Gaussian passive scalar dynamics. The theory predicts that in forced two-dimensional turbulence, coherent structures reside in a 'background' straining field. The coherent vortices will dominate the flow at a sufficiently large scale, with a fairly abrupt transition at a small scale to a flow in which the classical $1/k$ enstrophy spectrum holds. In this classical region small amplitude vortices do not survive because the (large-scale) straining field is of larger amplitude than the (small-scale) vorticity.

"PERTURBATION RESPONSE AND PINCH-OFF OF VORTEX RINGS AND DIPOLES"

Journal of Fluid Mechanics, Vol. 704, 2012, pp. 280-300.

The nonlinear perturbation response of two families of vortices, the Norbury family of axisymmetric vortex rings and the Pierrehumbert family of two-dimensional vortex pairs, is considered. Members of both families are subjected to prolate shape perturbations like those previously introduced to Hill's spherical vortex, and their response is computed using contour dynamics algorithms. The response of the entire Norbury family to this class of perturbations is considered, to bridge the gap between past observations of the behavior of thin-cored members of the family and that of Hill's spherical vortex. The behavior of the Norbury family is contrasted with the response of the analogous two-dimensional family of Pierrehumbert vortex pairs. It is found that the Norbury family exhibits a change in perturbation response as members of the family with progressively thicker cores are considered. Thin-cored vortices are found to undergo quasi-periodic deformations of the core shape, but detrain no circulation into their wake. In contrast, thicker-core Norbury vortices are found to detrain excess rotational fluid into a trailing vortex tail. This behavior agrees with previous results for Hill's spherical vortex, as well as with observations of pinch-off of experimentally generated vortex rings at long formation times. In contrast, the detraining of circulation that is characteristic of pinch-off is not observed for Pierrehumbert vortex pairs of any core size. These observations agree with recent studies that contrast the formation of vortices in two and three dimensions. We hypothesize that transitions in vortex formation, such as those occurring between wake shedding modes and in vortex pinch-off more generally, might be understood and possibly predicted based on the observed perturbation responses of forming vortex rings or dipoles.

"DETECTION OF HAZARDOUS METEOROLOGICAL AND CLEAR-AIR PHENOMENA WITH AN AIR TRAFFIC CONTROL RADAR"

Proceedings International Conf., Institution of Electrical Engineers, Oct, 1982, pp. 316-320

An account is given of the modifications made in the Airport Surveillance Radar (ASR-8) test bed at the FAA Technical Center at Atlantic City Airport (N.J.). The modifications, arrived at by the FAA, the Wave Propagation Laboratory, and MIT's Lincoln Laboratory, were made to observe low-level wind shear and turbulence associated with both thunderstorms and aircraft trailing wake-vortices. The modifications, consisting of a second antenna system and a separate receiver and Doppler processing chain, used the standby channel of the radar for these measurements. The results obtained are summarized. In describing the system, it is noted that the 15-foot parabolic antenna is interconnected with the ASR-8, operating with a peak transmitter power of 1 MW, a frequency of 2.79 GHz, a pulse repetition rate of 1030/sec, and a pulse length of 0.6 microsec. The separate receiver and Doppler processing chain comprises in phase and quadrature detectors, analog/digital converters, and a minicomputer with associated peripherals.

"MEASUREMENT OF AIRCRAFT WAKE VORTICES USING DOPPLER LIDAR"

J. Fluid Science and Technology, Vol. 3, No. 4, 2008, pp. 488-499

In this research, the wake turbulence from actual passenger airplanes taking off from Sendai airport was measured with Electronic Navigation Research Institute's Doppler laser radar (lidar). First, the influence of the surrounding wind on the behavior of wake vortices was investigated. The wake vortices in the crosswind case disappear more quickly from the runway than those of the low surrounding wind and head wind cases. In addition, the wake vortices in the case of large crosswind move faster than those in small crosswind. Next, the correction factor was estimated by using the pseudo lidar measurements based on Computational Fluid Dynamics. The corrected data for weak surrounding wind case agreed with the existing wake vortex model.

Oh, S. and Jung, S.

"EXPERIMENTAL STUDY ON THE NEAR FIELD STRUCTURE OF WING-TIP VORTEX"

AIAA Paper No. 2000-0792, Reno, NV, January 2000

The structure and development procedure of the wing-tip vortex in the near field of the downstream of the rectangular wing has been investigated. The experiments have been conducted with the wing with NACA 6409 airfoil cross-section. The flow field of the vortex was measured with a spherical type five-hole probe from $0.1c$ to $2.0c$ behind the trailing edge. Comparing with other experimental results using hot-wire system validates the results of current experiments. Through the experiments, the streamline patterns in the cross-flow plane confirm that the vortex flow is composed of inner viscous core, spiral out region, tightly wound spiral region, and the external potential vortex region. In addition, it is observed that the flow patterns in the potential vortex region show slight tendency of 'spiral in' characteristics. The tangential velocity components show similarity patterns and clear core region as studied previously, but the distribution of the axial velocity components provides more detailed information on the deformation procedure of the wing-tip vortex and shows some oscillation in magnitude. The maximum axial velocity at the vortex core is larger than that of the free stream, and decreasing in its magnitude with distance downstream, while the value of the averaged axial velocity in the vortex core region is still smaller than that of free stream velocity like other studies. The oscillation in the magnitude of the axial velocity around the vortex core region shows the similar characteristics of the shape of a hurricane. The total pressure and helicity distribution have been also studied to analyze the vortex structure. These properties show clear variation of the vortex structure, vortex core position, and its deformation in the near field. It has been also found that the vortex core structure is closely related between axial velocity and the tangential velocity components.

"A VISUAL STUDY OF VORTEX INSTABILITIES IN THE WAKE OF A ROTOR IN HOVER"

Journal of the American Helicopter Society, Vol. 57, 2012, pp. 042005-1 to 042005-8.

A visual study of the instability characteristics of the helical vortex filaments trailing from the tips of a three-bladed lifting rotor in a water tank is presented. The rotor diameter was 25.4 cm, and its rotation rate ranged from 4 to 12 revolutions per second. Soon after their formation, the vortex filaments

developed long- and short-wave instabilities. In the long-wave instability mode, two of the three vortices coming off the rotor orbited around each other and merged in about 0.4 of the theoretical orbit time of equistrength two-dimensional vortices, after which the third vortex joined the merger to form a single, apparently turbulent helical vortex filament. The wavelengths of the short-wave instabilities were about 0.4 of the wake radius, about 17 cycles over the circumference. The short waves exhibited a linear growth rate during the first half of their orbital motion and an exponential growth prior to merging. The linear growth rate was about 0.0034 D/rad. The e-folding time for the exponential growth rate was about 0.52 rad.

"INTERACTION OF A VISCOUS VORTEX PAIR WITH A FREE SURFACE"

Journal of Fluid Mechanics, Vol. 227, 1991, pp. 47-70.

A vortex pair in a viscous, incompressible fluid rises vertically toward a deformable free surface. The mathematical description of this flow situation is a time-dependent nonlinear free-surface problem that has been solved numerically for a two-dimensional laminar flow with the aid of the Navier-Stokes equations by using boundary-fitted coordinates. For several selected flow parameters, results are presented on the decay of the primary vortices and their paths, the generation of surface vorticity and secondary vortices, the development and final stage of the disturbed free surface, and the influence of surface tension. High and low Froude numbers represent the two extremes of free-surface yielding and stiffness, respectively. For an intermediate Froude number, a special rebounding due to the presence of secondary vortices has been observed: the path of the primary vortex center portrays a complete loop.

Okada, S. and Hiraoka, K.

"EXPERIMENTAL STUDIES OF REDUCTION OF THE WING TIP VORTEX BY SUCTION"

AIAA Paper No. 2003-3533, Orlando, FL, June 2003

The wing tip vortex occurs in the wing tip neighborhood on an aircraft in flight, and cannot be avoided for three-dimensional wing. Then the induced drag is generated by the wing tip vortex. So, the reduction of the wing tip vortex is a very important problem for an aircraft. There are many studies of the wing tip vortex and the flow control techniques near the wing tip for the reduction of the wing tip vortex. However, there is little study of control of the wing tip vortex by suction. In this paper at first, the characteristics of the wing tip vortex were explained in detail by the low-speed wind tunnel experiments using the two-dimensional hot wire anemometer. Next, controlling the flow near the wing tip by suction and effects against the reduction of the wing tip vortex were investigated. Suction was carried out at various positions of the wing tip. Then it is shown that the wing tip vortex is decreased by appropriate suction and the amount of reduction is different according to suction points.

"AERODYNAMIC CHARACTERISTICS AT LOW REYNOLDS NUMBERS FOR WINGS OF VARIOUS PLANFORMS"

AIAA Journal, Vol. 49, No. 6, June 2011, pp. 1135-1150.

The aerodynamic characteristics of various wing planforms at low Reynolds numbers (about 10,000) were studied by conducting wind-tunnel tests. These low Reynolds numbers correspond to the flights of small creatures, such as insects. Elliptical, rectangular, and triangular planforms with various aspect ratios were used in this study, as well as a swept rectangular (parallelogram) wing with an aspect ratio of four. The wing sections of all models were thin rectangular airfoils. The aerodynamic forces (lift and drag) and the pitching moment acting on the wing were measured for a wide range of angles of attack (including the maximum of 90 deg). Nonlinear characteristics of the lift coefficient were obtained, even at low angles of attack for high-aspect-ratio wings, whereas a small lift slope and a large maximum lift coefficient were obtained for low-aspect-ratio wings. The drag and the pitching moment coefficients also exhibited nonlinear characteristics. The effect of the Reynolds number based on the wing chord was comparatively small, but a distinctive phenomenon in low-Reynolds-number flow was observed in flow visualization using oil-film and smoke-wire methods.

Okamoto, S.

"VISUALIZATION OF IMPINGEMENT OF BROKEN-DOWN VORTEX ON TAIL"

Journal of Wind Engineering and Industrial Aerodynamics, Vol. 91, 2003, pp. 65-74.

The impingement of a streamwise vortex on a fin is investigated experimentally with high-image-density particle image velocimetry (PIV) and dynamic pressure transducers to relate the structure of vortex breakdown to the spectra of surface pressure along the fin. The instantaneous and ensemble-averaged distributions of vorticity from PIV show strong concentrations of vorticity along the edges of the breakdown region. Correspondingly, the amplitude response of the pressure spectra is the strongest when the fin is located near the edge of vortex breakdown. The dominant frequency of the surface pressure is insensitive to cross-stream displacements of the vortex axis relative to the leading edge of the fin. Spectra of surface pressure at crucial locations on the fin are related to these features of the instantaneous and averaged flow structure.

"EFFECT OF TRAIL AIRCRAFT TRIM ON OPTIMUM LOCATION IN FORMATION FLIGHT"

Journal of Aircraft, Vol. 52, No. 4, July-August 2015, pp. 1201-1213.

Aircraft flight generates vortices that induce nonuniform wind distribution in their wake. A trailing/follower aircraft will experience induced wind components and gradients with various magnitudes and directions, depending on its location relative to the leader. This paper explores two methods of determining the relative location for optimum formation flight, termed the sweet spot. The relative location with the highest lift-to-drag ratio on the follower is denoted as the static sweet spot. In

the second method, the trail aircraft is trimmed by adjusting the thrust and control surfaces to maintain its commanded position relative to the lead. The relative location requiring the least thrust is then assigned as the dynamic sweet spot. The results showed that, depending on the trail aircraft size, the static sweet spot might differ from the dynamic sweet spot. The effect of the leader weight and follower size on both static and dynamic sweet spot was also studied. It was discovered that the static and dynamic sweet-spot location changed when the size of the trail aircraft was modified. It was also observed that the static sweet spot remained the same but the dynamic sweet spot changed when the lead aircraft weight was modified.

Okolo, W., Dogan, A. and Blake, W.

"MODIFIED STUDY OF TRAIL AIRCRAFT TRIM EFFECT ON SWEET SPOT IN FORMATION FLIGHT"

AIAA Paper 2014-0541, January 2014, National Harbor, MD.

Aircraft flight generates vortices that induce nonuniform wind distribution in their wake. A trailing/follower aircraft will experience induced wind components and gradients with various magnitudes and directions, depending on its location relative to the leader. This paper explores two methods of determining the relative location for optimum formation flight, termed the sweet spot. The relative location with the highest lift-to-drag ratio on the follower is denoted as the static sweet spot. In the second method, the trail aircraft is trimmed by adjusting the thrust and control surfaces to maintain its commanded position relative to the lead. The relative location requiring the least thrust is then assigned as the dynamic sweet spot. The results showed that depending on the trail aircraft size, the static sweet spot might differ from the dynamic sweet spot. The effect of the leader weight and follower size on both static and dynamic sweet spot was also studied. It was discovered that the static and dynamic sweet spot location changed when the size of the trail aircraft was modified. It was also observed that the static sweet spot remained the same but the dynamic sweet spot changed when the lead aircraft weight was modified. This study, as opposed to the previous work of the authors, utilizes a different and improved aerodynamic coupling technique to model the effect of the lead on the trail aircraft.

"ALTERNATE TRIMMING METHODS FOR TRAILING AIRCRAFT IN FORMATION FLIGHT"

Journal of Guidance, Control, and Dynamics, Vol. 38, No. 10, October 2015, pp. 2018-2024.

This Note presented the results of using alternative trim mechanism at the static optimal location for an EQ-II aircraft trailing a KC-135R. The drag-inducing control effector deflections required to trim the induced moments on the EQ-II at the static optimal location nullified the expected benefit of formation flight. Thus, internal fuel transfer and differential thrusting were employed to reduce the deflections of the aileron and rudder, respectively. Combined, these techniques yielded fuel savings of 7 percent for the EQ-II behind the KC-135R. The fuel saving was increased to 8 percent when the alternative trimming methods were used for the EQ-II behind a heavy KC-135R. Although this fuel configuration

was the best-case scenario for the benefit of fuel transfer because it enables the largest lateral c.m. shift by fuel transfer, it was impossible to significantly affect the elevator deflections using internal fuel transfer.

"REVIEW OF EVOLVING TRENDS IN BLENDED WING BODY AIRCRAFT DESIGN"

Progress in Aerospace Sciences, Vol. 82, 2016, pp. 1-23.

The desire to produce environmentally friendly aircraft that is aerodynamically efficient and capable of conveying large number of passengers over long ranges at reduced direct operating cost led aircraft designers to develop the Blended Wing Body (BWB) aircraft concept. The BWB aircraft represents a paradigm shift in the design of aircraft. The design provides aerodynamics and environmental benefits and is suitable for the integration of advanced systems and concepts like laminar flow technology, jet flaps and distributed propulsion. However, despite these benefits, the BWB is yet to be developed for commercial air transport due to several challenges. This paper reviews emerging trends in BWB aircraft design highlighting design challenges that have hindered the development of a BWB passenger transport aircraft. The study finds that in order to harness the advantages and reduce the deficiencies of a tightly coupled configuration like the BWB, a multidisciplinary design optimization should be conducted with good handling and ride quality as objective functions within acceptable direct operating cost and noise bounds.

Okulov, V. L.

"ON THE STABILITY OF MULTIPLE HELICAL VORTICES"

J. Fluid Mech., Vol. 521, 2004, pp. 319-342

The classical problem of linear stability of a regular N-gon of point vortices to infinitesimal space displacements from an equilibrium of the vortex configuration is generalized to the one for N helical vortices (couple, triplet, etc., $N > 1$) for the first time. Because of this consideration, the analytical form for the stability boundaries has been obtained. This solution allows an efficient analysis to be made of the existence of stable helical vortex arrays, which were repeatedly observed in practice. Such a stability problem was earlier considered in theory, but only for the case of a plane polygonal array of N point vortices. As for helical vortices, owing to their complexity, intensive study has been mainly on the self-induced motion of the vortex. The algebraic representation for the velocity of motion of the N helical vortex array was originally obtained as an additional intermediate result. The new formula allows accurate calculations to be made within the whole range of helical pitch variations and has a simpler form than the known asymptotic expressions. Solution of these two classical problems of vortex dynamics has significance both for theoretic and applied mechanics, as well as for many other areas of natural science, where the rotor (vortex) concept is the basic one.

"INSTABILITY OF A VORTEX WAKE BEHIND WIND TURBINES"

Doklady Physics, Vol. 49, No. 12, 2004, pp. 772-777

Modern wind-power generators (wind turbines) often are grouped together to ensure an increased operating efficiency at the expense of using many turbines in the same terrain area. However, in this case, one or several turbines can turn out to be in the wake beyond other turbines. The airflow beyond a wind turbine is represented by a system of intense rotational helical vortices determining the dynamics of a far wake. The wake produces a significant periodic load for the structure of a wind turbine present in the wake. This fact, naturally, results in a reduction of the turbine in-service time. However, as is well known, for certain operating regimes of wind turbines, the vortex wake becomes unstable and breaks down. If a turbine is in a stable vortex wake, then the interaction with it may have more significant consequences than in the case of wake breakdown. Therefore, analysis of stability conditions for a vortex system simulating the vortex wake beyond wind turbines, screws, and aerodynamic propellers is of great practical importance.

"THE ROTOR THEORIES BY PROFESSOR JOUKOWSKY: VORTEX THEORIES"

Progress in Aerospace Sciences, Vol. 73, 2015, pp. 19-46.

This is the second of two articles with the main, and largely self-explanatory, title 'Rotor theories by Professor Joukowski.' This article considers rotors with finite number of blades and is subtitled 'Vortex theories.' The first article with subtitle 'Momentum theories' assessed the starring role of Joukowski in aerodynamics in the historical context of rotor theory. The main focus in both articles is on wind turbine rotors, but much of the basic theory applies to propellers and helicopters as well. Thus, this second article concentrates on the so-called blade element theory, the Kutta-Joukowski theorem, and the development of the rotor vortex theory of Joukowski. This article is largely based on our own work, which constitutes the first successful completion and further development of Joukowski's work by deriving the first analytical solution of his rotor. This rotor has a finite number of blades and will be compared with the rotor analysis of Betz and of others of the German school of aerodynamics.

"EFFECTS OF LARGE AIRPLANES' WAKE TURBULENCE ON SMALL AIRCRAFT"

Report JAXA-RR-07-029, 2008, Flight Systems Research Center, Tokyo, Japan.

Flight simulation test results are presented, comparing the effects on a small airplane Dornier Do228 and a helicopter Mitsubishi MH2000 encountering B747-400's wake turbulence. Results show that the response of the helicopter is much smaller than that of the airplane. The effects of some parameters such as visibility are examined. Information display system is also developed which shows the pilot the location and strength of the wake turbulence measured by a ground-based Doppler-lidar system.

"MEASUREMENT OF AMBIENT FLUID ENTRAINMENT DURING LAMINAR VORTEX RING FORMATION"

Experiments in Fluids, Vol. 44, 2008, pp. 235-247

Planar laser induced fluorescence (PLIF) and digital particle image velocimetry (DPIV) combined with Lagrangian coherent structure (LCS) techniques are utilized to measure ambient fluid entrainment during laminar vortex ring formation and relate it to the total entrained volume after formation is complete. Vortex rings are generated mechanically with a piston-cylinder mechanism for a jet Reynolds number of 1,000, stroke ratios of 0.5, 1.0 and 2.0, and three velocity programs (Trapezoidal, triangular negative and positive sloping velocity programs). The quantitative observations of PLIF agree with both the total ring volume and entrainment rate measurements obtained from the DPIV/LCS hybrid method for the jet Reynolds number of 1,000, trapezoidal velocity program and stroke ratio of 2.0 case. In addition to increased entrainment at smaller stroke ratios observed by others, the PLIF results also show that a velocity program utilizing rapid jet initiation and termination enhances ambient fluid entrainment. The observed trends in entrainment rate and final entrained fluid fraction are explained in terms of the vortex roll-up process during vortex ring formation.

"VISCOUS EFFECTS IN THE ABSOLUTE-CONVECTIVE INSTABILITY OF THE BATCHELOR VORTEX"

J. Fluid Mech., Vol. 459, 2002, pp. 371-396

The effects of viscosity on the instability properties of the Batchelor vortex are investigated. The characteristics of spatially amplified branches are first documented in the convectively unstable regime for different values of the swirl parameter q and the co-flow parameter a at several Reynolds numbers Re . The absolute-convective instability transition curves, determined by the Briggs-Bers zero-group velocity criterion, are delineated in the (a, q) -parameter plane as a function of Re . The azimuthal wavenumber m of the critical transitional mode is found to depend on the magnitude of the swirl q and on the jet ($a > -0.5$) or wake ($a < -0.5$) nature of the axial flow.

Olsen, J. H.

"AIRCRAFT WAKE TURBULENCE - AN EXPANDING AREA OF LOW-SPEED AERODYNAMICS RESEARCH"

Proceeding of the National Aerospace Electronics Conf., IEEE, 1971, pp. 17-22

A review of recent findings on the structure of a vortex wake and its interactions with following aircraft is given. Formation and disintegration processes are discussed including recently discovered instability mechanisms. Interactions between a wake and a following aircraft are shown to depend primarily on the circulation of the wake and the span of the following aircraft. Various methods suggested for reducing wake hazards are discussed. Finally, areas for further research are suggested.

Olsen, J. H.

"CONFIGURATION EFFECTS ON WAKE STRUCTURE AND AIRCRAFT INTERACTION"

FAA Symposium on Turbulence, Federal Aviation Administration, Washington, DC, March 1971, p. 24

A survey of results of recent flight tests and laboratory experiments was presented with discussion of possible means for reducing the hazard of a wake. Wing modifications, engine placement, and instability mechanisms were discussed as means for increasing the vortex core diameter. The possibility of shortening the hazardous region of the wake by exciting a natural instability of the vortex pair was described.

Olsen, J. H.

"RESULTS OF TRAILING VORTEX STUDIES IN A TOWING TANK"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 455-472

Flow visualization studies were performed in a towing tank using an electrochemically activated dye. Although test Reynolds numbers were far below flight Reynolds numbers, the results were strikingly like flight test data. Two types of instability were observed in the tank. An instability associated with the axial flow within the core was observed to destroy the flow near the core without destroying the motion far from the core. A second instability involving the mutual interaction of the two vortices was observed but somewhat masked by the first instability.

Olsen, J. H.

"RESULTS OF TRAILING VORTEX STUDIES IN A TOWING TANK"

D1-82-1004, September 1970, Boeing Research Labs, Seattle, WA

Flow visualization studies were performed in a towing tank using an electrochemically activated dye. Although test Reynolds numbers were far below flight Reynolds numbers (10 to the 4th versus 10 to the 7th power), the results were strikingly like flight test data. Two types of instability were observed in the tank. An instability associated with the axial flow within the core was observed to destroy the flow in the neighborhood of the core without destroying the motion far from the core. A second instability involving the mutual interaction of the two vortices was observed but somewhat masked by the first instability.

"AIRCRAFT WAKE TURBULENCE AND ITS DETECTION"

1st ed., Plenum Press, New York, 1971

Proceedings of a Symposium on Aircraft Wake Turbulence held in Seattle, Washington, September 1-3, 1970. The volume covers the properties of wakes, including their formation, stability, and decay, and provides data on interactions between wakes and following aircraft as well as experimental methods of observing wake properties.

Olsen, M. E.

"LagRST MODEL PREDICTIONS OF A WINGTIP VORTEX FLOWFIELD"

AIAA Paper 2015-2923, June 2015, Dallas, TX.

The performance of the new LagRST models is compared with curvature corrected eddy viscosity RANS models on the Chow-Zilliac wingtip flowfield. The Reynolds-stress models provide very good predictions of this flow without any additional curvature corrections. Along with comparison of predictions of the vortex itself, some of the other measurements included in the flowfield are compared with the predictions in the wake and over the wing. Differences in predictions between the various RANS models in the wake region are small -- not substantial, and all predictions are in line with experimental measurements from 0.005c to 0.67c downstream of the trailing edge, at odds with what self-similar wake analysis would predict.

Olsthoorn, J. and Dalziel, S. B.

"THREE-DIMENSIONAL VISUALIZATION OF THE INTERACTION OF A VORTEX RING WITH A STRATIFIED INTERFACE"

Journal of Fluid Mechanics, Vol. 820, 2017, pp. 549-579.

The study of vortex-ring-induced stratified mixing has long played a key role in understanding externally forced stratified turbulent mixing. While several studies have investigated the dynamical evolution of such a system, this study presents an experimental investigation of the mechanical evolution of these vortex rings, including the stratification-modified three-dimensional instability. The aim of this paper is to understand how vortex rings induce mixing of the density field. We begin with a discussion of the Reynolds and Richardson number dependence of the vortex-ring interaction using two-dimensional particle image velocimetry measurements. Then, using modern imaging techniques, we reconstruct from an experiment the full three-dimensional time-resolved velocity field of a vortex ring interacting with a stratified interface. This work agrees with many of the previous two-dimensional experimental studies, while providing insight into the three-dimensional instabilities of the system. Observations indicate that the three-dimensional instability has a similar wavenumber to that found for the unstratified vortex-ring instability at later times. We determine that the time scale associated with this instability growth has an inverse Richardson number dependence. Thus, the time scale associated with the instability is different from the time scale of interface recovery, possibly explaining the significant drop in mixing efficiency at low Richardson numbers. The structure of the underlying instability is a simple displacement mode of the vorticity field.

Olwi, I. and Ghazi, M.

"EFFECT OF WING TIP VORTICES ON A TRAILING AIRCRAFT"

AIAA Journal, Vol. 30, No. 9, September 1992, pp. 2186-2187

The effect of trailing vortices from a large leading wing on a trailing aircraft is studied experimentally. The aerodynamic response of the trailing aircraft is examined through measurements of lift, drag, and pitching moment for various angles of attack of the two models and different separation distances between them. The results show that trailing vortices cause a remarkable loss of lift on the trailing aircraft. This phenomenon becomes more significant as the angle of attack of the leading object is increased. Results demonstrate that in order to maintain the same lift, drag would increase as the leading wing angle of attack is increased.

Ooga, Y.

"WAKE TURBULENCE DETECTING SYSTEM"

US Patent 6,424,408 B1, July 2002.

Reducing blind spots of a laser radar observing wake turbulence is required for detecting efficiently the wake turbulence which appears behind the main wings of an aircraft and affects the flight of other aircraft. A first laser radar and a second laser radar each emit a laser beam from different positions. A signal processing device produces wake turbulence information based on the reception signal of the first and second laser radar. Further, the signal processing device specifies wake turbulence information for producing display data either by making a composite of wake turbulence information of two laser radar whose observation areas do not overlap each other or by selecting the larger value of wake turbulence information from two laser radar whose observation areas overlap each other and produces display data for indicating wake turbulence information on monitor display based on the specified wake turbulence information.

Oon, E. H.

"DECAY OF TRAILING VORTICES"

ARC-CP-1238, June 1971, Bristol Univ., Bristol, England. (Also, ARC-33215.)

Model wings of various planforms were plunged vertically into a water tank and the vortex patterns on the surface were studied. For each wing the wake drift rate was found to increase with incidence and to decrease with increasing core separation. The wake started off with discrete vortex cores which grew independently, maintained their initial separation, and had peak velocities which decayed as time to the minus one-half power. The edges of the cores ultimately came very close together and thereafter separation distance between the core centers increased with time, and the peak velocities tended to decay as the reciprocal of time.

"ACOUSTIC VALIDATION OF A NEW CODE USING PARTICLE WAKE AERODYNAMICS AND GEOMETRICALLY-EXACT BEAM STRUCTURAL DYNAMICS"

Proceedings 29th European Rotorcraft Forum, September 2003, Friedrichshafen, Germany.

This paper describes the validation of a new code for predicting both aeroacoustic and aeroelastic behavior of hingeless rotors. The structural component was based on a non-linear beam element model considering small strains and finite rotations, which uses a mixed variational intrinsic formulation. The aerodynamic component was built on a low-order panel method incorporating a vortex particle free-wake model. The aerodynamic and structural components were combined to form a closely coupled aeroelastic code that solves in the time-domain. The loading and thickness noise terms for the aeroacoustic calculations were calculated from the aerodynamic data using a formulation based on the Ffowcs Williams-Hawkings equation. The code was successfully validated for acoustic signature and BVI predictions using test cases from the HELINOISE program.

"ROTORCRAFT AERODYNAMIC AND AEROACOUSTIC MODELLING USING VORTEX PARTICLE METHODS"

ICAS Paper 2002-299, September 2002, Toronto, Canada.

The initial development of a combined active aeroelastic aeroacoustic rotorcraft code is discussed. The GENeral Unsteady Vortex Particle code (GENUVP) is used as the aerodynamic component of the combined code. A brief discussion of the theory behind GENUVP's use of an unsteady panel method with a vortex particle wake is presented. Modifications to GENUVP to increase its computational efficiency are discussed. The implementation of a new aeroacoustic component in GENUVP is summarized. An overview of the combined active aeroelastic aeroacoustic code under development is presented. Results from the current work, including aerodynamic modelling of the NASA/ARMY/MIT Active Twist Rotor (ATR) and acoustic modelling of a NASA scale UH1H rotor are presented.

"ON THE STRUCTURE OF A THREE-DIMENSIONAL COMPRESSIBLE VORTEX"

Computers and Fluids, Vol. 30, Issue 1, September 2000, pp. 115-135.

We present here self-similar solutions of the equations of motion of a viscous, heat conducting gas, for a family of slender vortices. Slenderness makes possible use of the boundary-layer-like 'quasi-cylindrical approximation.' For our solutions, velocity components at the vortex edge behave like a power of the axial coordinate, and the vortex core width varies like a power of the same variable -- $1/2$ in many of the results presented here. Effects due to the temperature dependence of the viscosity, and

varying the Prandtl number and specific-heat ratio are included. It appears that the location of the vortex 'edge' is actually an independently specifiable parameter of the solution.

O'Regan, M. S., Griffin, P. C. and Young, T. M.

"NUMERICAL AND EXPERIMENTAL INVESTIGATION OF THE MEAN AND TURBULENT CHARACTERISTICS OF A WING-TIP VORTEX IN THE NEAR FIELD"

Proceedings of Institution of Mechanical Engineers; Part G: Journal of Aerospace Engineering, Vol. 228, No. 13, 2014, pp. 2516-2529.

The near-field (up to three chord lengths) development of a wing-tip vortex is investigated both numerically and experimentally. The research was conducted in a medium speed wind tunnel on a NACA 0012 square tip half-wing at a Reynolds number of 320,000. A full Reynolds stress turbulence model with a hybrid unstructured grid was used to compute the wing-tip vortex in the near field while an x-wire anemometer and five-hole probe recorded the experimental results. The mean flow of the computed vortex was in good agreement with experiment as the circulation parameter was within 6 percent of the experimental value at $x/c=0$ and angle of attack of 10 degrees and the crossflow velocity magnitude was within 1 percent of the experimental value at $x/c=1$ and angle of attack of 5 degrees. The trajectory of the computed vortex was also in good agreement as it had moved inboard by the same amount (10 percent chord) as the experimental vortex at the last measurement location. The axial velocity excess is under predicted for angle of attack of 10 degrees, whereas the velocity deficit is in relatively good agreement for angle of attack of 5 degrees. The computed Reynolds shear stress component is in good agreement with experiment at $x/c=0$ for angle of attack of 5 degrees, but is greatly under predicted further downstream and at all locations for angle of attack of 10 degrees. It is thought that a lack of local grid refinement in the vortex core and deficiencies in the Reynolds stress turbulence model may have led to errors in the mean flow and turbulence results respectively.

O'Regan, M. S., Griffin, P.C., McNicholas, G. and Young, T. M.

"EXPERIMENTAL/NUMERICAL INVESTIGATION OF A WINGTIP VORTEX IN THE NEAR-FIELD"

AIAA Paper No. 2012-3331, June 2012, New Orleans, LA.

The three-dimensional wake in the near-field (x/c from 0 to 3) of a wingtip vortex has been studied both experimentally and computationally. The research was conducted in the University of Limerick's medium speed wind tunnel on a NACA 0012 square tip half wing at a Reynolds number of 310,000. Single hot wire measurements recorded a maximum turbulence intensity of 9 percent just after the trailing edge. Maximum turbulence intensity after $x/c = 0$ is observed in the vortex core which decays with downstream distance. Five-hole probe mean velocity measurements revealed jet like and wake like axial velocity profiles depending on wing angle of attack, with values of $1.33U$ and $0.83U$ (U is the freestream velocity) being measured for 10 degrees and 5 degrees. Axial vorticity is also observed to increase gradually with downstream distance. A full Reynolds stress turbulence model with a second order upwind differencing scheme is used to compute the vortex in the near-field. Vortex structure and

trajectory correlate well with experiment. It is thought that the dissipative nature of the second order convection scheme led to discrepancies between numerical and experimental results.

Orlandi, P.

"VORTEX DIPOLE REBOUND FROM A WALL"

Phys. Fluids A, Vol. 2, No. 8, August 1990, pp. 1429-1436

Accurate numerical simulations of vortex dipoles impinging on flat boundaries have revealed interesting new features. In the case of free-slip boundaries the dipole does not rebound from the wall. In the case of nonslip walls rebounding occurs and complex interactions of secondary and tertiary vortices appear. The numerical simulation of the first dipole rebound from the wall agrees with experimental visualizations. Numerical experiments extending in time beyond the real experiments show multiple rebounding. Each rebound is associated with the detachment of a secondary vorticity layer from the wall; these layers merge, and at a value of Reynolds number $Re = 1600$, form a new dipole. This dipole has sufficient circulation to induce on itself a motion in the opposite direction to the motion of the initial dipole.

Orlandi, P.

"TWO-DIMENSIONAL AND THREE-DIMENSIONAL DIRECT NUMERICAL SIMULATION OF CO-ROTATING VORTICES"

Physics of Fluids, Vol. 19, 2007, pp. 013101-1 -- 013101-18

Two-dimensional (2D) and three-dimensional (3D) simulations are presented for co-rotating vortices with distributed vorticity at different values of the separation distance b . The ratio between the vortices' radius a and b is smaller than the critical value $a/b \sim 0.30$ for merging in inviscid conditions of blobs of constant vorticity. The dependence of merging on Reynolds number and on a/b has been investigated in 2D simulations. In 2D the resolution can be increased to perform simulations at $Re = 30000$ when very long filaments are generated.

Orlandi, P. and Verzicco, R.

"VORTEX RINGS IMPINGING ON WALLS: AXISYMMETRIC AND THREE-DIMENSIONAL SIMULATIONS"

Journal of Fluid Mechanics, Vol. 256, 1993, pp. 615-646.

Accurate numerical simulations of vortex rings impinging on flat boundaries revealed the same features observed in experiments. The results for the impact with a free-slip wall compared very well with previous numerical simulations that used spectral methods, and were also in qualitative agreement with experiments. The present simulation is mainly devoted to studying the more realistic case of rings interacting with a no-slip wall, experimentally studied by Walker et al. (1987). All the Reynolds numbers studied showed a very good agreement between experiments and simulations, and,

at $Re > 1000$ the ejection of a new ring from the wall was seen. Axisymmetric simulations demonstrated that vortex pairing is the physical mechanism producing the ejection of the new ring. Three-dimensional simulations were also performed to investigate the effects of azimuthal instabilities. These simulations have confirmed that high-wavenumber instabilities originate in the compression phase of the secondary ring within the primary one. The large instability of the secondary ring has been explained by analysis of the rate-of-strain tensor and vorticity alignment. The differences between passive scalars and the vorticity field have been also investigated.

Orlandi, P., Carnevale, G. F. and Shariff, K.

"THERMAL PERTURBATION OF TRAILING VORTICES"

European Journal of Mechanics, B - Fluids, Vol. 20, 2001, pp. 511-524

The possibility of diminishing the danger of trailing vortices through thermal forcing is investigated. It is shown that heating the vortices would have two beneficial effects. First, it would cause the vortices to descend more rapidly thus clearing the flight path more quickly. Second, it would cause the vortices to draw closer together, thus greatly increasing the growth rate of the short-wave instabilities that can ultimately destroy the vortices through cross-diffusion.

Orlandi, P., Carnevale, G. F., Lele, S. K. and Shariff, K.

"DNS STUDY OF STABILITY OF TRAILING VORTICES"

Proceedings of the Summer Program, 1998, Center for Turbulence Research, pp. 187-208

Three-dimensional numerical simulations are used to investigate the possibility of diminishing the strength of trailing vortices. Direct numerical simulation is first used to reproduce results of recent laboratory experiments on the short-wave co-operative instability for two counter-rotating vortices. The effect of perturbing the vortices by internal and external density perturbations is considered. It is found that perturbing trailing vortices with temperature variations may be a useful means of initiating the short-wave instability and ultimately causing the cross diffusion of vorticity necessary to destroy the coherence and strength of the trailing vortices.

Orlandi, P., Eggermann, P. and Hopfinger, E. J.

"VORTEX RINGS DESCENDING IN A STRATIFIED FLUID"

Physics of Fluids, Vol. 10, No. 11, November 1998, pp. 2819-2827

Experimental and numerical results are presented of a laminar vortex ring descending in a linearly stratified fluid. It is observed that the ring shrinks in size as it penetrates the stratified environment and has nearly disappeared when it comes to a stop. This behavior is similar to what was observed by

Maxworthy for a turbulent vortex ring in a stratified environment. The ring position and size collapse on a single curve when appropriately scaled. It is shown that baroclinic vorticity production of opposite sign and cross diffusion is the cause for the disappearance of the ring. The instantaneous ring Froude number is always greater than or equal to 1 and, therefore, no internal waves are generated.

Orloff, K. L.

"TRAILING VORTEX WIND-TUNNEL DIAGNOSTICS WITH A LASER VELOCIMETER"

J. Aircraft, Vol. 11, No. 8, August 1974, pp. 477-482

A two-dimensional laser velocimeter whose focal volume can be rapidly traversed through a flow-field has been used to overcome the problem introduced by excursions of the central vortex filament within a wind-tunnel test section. The operation of the instrument is reviewed and data are presented which accurately define the trailing vortex from a square-tipped rectangular wing. Measured axial and tangential velocity distributions are given, both with and without a vortex dissipator panel installed. From the experimental data, circulation and vorticity distributions are obtained and the effect of turbulence injection into the vortex structure is discussed.

Orloff, K. L.

"SPANWISE LIFT DISTRIBUTION ON A WING FROM FLOWFIELD VELOCITY SURVEYS"

J. Aircraft, Vol. 17, No. 12, December 1980, pp. 875-882

The application of the incompressible three-dimensional momentum integral equation to a finite wing is reviewed. The objective is to interpret the resulting equations in a way that suggests an alternate experimental method for determining the spanwise distribution of lift. Consideration is given to constraints that must be placed on the character of the vortex wake of the wing to provide the familiar relationship between lift and bound vorticity. A novel technique is then presented for obtaining, from behind the wing, the spanwise lift distribution from velocity surveys that are made over only a short distance above and below the wing trailing edge. The necessary formalism is developed to use these measured values to obtain the actual span loading by using an equivalent single-horseshoe vortex model to account for the unmeasured portion of the downward (or upward) momentum. The results of a numerical simulation are presented for a typical loading distribution. The technique is then verified experimentally using laser velocimeter data for the flowfield around a model wing.

"VORTEX MEASUREMENTS BEHIND A SWEEPED WING TRANSPORT MODEL"

J. Aircraft, Vol. 11, No. 6, June 1974, pp. 362-364

A backscattering laser Doppler velocimeter (LDV) which simultaneously senses two components of the velocity (axial and tangential), has been used to traverse and measure the velocity distribution in

the near wake of a swept wing semispan transport model in the NASA-Ames 7x10-foot wind tunnel. These measurements demonstrate the effect of flap deflection (flap-retracted and flaps deployed 27 deg.) on the velocity profile.

Orloff, K. L. and Grant, G. R.

"THE APPLICATION OF A SCANNING LASER DOPPLER VELOCIMETER TO TRAILING VORTEX DEFINITION AND ALLEVIATION"

AIAA Paper No. 1973-0680, Palm Springs, CA, 1973

A two-dimensional laser Doppler velocimeter whose focal volume can be rapidly traversed through a flow field has been used to overcome the problem introduced by excursions of the central vortex filament within a wind-tunnel test section. The operation of the instrument is reviewed and data are presented which accurately define the trailing vortex from a square-tipped rectangular wing. Measured axial and tangential velocity distributions are given, both with and without a vortex dissipator panel installed. From the experimental data, circulation and vorticity distributions are obtained and the effect of turbulence injection into the vortex structure is discussed. The experimental velocity profiles are compared to the inviscid Betz theory (as presented by Rossow) and to the functional forms for the logarithmic and defect regions (given by Nielsen and Schwind).

Orloff, K. L., Ciffone, D. L. and Lorincz, D.

"AIRFOIL WAKE VORTEX CHARACTERISTICS IN THE FAR FIELD"

NASA TM-X-62318, November 1973, NASA Ames Research Center, Moffett Field, CA

Tangential and axial velocity profiles were measured in the far field wake vortices of several different airfoils. The results are summarized and discussed. A scanning laser velocimeter was used to obtain data up to 1000 chord lengths behind airfoils with rectangular, diamond-shaped, and swept wing planforms at several different angles of attack. The results show general agreement with wind tunnel measurements made in the near field. The results identify two separate flow regions for the dependence of vortex maximum tangential velocity on downstream distance: an inviscid region where the velocity remains constant after rollup to downstream distances of 200 chord lengths, and then a decay or viscous region that persisted to the limit of the test distance. The decay rates appear to be sensitive to both angle of attack and span loading. The maximum tangential velocity for downstream distances to 40 span lengths was reduced by a factor of 2 by changing from an elliptic (swept wing) or rectangular span loading to a triangular-like span loading (diamond-shaped planform wing). Measured axial velocity defects are shown to agree with those predicted by laminar theory.

"CAPACITY PAYOFFS AT LARGE HUB AIRPORTS FROM ATC INITIATIVES"

Proceedings Annual Assembly Meeting, RTCA, Washington, DC, November 1979, pp. 21-38

The paper reviews the current status of system capacity and delay analysis with particular reference to ongoing FAA efforts in the E&D field. The main emphasis of the capacity element of existing E&D programs is on increasing system capacity through reductions in minimum IFR radar longitudinal separations between arrival aircraft. The biggest problem associated with achieving reduced longitudinal separation of any type is the ability to deal effectively with wake turbulence. Analysis at high-activity airports indicates that gains in system capacity and reductions in aircraft travel time may be achieved by methods other than reduction in minimum longitudinal separations. A summary of 14 of the more promising methods is presented, including examples of potential site-specific applications and benefits.

Ormiston, R. A.

"AN ACTUATOR DISC THEORY FOR ROTOR WAKE INDUCED VELOCITIES"

AGARD CP-111, Aerodynamics of Rotary Wings, February 1972, pp. 2-1 - 2-19

A general actuator disc theory is presented for predicting the time-averaged downwash distribution, and steady state force and moment response characteristics of helicopter rotors in forward flight. Particular attention is given to a proper definition of the rotor potential flow problem. The formulation of the theory is conceptually based on classical fixed-wing lifting-line theory to enhance its versatility and provide insight about the complex physical features of the rotor downwash distribution. It is shown that the rotor wake vorticity can be assumed to lie in a flat planar wake for a wide range of flight conditions, thus simplifying the Biot-Savart integration for the downwash.

"STUDY OF THE FEASIBILITY OF USING A SAILPLANE AS AN INSTRUMENT PLATFORM FOR THE STUDY OF WAKE VORTEX PHENOMENA"

NASA CR-140603, September 1974, Illinois Univ., Urbana, IL

The feasibility of utilizing instrumentation mounted on a sailplane wing is investigated to determine vortex wakes from a large aircraft. The instrumentation consisted of static and total pressure tubes and a rotating vane vorticity meter mounted in a pod on the glider wing tip. It was concluded that the study was not feasible.

"SCALING WAKE-PARTICLE INTERACTIONS FOR AERIAL APPLICATIONS RESEARCH"

J. Aircraft, Vol. 18, No. 7, July 1981, pp. 592-596

The differential equation for the trajectory of a spherical particle injected into an aircraft wake was developed and the proper scaling relations extracted. After some simplification, a convenient set of similarity parameters was established. Using these similarity parameters a scale-model test program was designed and performed in the NASA Langley Vortex Research Facility. The results of the tests demonstrated the validity of the similarity parameters in conducting scale-model testing for aerial applications research.

Ornberg, T.

"A NOTE ON THE FLOW AROUND DELTA WINGS"

KTH AERO TN 38, 1954, Royal Institute of Technology, Stockholm, Sweden.

To find reasons for some irregularities in delta wing force and moment curves as measured in wind-tunnels, some investigations have been made of the flow on and around wings of this type and its effect on the pressure distributions. The flow on and around wings with various sweep angles and profile thicknesses has been investigated at low speeds (the boundary layer flow on the suction side also at supersonic speeds). Low speed pressure distributions have been measured on and above the suction side of these wings. The low-speed investigations show that edge vortices are produced by separation at highly swept leading edges and have a marked effect on the surface pressure distribution. The cores of these vortices have also been localized and measured at different angles of incidence. The supersonic tests suggest that the vortices still exist provided that the leading edge is well behind the nose Mach cone. The behavior of these vortices under different conditions appears to explain the above-mentioned irregularities in force and moment curves.

Ortega, J. M.

"STABILITY CHARACTERISTICS OF COUNTER-ROTATING VORTEX PAIRS IN THE WAKES OF TRIANGULAR-FLAPPED AIRFOILS"

PhD Thesis, Spring 2001, University of California, Berkeley, CA.

A rapidly growing instability is observed to develop between unequal strength, counter-rotating vortex pairs in the wakes of airfoils with outboard triangular flaps. To investigate the physical mechanisms for this instability, a linear stability analysis is performed on a single vortex pair. This analytical model reveals that the instability is driven by the strain rate field from one vortex acting on the perturbations of its neighboring vortex. Another linear stability analysis is conducted to include the effects of the other counter-rotating vortex pair. The qualitative features of the instability, such as its wavelength and non-linear evolution, are examined by flow visualization measurements that are made in a towing tank facility at a chord Reynolds number of order 100,000. From these observations, a sinuous instability is seen to develop on the weaker flap vortices and have a wavelength of order one wingspan. The instability wavelengths that are observed in the flow visualization data compare favorably with those predicted by the two- and four-vortex linear stability analyses, demonstrating that the analytical models capture the essential physics of the instability growth. Quantitative

measurements of the vortex wakes are made with a PIV technique, allowing the vortex structure, trajectories, kinetic energy, and distribution to be assessed up to several hundred wingspans downstream of the airfoils. Additionally, the circulation-based Reynolds number is seen to be of order 100,000. The PIV data indicate that the wake's two-dimensional kinetic energy decreases substantially as the instability transforms the two-dimensional nature of the wake into a three-dimensional one. Finally, the wake alleviation properties of this instability are measured by computing the maximum rolling moment and downwash that a following wing might experience if it were placed in the wakes of these airfoils. These calculations show that by 75 wingspans, the wakes of the triangular-flapped airfoils have rolling moments and downwash that are always less than those of a conventional rectangular airfoil. This rapid reduction in the rolling moment and downwash leads to the conclusion that this instability between unequal strength, counter-rotating vortex pairs has the potential to solve the wake hazard problem.

Ortega, J. M.

"PASSIVE WAKE VORTEX CONTROL"

UCRL-ID-146320, Oct. 2001, University of California, Livermore, CA.

We address a concept called passive wake vortex control (PWVC), which has been demonstrated to rapidly break apart a trailing vortex wake and render it incoherent. PWVC functions by introducing unequal strength, counter-rotating control vortices next to the tip vortices (Figure 1b). The presence of these control vortices destabilizes the vortex wake and produces a rapidly growing wake instability.

Ortega, J. M. and Savas, O.

"RAPIDLY GROWING INSTABILITY MODE IN TRAILING MULTIPLE-VORTEX WAKES"

AIAA Journal, Vol. 39, No. 4, April 2001, pp. 750-754

This note presents the results from an experimental effort designed to trigger early onset of instability in wingtip vortices. The experiments involved placing close together vortices of unequal strengths and opposite signs, such that the interaction leads to a cooperative instability quicker than the classical Crow instability. The instability was first developed on the weaker flap vortices at approximately 20 spans downstream of the wing, having a wave length of the order of one wingspan. The rapid growth of the instability and the exchange of vorticity with the wingtip vortex may represent a strategy for controlling the vortex wake and, perhaps, reducing the wake hazard.

Ortega, J. M., Bristol, R. L. and Savas, O.

"WAKE ALLEVIATION PROPERTIES OF TRIANGULAR-FLAPPED WINGS"

AIAA Journal, Vol. 40, No. 4, 2002, pp. 709-721

The wake alleviation properties of wings with outboard, triangular flap extensions are estimated using data from particle image velocimetry. The experiments are conducted in a towing tank at chord-based Reynolds numbers of $O(100,000)$. The triangular-flapped wings generate two unequal strength, counter-rotating vortex pairs that have circulation strength ratios ranging from -0.4 to -0.7. Introducing the oppositely signed flap vortices near the tip vortices causes a rapidly growing instability to occur between the vortices on either side of the wake. The resulting nonlinear interactions between the vortices result in a wake that is highly three-dimensional and incoherent. These effects are reflected in a marked decrease in both the rolling moment and downwash on a simulated following wing. To determine the wake alleviation properties of the triangular-flapped wings, their wakes are compared to that of a conventional, rectangular wing. For all the experimental runs, the wakes of the triangular-flapped wings have maximum rolling moments and downwashes that are substantially less than those of the rectangular wing. The results indicate that the instability in the wake of the triangular-flapped wings offers a possible mechanism to reduce significantly the wake hazard problem.

"THE FORMATION REGION BEHIND A BLUNT BODY FITTED WITH SPLITTER PLATES"

AIAA Paper No. 2007-132, Reno, NV, January 2007

An investigation of the formation region at the base of a two-dimensional blunt-trailing-edged body is attempted with the help of a DNS numerical tool. This work is a natural extension, focused on the theme of the flow about blunt bodies, of a former research effort by the present authors. Here, the formation region is better investigated, and the aim is directed towards the understanding of the most important physical mechanisms that operate upon this very important region. It is known that, what happens in this region is decisive to the characteristics of the following wake. In principle, the study is initially based on the idea that the extent of the formation region is given by the position, in relation to the base, at which the velocity fluctuation is larger. We, then, concentrate on the analysis of several aspects related to this position, trying to relate it in some way to the idea of the vortex's formation. For example, the dependence of the formation region extent as function of Reynolds number and splitter plate length is analyzed, and a comparison with the formation of the vortices in real time is attempted.

Ortiz, S., Donnadieu, C., Chomaz, J.-M. and Billant, P.

"RECEPTIVITY AND TRANSIENT GROWTH IN WAKES"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

We investigate numerically the transient growth of three-dimensional secondary instability of wakes forming behind a thin flat plate (von Karman vortex street) and an aircraft (vortex dipole). An aircraft wake is made of counter-rotating vortices and is known to be affected by a long (Crow) and a short (elliptic) wavelength instability. With the same numerical techniques developed on the von Karman vortex street, we recover instability peaks corresponding to Crow and elliptic modes but also observe

less unstable oscillatory instabilities with very broad peaks that seem to correspond to higher order elliptic instability. The study of the transient growth demonstrates the crucial role of the region of maximum strain that, for a vortex dipole, is not located close to the hyperbolic point but inside the cores of the vortices. Further investigations on the dynamics of trailing vortices in stratified fluids will be performed.

"BIFURCATION OF AN ELLIPTIC VORTEX RING"

Fluid Dynamics Research, Vol. 3, 1988, pp. 133-139.

Time-dependent vorticity fields of elliptic vortex rings of aspect ratios 2, 3 and 4 were measured by means of hot-wire anemometry. The time evolution of their vorticity fields was analyzed and the processes of vortex ring formation, advection, interaction and decay, and the mechanism of vortex bifurcation are studied. The following crosslinking model is proposed. A thick vortical region composed of many equivalent vortex filaments with distributed cores is initially formed at the orifice and they behave as inviscid filaments. The elliptic ring deforms and the end parts of its major axis get closer. Then, the vortex filaments interact at the touching point and the ring partially bifurcates. Almost simultaneously, turbulent spot appears at this point, and propagates around the ring cross section, thus preventing further bifurcation. And it becomes a turbulent blob. This model is also supported by numerical simulation by a high-order vortex method and the Navier-Stokes solution.

"PHENOMENOLOGICAL MODEL OF FORMING FLOW ANGULARITY BEHIND AN AIRFOIL CASCADE IN THE OPEN-JET WIND TUNNEL"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 178-187

To simulate the effect of time-varying flow angularity on aircraft, tests of elastic models are carried out in wind tunnels where the variations of the incoming flow are provided with the aid of the cascades of deflectable airfoils. The amplitude of varying flow angle in the test section therewith depends on both the law of cascade angle-of-attack variation and the process of vortex generation in the shear layer at the jet boundary of the test section. Based on special studies in TsAGI's water and wind tunnels and the results of theoretical investigations into submerged jets, a phenomenological flow model has been constructed which enables reliably describing the processes of formation and development of variable flow angularity behind an airfoil cascade in open-jet wind tunnels. "INSTABILITY OF CO-ROTATING VERTICAL VORTICES IN A STRATIFIED FLUID"

In IUTAM Symposium on Elementary Vortices and Coherent Structures: Significance in Turbulence Dynamics, edited by S. Kida, Springer, The Netherlands, 2006, pp. 219-224.

We show numerically, theoretically, and experimentally that two co-rotating vertical vortices in a stably stratified fluid are subjected to a new three-dimensional instability similar to the zigzag instability observed on counter-rotating vortices (Billant & Chomaz, 2000). This zigzag instability induces the formation of thin horizontal layers with a thickness inversely proportional to the Brunt-Vaisala frequency. This three-dimensional instability is believed to make stratified turbulence depart from two-dimensional turbulence since it alters the merging of vortices.

Otheguy, P., Billant, P. and Chomaz, J.-M.

"THEORETICAL ANALYSIS OF THE ZIGZAG INSTABILITY OF A VERTICAL CO-ROTATING VORTEX PAIR IN A STRONGLY STRATIFIED FLUID"

J. Fluid Mech., Vol. 584, 2007, pp. 103-123

A long-wavelength stability analysis of two co-rotating Gaussian vertical vortices in an inviscid strongly stratified fluid is conducted for vortices separated by a large distance compared to their radius. This analysis predicts and explains the zigzag instability found by a numerical stability analysis in a companion paper (Otheguy, Chomaz, and Billant, J. Fluid. Mech. Vol. 553, 2006, p. 253). The zigzag instability results from the coupling between the bending perturbations of each vortex and the external strain that one vortex induces on the other. The analysis predicts that the maximum growth rate of the instability is twice the strain and that the most unstable vertical wavelength scales as the buoyancy length. The asymptotic results are in very good agreement with the numerical results.

Otheguy, P., Chomaz, J.-M. and Billant, P.

"ELLIPTIC AND ZIGZAG INSTABILITIES ON CO-ROTATING VERTICAL VORTICES IN A STRATIFIED FLUID"

J. Fluid Mech., Vol. 553, 2006, pp. 253-272

We present a three-dimensional linear stability analysis of a couple of co-rotating vertical vortices in a stratified fluid. When the fluid is non-stratified, the two vortices are unstable to the elliptic instability owing to the elliptic deformation of their core. These elliptic instability modes persist for weakly stratified flow: $F > 10$, where F is the horizontal Froude number. For strong stratification ($F < 2.85$), a new zigzag instability is found that bends each vortex symmetrically with almost no internal deformation of the basic vortices. This instability may modify the vortex merging since at every half-wavelength along the vertical, the vortices are alternately brought closer, accelerating the merging, and moved apart, delaying the merging. The most unstable vertical wavelength of this new instability is shown to be proportional to Fb where b is the distance between the vortices, implying that the vertical wavelength decreases with increasing stratification. The maximum growth rate, however, is independent of the stratification and proportional to the strain. These scaling laws and the bending motion induced by this instability are like those of the zigzag instability of a counter-rotating vortex pair in a stratified fluid.

"DISPERSION AND SUBSIDENCE OF THE EXHAUST OF A SUPERSONIC TRANSPORT IN THE STRATOSPHERE"

J. Aircraft, Vol. 10, No. 12, 1973, pp. 720-728

A theoretical model is presented that describes the early time history of the wake of an aircraft. This theory shows that far downstream of the aircraft, buoyancy dominates the growth of the wake. For a supersonic transport flying in the stratosphere, the stable stratification will limit the growth of the wake. Data of the visible width of the wake from laboratory experiments in a towing tank and from studies on the growth of contrails from subsonic aircraft verify the model for a neutral atmosphere. A model is developed to show that the exhaust gases of a supersonic transport can sink due to differential radiative cooling caused by the high concentration of water vapor and the lower concentration of ozone in the wake. Estimates of the rate of subsidence are given for aircraft flying between 16 and 27 km.

Overcamp, T. J. and Fay, J. A.

"DISPERSION OF SST TRAILS IN THE STRATOSPHERE"

AIAA Paper No. 1972-0650, Boston, MA, June 1972

A simple theory for the dispersion of the exhaust of a supersonic transport cruising in the stratosphere is presented. The model shows that far downstream of the aircraft, buoyancy dominates the growth of the wake. This growth is limited by the stable stratification of the atmosphere. Data on the visible width of the wake from scaled experiments in a towing tank and from studies on the growth of contrails of subsonic aircraft verify the growth of the wake in an unstratified atmosphere is predicted by the model. This growth is faster than would be predicted for the wake of an axisymmetric body with no buoyancy.

"VORTEX BREAKDOWN AND CONTROL EXPERIMENTS IN THE AMES-DRYDEN WATER TUNNEL"

AGARD Conf. Proceedings No. 413, Aerodynamic and Related Hydrodynamic Studies Using Water Facilities, June. 1987, pp. 2-1 to 2-10.

Flow-field measurements have been made to determine the effects of core blowing on vortex breakdown and control. The results of these proof-of-concept experiments clearly demonstrate the usefulness of water tunnels as test platforms for advanced flow-field simulation and measurement.

Owen, P. R.

"THE DECAY OF A TURBULENT TRAILING VORTEX"

ARC Report 25818, Apr. 1964, Imperial College of Science and Technology, London, England

The decay of a trailing vortex which contains turbulence in its core is examined according to the argument that the turbulence is partly sustained by and interacts with the irrotational flow through viscous diffusion of eddies across the core boundary. The region of interaction between the turbulence and the mean flow is a narrow one, separating the core from the outer irrotational flow, and expands with time as the square root of time characteristic of viscous diffusion.

Owen, P. R.

"THE DECAY OF A TURBULENT TRAILING VORTEX"

Aero. Quarterly, Vol. 21, February 1970, pp. 69-78

The decay of a trailing vortex containing a turbulent core is examined according to the argument that turbulence is partly sustained by, and interacts with, the irrotational flow through viscous diffusion of eddies across the core boundary. The region separating the core from the outer irrotational flow, in

which the interaction between the turbulence and the mean flow occurs, expands with time like $(\text{time})^{1/2}$, characteristic of viscous diffusion. The essential difference from Squire's solution found here is that the apparent viscosity is not simply proportional to the initial circulation about the vortex as he proposed, but depends on the Reynolds number defined with respect to the circulation.

Ozger, E., Schell, I. and Jacob, D.

"ON THE STRUCTURE AND ATTENUATION OF AN AIRCRAFT WAKE"

Journal of Aircraft, Vol. 38, No. 5, September-October 2001, pp. 878-887.

The results of an experimental investigation of the wake-vortex structure behind a swept and tapered wing with slats and flaps are presented. The wind tunnel test is part of a project funded by the German Research Association (DFG) to investigate the flow structure of wings with different flap extensions. The investigation aims at studying the characteristics of lift generated vortices to find ways to attenuate dangerous wake vortex encounters for following aircraft during start and landing such that an increase in airport capacity can be achieved. The wake structure is investigated for different flap settings by means of hotwire anemometry measuring the velocity field at different streamwise positions in the near field behind the wing. The measured data are evaluated to examine vortex parameters such as core radius, maximum tangential velocities, circulation distributions, turbulence levels and maximum induced rolling moments on a following aircraft. In addition, for one flap setting means of alleviation with a wing fin at different angles of incidence mounted at the outboard flap edge region are examined. The fin causes a large increase of the vortex core and a reduction of the maximum induced rolling moment within the measured region.

"TIGHT FORMATION FLIGHT CONTROL"

Journal of Guidance, Control, and Dynamics, Vol. 24, No. 2, March-April 2001, pp. 246-254.

The tight formation flight control problem is addressed. The formation consists of a lead and wing aircraft, where the wing flies in tight formation with the lead, such that the lead's trailing vortices aerodynamically couple the lead and the wing, and a reduction in the formation's induced drag is achieved. A controller (i.e., a formation-hold autopilot for the wing aircraft) is designed such that the formation's geometry is maintained in the face of lead aircraft maneuvers. In the formation flight control system, the wing and lead aircraft dynamics are coupled due to kinematic effects, and, in the case of tight formations, additional aerodynamic coupling effects are introduced. These additional aerodynamic coupling effects are properly modeled. The most significant aerodynamic coupling effect introduced by tight formation flight entails the coupling of the lateral/directional channel into the altitude-hold autopilot channel. It is shown that formation-hold autopilots designed ignoring the aerodynamic coupling effect yield satisfactory performance in tight formation flight.

Padakannaya, R.

"THE VORTEX LATTICE METHOD FOR THE ROTOR-VORTEX INTERACTION PROBLEM"

NASA CR-2421, July 1974, The Pennsylvania State University, University Park, PA.

This study is concerned with the rotor blade-vortex interaction problem and the resulting impulsive air loads which generate undesirable noise levels. A numerical lifting surface method to predict unsteady aerodynamic forces induced on a finite aspect ratio rectangular wing by a straight, free vortex at an arbitrary angle in a subsonic incompressible free stream is developed first. Using a rigid wake assumption, the wake vortices are assumed to move downstream with the free stream velocity. Unsteady load distributions are obtained which compare favorably with the results of planar lifting surface theory. The vortex lattice method has been extended to a single bladed rotor operating at high advance ratios and encountering a free vortex from a fixed wing upstream of the rotor. The predicted unsteady load distributions on the model rotor blade are generally in agreement with the experimental results. This method has also been extended to full scale rotor flight cases in which vortex induced loads near the tip of a rotor blade were indicated. In both the model and the full-scale rotor blade air load circulations a flat planar wake was assumed which is a good approximation at large advance ratios because the downwash is small in comparison to the free stream at large advance ratios. The large fluctuations in the measured air loads near the tip of the rotor blade on the advance side is predicted closely by the vortex lattice method.

Padakannaya, R.

"EFFECT OF WING TIP CONFIGURATION ON THE STRENGTH AND POSITION OF A ROLLED-UP VORTEX"

M.S. Thesis, March 1970, Penn. State Univ., University Park, PA. (Also, NASA CR-66916.)

This thesis studies the effects of different wing tip configurations on the associated rolled-up vortex. The spanwise load distribution on plain rectangular wings and on wings with dropped tips was calculated by vortex lattice theory, to determine the effects of the droop on the strength and the location of the vortex. The load distribution on wings with drooped tips shows that the stronger vortex moves from the tip of the wing to the hinge of the drooped tip as the droop angle increases. The experimental results confirmed the movement of the stronger vortex from the tip of the wing to the hinge of the drooped tip as the droop angle increases.

Padfield, G. D.

"HELICOPTER ENCOUNTERS WITH AIRCRAFT VORTEX WAKES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Results are presented from a study concerning the risks associated with locating a helicopter Final Approach and Take-Off area (FATO) alongside an active runway at a busy international airport. Specifically, the problem of a helicopter encountering the shed wing tip vortex from a large transport aircraft is addressed. Data derived from measurements of tip vortices taken using a coherent laser radar located under the final approach path are used to validate a model of the distribution of the flow velocities occurring in the shed vortices. The data has also provided an opportunity to examine the length of time these vortices can retain an appreciable strength. A 'worst case' scenario is defined in which the shed wing tip vortices from a Boeing 747 are encountered by a hovering 5000 kg helicopter located at 250 m from the line of the main runway. No significant decay in vortex strength is assumed in the time taken for the vortex to travel from source aircraft to the helicopter. The simulations show, for a range of flight conditions, that the helicopter can experience transient attitude changes of up to 40 degrees and accumulated descent rates of 1500 ft/min during the encounter, assuming no pilot intervention. Established handling qualities metrics relating to attitude quickness (related to time to change attitude) and transient response following system failures have been applied to the problem and suggest that these responses may produce handling difficulties. The worst transient attitude response occurs when the helicopter encounters the inner core of the vortex. The sensitivity of the response to offsets between helicopter and vortex center during near misses is shown to be high, resulting in a decrease in the probability of the worst case occurring. In the study, the simulations were expanded to consider the influence of various helicopter design parameters on the magnitude of response and the effects of considering shed vortices from source aircraft other than the Boeing 747.

"HELICOPTER ENCOUNTERS WITH AIRCRAFT VORTEX WAKES"

Twentyfifth European Rotorcraft Forum, Paper H2, September 1999, Rome, Italy, pp. H2-1 to H2-14.

This paper presents the results of a study into wake vortex-related safety issues associated with simultaneous rotary and fixed-wing aircraft operations at busy airports. An analysis conducted using both simple conceptual models and high fidelity FLIGHTLAB simulations has considered a helicopter located in the hover above the landing point and during approach and landing. Tip vortices from a Boeing 747 are shed and are assumed to be travelling in a horizontal plane by the time they reach the helicopter. A worst-case scenario is simulated, with no vortex ageing or attenuation due to ground effect. Both simple and high-fidelity simulations indicate that the rates of climb and descent induced by the vortex tails can be significant. When the helicopter flies through the vortex core, large transient excursions in attitude occur within a few seconds. When the helicopter does not pass through or close to the core, while the flight path perturbations are still significant, the attitude response is shown to be significantly reduced. The predicted cyclic control power required to counteract the vortex-induced hub moments is about 40 percent of full control, compared with more than 100 percent for an 'equivalent' fixed-wing aircraft. The control power required in the vertical, collective, axis to overcome the downdraught and updraught in the vortex tails can be as high as 15-20 percent. While the authors have not tried to make judgements as to whether pilots would find the transients manageable, an approach to quantifying the extent of the hazard has been suggested using the transients failure criteria from the handling qualities performance standard ADS-33. Combined with analysis of the likelihood of such occurrences at airports, such response criteria offer a rational approach to developing safety cases for simultaneous operations.

"HELICOPTER ENCOUNTERS WITH AIRCRAFT VORTEX WAKES"

Aeronautical Journal, January 2001, pp. 1-8

This paper presents the results of a study into wake vortex-related safety issues associated with simultaneous rotary and fixed-wing aircraft operations at busy airports. An analysis conducted using both simple analytic models and high fidelity FLIGHTLAB simulations has considered a helicopter located in the hover above the landing point and during approach and landing. Tip vortices from a Boeing 747 are shed and are assumed to be travelling in a horizontal plane by the time they reach the helicopter. A worst-case scenario is simulated, with no vortex ageing or attenuation due to ground effect. Both simple and high-fidelity simulations indicate that the rates of climb and descent induced by the vortex tails can be significant. When the helicopter flies through the vortex core, moderately large transient excursions in attitude occur within a few seconds. When the helicopter does not pass through or close to the core, while the flight path perturbations are still significant, the attitude response is shown to be significantly reduced. The predicted cyclic control power required to counteract the vortex-induced hub moments is about 40% of full control, compared with more than 100% for an 'equivalent' fixed-wing aircraft. The control power required in the vertical, collective, axis to overcome the downdraught and updraught in the vortex tails can be as high as 15-20%. While the authors have not tried to make judgements as to whether pilots would find the transients manageable,

an approach to quantifying the extent of the hazard has been suggested using the transients failure criteria from the handling qualities performance standard ADS-33. Combined with analysis of the likelihood of such occurrences at airports, such response criteria offer a rational approach to developing safety cases for simultaneous operations.

"A SEVERITY ANALYSIS FOR ROTORCRAFT ENCOUNTERS WITH VORTEX WAKES"

28th European Rotorcraft Forum, Bristol, UK, September 2002

Our paper concerns the severity of the response of a rotorcraft encountering the vortex of a fixed-wing aircraft. One of the key questions is whether a rotorcraft designed to meet handling performance standards will have sufficient control margin for the pilot to overcome the effects of a vortex encounter. This question is addressed through an analytical study supported by preliminary piloted simulation tests. The handling criteria are found to be well suited to establishing the severity and associated hazard category of typical encounters. Cases are illustrated where insufficient control margin is available to overcome the effects of the encounter. The pilot intervention time is critical as expected. In risk assessment parlance, an intervention time of 3 seconds leads to hazardous encounters (> Level 3 HQs) while a reduced intervention time of 1.5 seconds is more likely to be major (Level 3 HQs).

"RCS COMPUTATION OF 3D-WAKE VORTEX USING METHOD OF MOMENTS"

Progress in Electromagnetics Research Symposium Proceedings, August 2014, Guangzhou, China, pp. 1319-1322.

An efficient and accurate 3D full wave numerical solution model for computing the radar cross section of wake-vortex is presented, by solving Euler equation to compute the pressure in the aircraft wake region by computational fluid dynamics model and parallel integral equation, based on method of moments is used to compute the volume polarization currents, under the plane wave incidence. Then the currents are used to compute far-field from the vortex region.

"THE WAKE VORTEX PROBLEM REVISITED"

Annual Assembly and Technical Symposium Proceedings, Radio Technical Commission for Aeronautics, December 4-6, 1989, pp. 99-123

The FAA Wake Vortex Program and its objectives are presented, with emphasis on new aircraft classification and separation standards, vortex advisory systems and procedures based on vortex behavior, new mechanisms for wake vortex alleviation, wake vortex models, measurement techniques, and user education materials and information. Focus is placed on an enhanced vortex advisory system, including its operational requirements, concept, prototype development and installation, operational evaluation, and specification. It is noted that to enhance the wake vortex system, an airborne Doppler sensor could be developed to locate and evade a wake vortex, and laser Doppler velocimeters could be improved to perform the automatic collection and analysis of wake vortex data. The utilization of the tower- fly-by technique and monostatic acoustic vortex sensing system is assessed.

Page, R. D.

"THE WAKE VORTEX PROBLEM REVISITED"

Proceedings of the 1989 Annual Assembly Meeting and Technical Symposium, RTCA, Washington, DC, 1989, pp. 99-123

There are several possible approaches to be investigated in solving the wake vortex problem; however, the overall objective of the FAA's Wake Vortex Program is to increase airport capacity without a reduction in safety. To accomplish this objective, the following specific activities have been identified. They are: (1) To develop new aircraft classification and separation standards; (2) To develop vortex advisory systems and procedures based on vortex behavior; (3) To update, revise or develop user education materials and information; (4) To develop new mechanisms for wake vortex alleviation; and (5) To develop Wake Vortex models and improve measurement techniques.

"PANEL DISCUSSION ON TOWER FLY-BY TESTING - 1990 FALL SERIES"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 49-1 - 49-53

In September 1990 the FAA conducted tests at the National Oceanic and Atmospheric Administration (NOAA) Wake Vortex test facility in Idaho to study the wakes of new generation aircraft (B-757, B-767). Also studied were the wakes of a Boeing 727 equipped with smoke generators to enhance flow visualization. The tests were conducted to determine the characteristics of the vortices produced by these new generation aircraft and to see how they might fit into existing or new separation standards. Several measurement techniques and systems were employed to gather the necessary data. Included were: a 200-foot-high tower instrumented with hot film anemometers and meteorological sensors; a laser doppler system; a monostotic acoustic doppler system; a high-resolution anemometer system; and long line sensors. An overview is presented of the techniques and equipment used and preliminary results of the data analyses. Comparisons of B-727 versus B-757 and B-767 wakes are presented. Similar tests were conducted in 1987 using only the tower fly-by technique to study the vortices of the Lockheed C5A/B Galaxy, the C-141B Starlifter and the C-130E Hercules. Pertinent findings from this activity are also presented.

"PROGRAM PLAN WAKE VORTEX"

DOT/FAA/CT-90/12, May 1990, FAA Technical Center, Atlantic City, NJ

This program plan describes the studies and research which will result in an increase in airport capacity without a reduction in safety. Although earlier programs made progress in several areas, they were terminated before they could significantly impact operations. Due to the need for increased capacity at airports, and in response to recommendations of an industry task force, the Federal Aviation Administration has revitalized its wake vortex research. These revitalized activities are presented in this Wake Vortex Program Plan. The Wake Vortex Program Plan will focus on areas wherein existing knowledge is inadequate and wherein the greatest gains may be possible. Six major activities are addressed: (1) review and analysis of wake vortex research; (2) development of new recommended aircraft classification and separation standards; (3) characterization of wake vortices; (4) development of wake vortex warning systems; (5) vortex alleviation and modification; and (6) updating or development of user educational materials and information. A phased approach will be used, with decision points at the completion of each program phase.

"INSTABILITIES DEVELOPING IN A COUNTER-ROTATING VORTEX PAIR"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

An experimental study was performed to examine the behavior of trailing vortices going down towards the ground and to analyze the instabilities present in their core. A particular attention has been focused on the detection and the characterization of the more unstable large-scale instability. Experiments have been carried out in a tunnel at two reference velocities of 2 m/s and 1.2 m/s respectively for laser and hot-wire measurements. The vortex pair was generated (as Devenport et al.)

by two rectangular wings (NACA0015 section with a chord length c of 0.10 m) facing each other and separated a quarter of chord apart from one another. This leads for the reference velocity 2 m/s to a free stream Reynolds number based on the model chord length of 200,000. Trailing vortex core unsteadiness was clearly pointed out from flow visualizations associated to an adapted image processing technique. The identification of the instabilities mechanisms was undertaken by single and two-point hot-wire measurements. The main feature of this experimental study is the clear identification of the two classes of instability occurring simultaneously in a vortex pair. The characteristic wavelength of both Widnall and Crow instability has been precisely measured. These results permitted to lay the foundations of a strategy of forced vortex reconnection. It is now possible to analyze how the growth of the Crow instability could be affected by an 'external' periodic perturbation applied in the trailing edge region of the wings.

Pailhas, G., Victor, X. and Touvet, Y.

"BEHAVIOUR OF TRAILING VORTICES IN THE VICINITY OF THE GROUND"

10th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, July 2000

The aim of this experimental study is to analyze the mean velocity field and the turbulence occurring in the core of a counter-rotating vortex pair in the vicinity of the ground. This experiment constitutes the second stage of a previous one the objective of which was to give a general view of a vortex pair close to the wall; it has been conducted in the THALES water tunnel fitted with a moving belt on the test section floor. In this way, the simulation of ground effect has been undertaken. A three-dimensional component laser Doppler Anemometer has been used to measure the three components of the velocity and every component of the Reynolds stress tensor in a YOZ plane perpendicular to the direction of the flow. Measurements in various crosswise planes have been made in sufficiently refined grids allowing a precise description of the vortex flow. The high density of data points obtained in this experiment makes possible the analysis of vorticity and associated circulation fields. It was observed that the axial vorticity was distributed into concentric paths at the first streamwise location; farther downstream, a strong deformation of these iso-contour lines seems to be connected to the movement of the vortex centers when approaching the ground. Another main feature in the evolution of the vortex concerns the turbulence in the core; its constant level is notable whatever the measurement station considered in the streamwise direction. Values as high as 15% indicates that a part of the velocity fluctuations comes probably from the wandering of the vortices. Information, as the orientation of the main shear stress axis in the core, have been gained by investigating contour plots of the joint probability density functions relating to transverse velocity fluctuations and their corresponding correlation. Laser sheet visualizations have been performed to identify the instabilities present in the vortex core.

Paillet, F. L.

"HYDRODYNAMIC STABILITY OF AN AXISYMMETRIC SWIRLING WAKE"

Ph.D. Thesis, June 1974, Rochester University, Rochester, NY

The stability of a superimposed wake and vortex, designed to resemble the far field flow in an aircraft trailing vortex, is investigated using linearized small perturbation theory. Inviscid and viscid stability are both considered. The mean velocity profiles used are the axisymmetric similarity wake for the axial component, and the asymptotic form of the convecting and diffusing vortex (the Lamb vortex) for the swirling component. Radial mean flow is neglected, and profiles are assumed constant over an axial distance much greater than the disturbance wavelength. Stability characteristics are calculated as a function of the ratio of maximum swirling velocity to maximum wake velocity defect for the lowest non-axisymmetric modes.

Paillet, F. L., editor

"PROCEEDINGS OF THE AFFDL/NASA/FAA WAKE TURBULENCE WORK SHOP"

AFFDL-TM-75-16-FGC, September 1974, Flight Dynamics Lab., Wright-Patterson Air Force Base, OH

Summaries of presentations given by ten authorities in the area of wake turbulence are included, along with conclusions on how the present state of wake research relates to USAF operations. Specific attention is paid to wake formation and stability, accident statistics, wind tunnel tests of vortex theories, the simulation of vortex encounter, similarity theory, prediction of vortex encounter severity, and the testing of various vortex dissipation schemes by NASA.

"A VORTEX SUBJECTED TO A SHEAR: AN EXPERIMENTAL STUDY"

Journal of Fluid Mechanics, Vol. 351, 1997, pp. 1-16.

The two-dimensional erosion of a vortex subjected to an external, adverse shear is studied experimentally. The flow takes place in a thin stratified layer; the vortex is produced by electromagnetic forcing, whereas the shear is driven mechanically. The system thus allows the vortex strength and the external shear to be controlled independently. We observe the so-called 'erosion' process, i.e. the progressive decrease of the vortex area, leaving the vortex core unaffected. This process is controlled by the ratio $G=S/W$, where W and S are respectively the maximum vorticity of the vortex and the external shear. At small G , the erosion is weak and the vortex survives over the duration of the experiment. At large G , the vortex is first eroded, and then, after a critical time, becomes stretched and eventually breaks up into filaments. During the first period, the compensated maximum vorticity (with friction decay removed) is constant and the vortex area decreases, while beyond the critical time, both quantities decrease with time. A critical value for G , defining the transition between these two regimes, is determined experimentally: $G=0.051 \pm 0.017$. The breaking process itself, during which the vorticity of the vortex core decreases, is investigated. All the qualitative aspects of the erosion process, the onset of breaking and the breaking process itself are found to be in excellent agreement with the theoretical and numerical description. The experimental value of G , and the properties of the filamentation process are consistent with the numerical estimates.

"TO THE ISSUE ON SELECTING DIFFERENTIAL TURBULENCE MODELS FOR CALCULATING TWO-DIMENSIONAL VORTEX FLOWS"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 90-99

For the conditions of the evolution of an axisymmetric two-dimensional vortex featuring a self-similar tangential velocity profile, a self-similar law of vortex-viscosity distribution within the vortex core has been obtained. The capability is considered of standard variants of three differential turbulence models to describe the stabilizing effect of the vortex swirl in the vortex core and the ways of their modification are proposed. [In Russian.]

Pakin, A. N.

"APPLICATION OF A MODIFIED Q-W TURBULENCE MODEL TO SIMULATION OF TWO-DIMENSIONAL VORTEX GAS MOTION"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 79-92

A modified version of the q-w isotropic eddy viscosity model is proposed, which accounts for a stabilizing effect of flow swirl in the vortex core. By the example of numerical simulation of a vortex pair's evolution in an aircraft's far wake with and out of ground effect, peculiarities are considered of the application of an isotropic eddy viscosity concept of Reynolds stresses in gas vortex motions. In addition, mechanisms of decreasing the total circulation of the core of a vortex in a vortex pair are discussed and the interaction between a vortex pair and the ground boundary layer is analyzed.

"STUDIES OF REYNOLDS NUMBER EFFECTS ON WING TIP VORTEX POSITIONS BY MEANS OF LASER LIGHT SHEET AND BACKGROUND ORIENTED SCHLIEREN TECHNIQUE UNDER CRYOGENIC CONDITIONS"

New Results in Numerical and Experimental Fluid Mechanics VI, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 96, 2008, pp. 104-112.

The Background Oriented Schlieren Method and the Laser Light Sheet technique were successfully adapted to the cryogenic European Transonic Windtunnel (ETW) and applied to wing tip vortex investigations. Applying optical measurement techniques to ETW is difficult, because of the extreme wind tunnel conditions (temperature, pressure, poor optical access). The near field of a half model of a large modern transport aircraft with landing configuration was investigated at different angles of attack and Reynolds numbers. The results show a small, but significant dependency of the wing tip vortex

position on the Reynolds number for certain angles of attack. The differences are up to 3% of the half-span width.

Panagakos, A. and Lee, T.

"TIP VORTEX CONTROL VIA AN ACTIVE TRAILING-EDGE TAB"

Journal of Aircraft, Vol. 43, No. 4, July-August 2006, pp. 1152-1158

The effect of a movable trailing-edge tab on a tip vortex generated by an oscillating NAC 0015 wing was investigated at $Re = 1.86 \times 100,000$ by using a miniature triple hot-wire probe. Both upward and downward tab deflections, actuated with different start times and durations, were tested. The downward tab motion was most effective in displacing the vortex position. The earlier the actuation the larger the displacement. The upward tab motions were, however, found to be more effective in diffusing the tip vortex and rendered a significantly reduced peak tangential velocity and core circulation, compared to an uncontrolled baseline wing. The earlier and longer the upward tab actuations the lower the vortex core strength and peak tangential velocity. The vortex core radius was rather insensitive to the tab motion. The upward tab deflection, however, produced less induced drag compared to a downward deflection.

"EXPERIMENTAL INVESTIGATION OF THE WAKE AND THE WINGTIP VORTICES OF A UAV MODEL"

Aerospace, Vol. 4, Issue 4, November 2017, pp. 53-1 to 53-17.

An experimental investigation of the wake of an Unmanned Aerial Vehicle (UAV) model using flow visualization techniques and a 3D Laser Doppler Anemometry (LDA) system is presented in this work. Emphasis is given on the flow field at the wingtip and the investigation of the tip vortices. A comparison of the velocity field is made with and without winglet devices installed at the wingtips. The experiments are carried out in a closed-circuit subsonic wind tunnel. The flow visualization techniques include smoke-wire and smoke-probe experiments to identify the flow phenomena, whereas for accurately measuring the velocity field point measurements are conducted using the LDA system. Apart from the measured velocities, vorticity and circulation quantities are also calculated and compared for the two cases. The results help to provide a more detailed view of the flow field around the UAV and indicate the winglets' significant contribution to the deconstruction of wing-tip vortex structures.

"EFFECT OF COUNTER-ROTATING VORTICES ON THE DEVELOPMENT OF AIRCRAFT WAKES"

Aeronautical Journal, Vol. 106, Nov. 2004, pp. 585-592.

A two-dimensional vortex particle model is used for studying the development of the vortex wake generated by the wing of an aircraft in the Trefftz plane. Two-dimensional, finite-area vortex structures simulate the initial vorticity distribution at a near-field cross-section of the wing, as provided by either measurements or simulations. The code is used for studying the effect of weak or strong counter-rotating vortices on the development of an aircraft wake. Application in a three-vortex configuration, consisting of the tip and flap vortices, plus a weak negative vorticity sheet lying between them, supports the hypothesis of Graham that the merging of the tip and flap vortices is prevented, because in such an arrangement the counter-rotating vorticity sheet is wrapped around the primary vortices. The present results indicate that even in the far field the tip and flap vortices remain distinct and follow a helical trajectory with large-pitch and small-radius. The code is next applied to the two-vortex system of Savas's triangular wing, in which the circulation of the flap vortex is comparable to that of the tip. Although a 2D analysis is inappropriate for stability analysis it is still useful for a quick qualitative investigation. Results indicate that the flap and tip vortices follow a helical trajectory with large-pitch but also very large radius. During one period, the flap vortex covers a span wise distance equal to the wing span. Such a flow has not been observed in flight or in laboratory tests. Ortega et al, who studied experimentally the triangular wing of O. Savas, found out that before concluding one full spiral, the vortices are literally destroyed (rapid spreading of their vorticity) by an instability mechanism.

Panton, R. L. and Stifle, K. E.

"EXPERIMENTAL STUDY OF A VORTEX SUBJECTED TO IMPOSED STRAIN"

NASA CR-189757, August 1991, Texas Univ. at Austin, Austin, TX

An experimental project was undertaken to investigate the character of vortex breakdown with regard to the waveguide theories of vortex breakdown. A rectangular wing based on the NACA 0012 airfoil was used to produce a trailing vortex which convected downstream without undergoing breakdown. Dye marked the vortex location. A disturbance was then introduced onto the vortex using a small moving wire to 'cut' the vortex. The development of upstream and downstream propagating disturbance waves was observed and the propagation velocities measured. The downstream traveling wave produced a structure similar in appearance to a vortex breakdown. The upstream wave produced a moving, swirling, turbulent region that was not a vortex breakdown. The waves moving in either direction have the same swirl velocity profiles but quite different axial velocity profiles. The upstream disturbance (turbulence) moved into a flow with an axial velocity profile that had a wake-like defect in the core region. The downstream moving vortex breakdown moved into a flow with a jet-like overshoot in the core region. The fact that no breakdown was observed for the wake-like defect and breakdown was observed for the jet-like overshoot is not consistent with computational fluid dynamics (CFD) calculations. Although there are not a lot of examples, CFD results show breakdown for both types of profiles. The longitudinal and swirl velocity profiles were documented by Laser Doppler Velocimeter (LDV) measurement. Wave velocities, swirl angles, and swirl parameters are reported.

Panton, R. L., Oberkampf, W. L. and Soskic, N.

"FLIGHT MEASUREMENTS OF A WING TIP VORTEX"

J. Aircraft, Vol. 17, No. 4, April 1980, pp. 250-259

Detailed flight measurements of the wing tip vortex generated by a DeHavilland Beaver were made with instruments mounted on a sailplane, which was towed behind the aircraft. Data at three different downstream locations were obtained by using three different tow rope lengths. The measurement stations were 4, 8, and 16 span lengths behind the aircraft, and the vortex Reynolds number was slightly above 106. Results of the tests differed considerably from those of previous authors. Although the customary similarity variables for vortex decay were verified, the velocities were a factor of 2.5 higher than previous results. The vortex core radius and turbulence levels also proved to be substantially smaller than earlier measurements. These results indicate that the final similarity state of the vortex may depend strongly upon the initial tip shape, initial turbulence levels of the vortex, and/or the ambient turbulence levels.

"VORTEX TRAILS IN STRATIFIED FLUIDS"

Johns Hopkins APL Technical Digest, Vol. 3, Jan.-Mar. 1982, pp. 12-18

A framework is proposed which accounts for the properties of atmospheric vortex trails used by wind flow. Similarities between atmospheric vortex patterns and those in stratified fluids are observed noting that the generation of vortex trails is primarily due to density stratification. Horizontal vortices form for values of Froude numbers between 2-505, and for Reynolds numbers between 600-100,000. The cause of late-wake vortices and the reason for their great regularity is the presence of a large-scale coherent structure in the early wake. A critical Froude number exists above which no horizontal vortices form and its value for a bluff body is about 160. Finally, it is also noted that ambient shear can prevent or destroy late-wake horizontal vortices.

Paoli, R. and Garnier, F.

"INTERACTION OF EXHAUST JETS AND AIRCRAFT WAKE VORTICES: SMALL-SCALE DYNAMICS AND POTENTIAL MICROPHYSICAL-CHEMICAL TRANSFORMATIONS"

C. R. Physique, Vol. 6, 2005, pp. 525-547

This paper summarizes recent progress made in the understanding of the interaction between exhaust jets and trailing vortices in the near field of an aircraft wake. Emphasis is placed on the effects of the jet on the wake vortex dynamics and the effects of the wake on the exhaust dispersion, as well as their potential microphysical and chemical transformations. We discuss in detail results of high-resolution numerical simulations of jet/vortex interaction that include microscale turbulent mixing, gas-phase chemistry, and contrail formation.

Paoli, R. and Shariff, K.

"CONTRAIL MODELING AND SIMULATION"

Annual Review of Fluid Mechanics, Vol. 48, 2016, pp. 393-427.

There is large uncertainty in the radiative forcing induced by aircraft contrails, particularly after they transform to cirrus. It has recently become possible to simulate contrail evolution for long periods after their formation. We review the main physical processes and simulation efforts in the four phases of contrail evolution, namely the jet, vortex, vortex dissipation, and diffusion phases. Recommendations for further work are given.

Paoli, R., Cariolle, D. and Sausen, R.

"REVIEW OF EFFECTIVE EMISSIONS MODELING AND COMPUTATION"

Geoscientific Model Development, Vol. 4, 2011, pp. 643-667.

An important issue in the evaluation of the environmental impact of emissions from concentrated sources such as transport modes, is to understand how processes occurring at the scales of exhaust plumes can influence the physical and chemical state of the atmosphere at regional and global scales. Indeed, three-dimensional global circulation models or chemistry transport models generally assume that emissions are instantaneously diluted into large-scale grid boxes, which may lead, for example, to overpredict the efficiency of NO_x to produce ozone. In recent times, various methods have been developed to incorporate parameterizations of plume processes into global models that are based e.g. on correcting the original emission indexes or on introducing 'sub grid' reaction rates in the models. This paper provides a review of the techniques proposed so far in the literature to account for local conversion of emissions in the plume, as well as the implementation of these techniques into atmospheric codes.

Paoli, R., Helie, J. and Poinso, T.

"CONTRAIL FORMATION IN AIRCRAFT WAKES"

J. Fluid Mech., Vol. 302, 2004, pp. 361-373

The process of the formation and early evolution of a condensation trail ('contrail') in the near field of an aircraft wake was numerically studied by means of a mixed Eulerian/Lagrangian two-phase flow approach. Large-eddy simulations were used for the carrier phase, while, for the dispersed phase, a Lagrangian particle tracking method was used, coupled with a microphysics model to account for ice nucleation. The basic configuration was an exhaust engine jet loaded with soot particles and water vapor and interacting with a wing-tip trailing vortex. The thermodynamic conditions for contrail formation were identified by tracking the spatial distribution of supersaturation around particles. A strong mass coupling between the two phases was demonstrated by the simulations: the condensation

of water vapor over soot particles, induced by exhaust dispersion into cold ambient air, leads to the formation of ice crystals whose size grows until thermodynamic equilibrium between the two phases is reached. Finally, local vapor depletion causes significant deviation from the classical mixing line theory and is also responsible for polydispersion of particle radii.

Paoli, R., Laporte, F. and Cuenot, B.

"DYNAMICS AND MIXING IN JET/VORTEX INTERACTIONS"

Physics of Fluids, Vol. 15, No. 7, July 2003, pp. 1843-1860

This study describes large eddy simulations of the interaction between an exhaust jet and a trailing vortex, in the near-field of an aircraft wake. Two cases are analyzed: in the first one, typical of cruise flight, the jet and the vortex axes are sufficiently well separated to study first the jet dynamics before considering its interaction with the vortex. Dynamics and mixing are controlled both by the jet diffusion and its entrainment around the vortex core. In the second case the jet partially blows in the vortex core, making the flow like a Batchelor vortex. The strong perturbations injected into the core cause an instability of the system which is continuously fed by the jet elements wrapping around the core. This leads to a strong decay of angular momentum and diffusion of the core. Global mixing properties, such as plume area and global mixedness evolutions, are analyzed and two applications to environmental problems are finally discussed.

Paoli, R., Laporte, F. and Cuenot, B.

"JET VORTEX INTERACTIONS IN AIRPLANE WAKES"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

The objective of the present work is to study numerically the interaction between a wing generated vortex and the exhaust jets emitted by the engines, in the near-field of an aircraft wake. We analyzed two different configurations which are representative of the interaction in two and four-engine airplanes in cruise or during approach for landing. In the jet entrainment case, the jet dynamics including transition to turbulence by the Kelvin-Helmoltz instability is simulated, and the mixing characteristics are analyzed. After the jet has become turbulent, a Lamb-Oseen vortex is inserted in an enlarged simulation domain. All flow characteristics have been taken from experimental results. It is shown that the dynamics is mainly governed by the vortex, and that the mixing is greatly enhanced during this second phase. In the blowing jet case, two configurations are investigated. One model configuration consists of a Lamb-Oseen vortex which is superimposed close to the jet. This flow can be interpreted as a q-vortex which is found to amplify helical unstable modes, leading to the transition to turbulence.

Paoli, R., Nybelen, L., Picot, J. and Cariolle, D.

"EFFECTS OF JET/VORTEX INTERACTION ON CONTRAIL FORMATION IN SUPERSATURATED CONDITIONS"

Physics of Fluids, Vol. 25, 2013, pp. 053305-1 to 053305-28.

The effects of the interaction between a model of aircraft trailing vortex and engine jets on the formation of a contrail in supersaturated ambient air are studied using Eulerian-Lagrangian two-phase flows large-eddy simulations. The three-dimensional structure of the contrail, the mean flow properties, and the statistical correlations between ice and water vapor are analyzed for different jet and vortex parameters and different soot particle numbers. The interaction is characterized by the entrainment of the jets by the trailing vortex. In the four-engine case, particles exhausting the outboard jets are exposed to local higher supersaturation due to the temperature drop in the low-pressure vortex core region. The soot particle number affects both the structure and the global characteristics of the contrail. The increase in soot loading results in stronger vapor depletion -- which leads to larger ice production -- and to smaller ice particles for a given amount of vapor exhaust. The fraction of activated particles decreases with soot loading because of the increased competition for the vapor available for condensation. Of particular interest is the interaction between the jet/vortex turbulence and ice microphysics (activation, condensation, particle size distribution, and optical depth). It is found that the characteristic timescales of mixing and condensation can be of the same order in the jet regime. For the present high ambient supersaturation conditions, the competition between the entrainment of humid ambient air and vapor depletion plays an important role in determining the initial growth of the contrail and the spatial and size distributions of ice particles.

"HELICOPTER ROTOR DOWNWASH CALCULATION USING THE VORTEX ELEMENT METHOD FOR THE WAKE MODELLING"

ICAS 1996, September 1996, Sorrento, Napoli, Italy.

This paper presents the calculation of the nonuniform induced downwash of a helicopter rotor in forward flight by utilizing efficient physics-mathematical modeling based on the Vortex Element Method (VEM) for the description of the arbitrary vortex wake, which determines the rotor flowfield. The wake model consists of the concentrated tip vortex, the trailing vortices and the shed vorticity which are discretized into vortex elements. The induced velocity is calculated by means of the Biot-Savart law integration over each of these elements. A computer code has been developed for the calculation of the bound circulation distribution, wake geometry and circulation as well as blade air loading. In the computational procedure the rotor wake contraction and distortion, the vorticity dissipation, the vortex core modeling, the inboard vorticity and wake roll up process are numerically simulated and their influences on the rotor downwash are demonstrated.

Papka, R. J.

"MODELING THE WAKE AS A CONTINUOUS VORTEX SHEET IN A POTENTIAL-FLOW SOLUTION USING VORTEX PANELS"

AFIT/GAE/ENY/89D-26, December 1989, Air Force Institute of Tech., Wright-Patterson AFB, OH

An investigation was made to determine the advantages of modeling the wake as a continuous vortex sheet in an unsteady potential-flow computer model. The existing program modeled the body as a continuous vortex sheet, and modeled the wake as discrete vortex cores employing principles of vortex lattice methods. A method is developed to approximate the wake with triangular vortex panels. The method accounts for redistributing vortex strength as the panels expand and deform. Comparisons are made with results of the original program for a rectangular wing at varying angles of attack. Limited results suggest the method is valid, and areas for further study are recommended.

"STUDY OF MULTIPLE WAKE VORTEX SYSTEM BEHIND AIRCRAFT NEAR GROUND PROXIMITY USING PRANDTL-LIFTING LINE THEORY"

Tenth International Conference on Computational Fluid Dynamics (ICCFD10), July 2018, Barcelona, Spain.

In this research, a simplified method using Prandtl-Lifting line theory is proposed to model the multiple wake-vortex system shed behind an aircraft in various high-lift lift configurations. It is proven that the spanwise lift distribution has a great effect on the initial structure, strength and number of vortices formed downstream and their evolution. Further, a particular combination of strength and position of flap vortices are found to effectively enhance the secondary vortex formation in the presence of crosswind. This is evident from the plots of Modified landing configuration which has lowest circulation of all configurations. Hence, this proposed method is also helpful in finding out the optimum lift distribution that alleviates the wake-vortex hazard in shorter duration.

Paramasivam, S., Skote, M., Dan, Z. and Schluter, J. U.

"DETAILED STUDY OF EFFECTS OF CROSSWIND AND TURBULENCE INTENSITY ON AIRCRAFT WAKE-VORTEX IN GROUND PROXIMITY"

AIAA Paper 2016-4184, June 2016, Washington, DC.

We present Large-Eddy Simulations of aircraft wake vortices for different crosswind velocities at zero turbulence intensity, and for different turbulence intensities at a crosswind velocity equal to the descent speed of the aircraft wake vortex, to study their impacts on a pair of fully developed wake vortices. The parameters such as circulation, lateral and vertical position of the vortex center, vortex separation distance are investigated with the aid of necessary graphs. Low crosswind velocities are not sufficient to accelerate the decay and push the vortex out of the domain while higher crosswind velocities can intensify the vortex decay earlier and can push the downwind vortex out of the flight path. To have a clear understanding of response of wake-vortices for various crosswind velocities, the slope of lateral movement of vortices with respect to time is represented as a function of crosswind velocity. In addition to the movement, the exit time is also formulated mathematically as a function of crosswind velocity. The effect of lower turbulence intensity levels is found to be insignificant while higher levels have a profound influence on the size of the local secondary vortices formed.

"THREE-DIMENSIONAL SOLUTIONS OF TRAILING-VORTEX FLOWS USING PARABOLIZED EQUATIONS"

AIAA Journal, Vol. 51, No. 12, December 2013, pp. 2763-2770.

Flows of practical significance exist, like systems of trailing-vortices, which are inhomogeneous in two directions and weakly dependent along the third spatial direction. Exploiting these characteristics, an integration of the Navier-Stokes equations using the parabolic Navier-Stokes concept is proposed for the recovery of steady solutions that might be used subsequently in the scope of primary instability analyses. The parabolic Navier-Stokes equations are first formulated in a cylindrical coordinate frame and used to calculate the solution of an isolated, axisymmetric nonparallel (axially developing) vortex. Then, the fully three-dimensional flow corresponding to a counter-rotating pair of nonparallel vortices is obtained by parabolic Navier-Stokes formulated in Cartesian coordinates. Stable high-order finite-difference-based numerical schemes are used for the spatial discretization to exploit the benefits of using a sparse direct solver for the inversion of the large matrices resulting from the discretization of the partial-derivative-based parabolic Navier-Stokes equations. Solutions recovered converge to the analytically obtained evolution of an isolated vortex in the limit of large distance between vortices and depart from this idealized situation when the distance becomes of the same order as the radii of the vortices.

Paredes, P., Theofilis, V. and Rodriguez, D.

"PARABOLIC NAVIER-STOKES SOLUTIONS OF TRAILING VORTEX FLOWS"

AIAA Paper No. 2012-3348, June 2012, New Orleans, LA.

Flows of practical significance exist, such as systems of trailing vortices, which are inhomogeneous in two and weakly dependent on the third spatial direction. Exploiting these characteristics, an integration of the Navier-Stokes equations using the Parabolic Navier-Stokes (PNS) concept is appropriate. The PNS equations for vortical systems are first formulated in a Cartesian coordinate frame; the formulation is validated by recovering results for the Blasius boundary layer. Subsequently, a cylindrical coordinate transformation is used to calculate the solution of an isolated non-parallel vortex. Finally, a fully three-dimensional steady laminar flow composed of a counter-rotating pair of non-parallel vortices is obtained by PNS. Stable high-order finite-difference-based numerical schemes are used for spatial discretization to exploit the benefits of using a sparse direct solver for the inversion of the large matrices resulting from the discretization of the partial-derivative based PNS equations. Solutions recovered approach the analytical result in the limit of large distance between vortices, but depart from this idealized situation when the distance becomes of the same order as the radii of the vortices. When the flow swirl parameter is increased, stationary flow instabilities manifest themselves in the obtained solutions.

Park, B H. and Han, Y. O.

"EVOLUTION OF TIP VORTICES GENERATED BY TWO BLADED ROTOR IN HOVER AT EARLY WAKE AGES"

International Journal of Aeronautical and Space Sciences, Vol. 10, No. 2, Nov. 2009, pp. 106-116.

To investigate change of vortex structures and its evolving processes, two dimensional LDV system was used for measurement of velocity vectors of tip vortex, and PIV system was also used for visualizations of tip vortex array for two bladed rotors, respectively. Experiments provided vortex locations, tangential and axial velocity components of tip vortex at six wake ages of 9.5, 10.5, 60.5, 99.5, 129.5, 169.5 and corresponded six wake ages shifted with 180 degrees per each. It was resulted that tip vortices generated by the first blade satisfy Landgrebe's model for their vortex locations even after they were accelerated by the second blade in downstream. Tangential velocity components of tip vortices follow Vatistas' $n=2$ model on both inside and outside regions of rotor slipstream without loss of vortex circulation. Axial velocity profiles revealed that there were small but significant perturbations just outside the primary vortex core which implies the second blade affects the wake substantially. It was also found that tip paths of each blade were not willing to be coincided intrinsically.

"NUMERICAL PREDICTION OF TIP VORTEX CAVITATION BEHAVIOR AND NOISE CONSIDERING NUCLEI SIZE AND DISTRIBUTION"

Applied Acoustics, Vol. 70, 2009, pp. 674-680.

The tip vortex cavitation behavior and sound generation were numerically analyzed. A numerical scheme combining Eulerian flow field computation and Lagrangian particle trace approach was applied to simulate tip vortex cavitation. Flow field was computed by using hybrid method which combines Reynolds-Averaged Navier-Stokes solver with Dissipation Vortex Model. The trajectory and behavior of each cavitation bubble were computed by Newton's second law and Rayleigh-Plesset equation, respectively. According to nuclei population data, the cavitation nuclei were distributed and convected into the tip vortex flow. Calculated volume of the cavitation bubble and the trajectory were used as the input of cavitation bubble noise analysis. The relationship of cavitation inception, sound pressure level, and cavitation nuclei size was studied at several cavitation numbers. It was found that cavitation inception of smaller nuclei is more sensitive to the change of cavitation number and cavitation noise due to the cavitation smallest nuclei has the most influence on overall tip vortex cavitation noise.

Park, P. S. and Rokhsaz, K.

"EFFECTS OF A WINGLET RUDDER ON LIFT-TO-DRAG RATIO AND WAKE VORTEX FREQUENCY"

AIAA Paper No. 2003-4069, Orlando, FL, June 2003

Computational study of the aerodynamic characteristics of a wing and winglet equipped with a control surface is presented. The wing used for this investigation is similar in design to those employed on business jets. Two aspects of this configuration are studied. The first is the effect of the control surface deflection on the optimum lift-to-drag ratio and its corresponding lift coefficient. The second is

the influence of the control surface deflection on the spiraling frequency in the wake of the winglet. It is demonstrated that any control surface deflection on an otherwise optimized winglet results in reduction of the maximum lift-to-drag ratio. However, the spiraling frequency in the wake of the winglet can be controlled quite well. It is speculated that this type of geometry can be used to exploit the naturally unstable modes of motion of the wake vortex system.

"HOT-WIRE MEASUREMENTS OF NEAR WAKES BEHIND AN OSCILLATING AIRFOIL"

AIAA Journal, Vol. 28, No. 1, January 1990, pp. 22-28

An experimental investigation was carried out to study the unsteady, near wakes behind an oscillating airfoil. The airfoil was given the harmonic pitching motion about the one-quarter chord axis at two reduced frequencies 0.1 and 0.2. The amplitude of oscillation was 7.4 deg. To assess the effect of mean incidence the mean incidence of oscillation was varied from 0-4 deg. When the mean incidence was 4 deg. the airfoil was found to undergo a deep stall. Streamwise velocity and turbulence intensity profiles were measured by hot-wire anemometry and are presented in the paper. The near-wake measurements made it possible to detect and characterize the emergence of unsteady separation. It was found that the unsteady boundary-layer separation occurred at a greater phase angle (i.e., separation was delayed) when the reduced frequency was greater. When the mean incidence of oscillation was larger, the unsteady separation occurred at a smaller phase angle (i.e., separation was promoted). The linear relationship between the phase angle and the reduced frequency obtained in the present range of the experiment assured us that the characteristic time scale of unsteady separation was the flow time scale given by the ratio of chord length to freestream velocity. Smoke-wire flow visualization was also used to elucidate the link between some of the measured wake data and the various flow states around the airfoil. The phase lag of wake velocity profile relative to the motion of the trailing edge was estimated. The phase lag was found to increase linearly with downstream distance except for the region very near the trailing edge.

"CHARACTERISTICS OF THE VORTEX STREET BEHIND A FINITE ASPECT-RATIO FLAPPING WING"

AIAA Paper No. 2006-1304, Reno, NV, January 2006

Aspects of the evolution of vorticity behind a thrust-producing flapping wing are discussed based on quantitative experiments. Multiple planes of stereoscopic particle image velocimetry measurements are conducted at several locations along the span of a NACA0030-type wing at a Strouhal number of 0.35. Of particular interest is the effect of wingtip vortices on the structure of the flow behind the wing since there is an interrelationship between the wing motion and the flow structure. The spanwise distribution of vorticity is found to be dominated, in the large scale, by a single pair of intense counter-rotating vortices. Over one complete oscillation cycle, the characteristics of the flow in the plane of symmetry is like a reverse Karman vortex street. Each member of the large-scale vortex pair is

constituted by two smaller co-rotating vortices that constructively merge in the initial stages of flow separation. Toward the wingtip the effect of wing three-dimensionality is more significant. The spatio-temporal variations of transverse and spanwise vorticity in these regions suggest severe local flow deformation. Measurements reveal that flow morphology is highly complex and three-dimensional unlike any previously observed, 2D-wing based vortex sheets.

"THE APPLICATION OF PIV TO THE WAKE OF A WIND TURBINE IN YAW"

4th International Symposium on Particle Image Velocimetry, Paper 1154, September 2001, Gottingen, Germany.

PIV has been used in a wind tunnel study of the wake of a 0.25m diameter two bladed model horizontal axis wind turbine (HAWT). Velocity fields of the wake from one to five rotor diameters downstream of the wind turbine model are shown, both with the turbine aligned in the flow and yawed. Data analysis is mainly based on time averaged velocity profiles of the wake for a range of yaw angles $[0 \pm 10, \pm 20, \pm 30]$ in a plane parallel to the flow. Results show the size and persistence of the velocity deficit and tip vortices in the wake, and the wake deflection in yaw. It is shown that active control of turbine yaw angles could be an advantage for overall maximization of power output from wind farms.

"A DYNAMIC ANALYSIS OF AEROPLANES ENCOUNTERING VORTEX WAKE TURBULENCE"

ATN-7301, January 1973, University of Sidney, Sidney, Australia

A six degree of freedom flight simulation model was developed for digital computers to investigate the response of aircraft to a pair of trailing vortices. The model was used to simulate the flight of a light, two-seat training aircraft and a twin-engine commercial transport into the vortices shed by medium weight and heavy weight aircraft.

"RECONSTRUCTION OF THE 1994 PITTSBURGH AIRPLANE ACCIDENT USING A COMPUTER SIMULATION"

J. Aircraft, Vol. 35, No. 5, September-October 1998, pp. 665-670.

On September 8, 1994, a Boeing 737-300 airplane was on a downwind approach to the Pittsburgh International Airport at an altitude of 5000 feet above ground level (6000 feet MSL). While in a shallow left turn onto a downwind approach heading, the airplane crossed into the vortex trail of a B-727 flying in the same approach pattern about 4 miles ahead. The B-737 airplane rolled and turned sharply to the left, exited the vortex wake and plunged into the ground. Weather was not a factor in the accident. The airplane was equipped with a 11+ channel digital Flight Data Recorder (FDR) and a multiple channel

Cockpit Voice Recorder. Both recorders were recovered from the crash site and provided excellent data for the development of an accident scenario. Radar tracking of the two airplanes as well as the indicated air speed perturbations clearly visible on the B-737 FDR recordings indicate that the upset was apparently initiated by the airplane's crossing into the wake of the B-727 flying ahead in the same traffic pattern. A 6 degree-of-freedom simulation program for the B-737 airplane was constructed. The simulation was initialized at the stabilized flight conditions of the airplane about 13 seconds prior to its entry into the vortex trail of the B-727 airplane. By assuming a certain combination of control inputs, it was possible to produce a simulated motion that closely matched that recorded on the FDR.

"IDENTIFICATION OF VORTEX-INDUCED CLEAR AIR TURBULENCE USING AIRLINE FLIGHT RECORDS"

J. Aircraft, Vol. 22, No. 2, February 1985, pp. 124-129

The nature and cause of clear-air turbulence is being investigated in cooperation with the National Transportation Safety Board, using the flight records available from airline encounters with severe turbulence. This paper presents two case studies of severe turbulence which indicate that the airplanes involved encountered vortex arrays which were generated by destabilized wind-shear layers near the tropopause. In order to identify and analyze vortex patterns (i.e., vortex strength, size, and spacings), potential-flow models of vortex arrays were developed that describe reasonably well the wind patterns derived from the airliner flight records. The results of this analysis indicate that in the two cases studied, the vortex cores had diameters in the range of 900 to 1200 ft. with tangential velocities in the range of 70 to 85 ft./s. This study presents the first identification and analysis of vortex arrays from airline flight data. The results are compared with theoretical predictions and previous observations.

Parks, P. C.

"A NEW LOOK AT THE DYNAMICS OF VORTICES WITH FINITE CORES"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 355-388

The stability theory for wave-like disturbances in a pair of trailing line vortices developed by Crow has been modified to take account of finite core radii and appropriate distributions of vorticity within these cores. The essential features of Crow's theory are confirmed with small numerical changes. The effect of axial flow within the cores may be considered by wrapping the core in a sheath of vortex rings. This model leads to a new stability criterion for a single 'jet-vortex'. The theory, which assumes the vortices extend from infinity to infinity, cannot be used to calculate the growth of perturbations deliberately introduced at the wing of the aircraft, but a modified discretized theory amenable to digital computation has been developed to investigate initial growth of these excited waves.

Parras, L. and Fernandez-Feria, R.

"SPATIAL STABILITY AND THE ONSET OF ABSOLUTE INSTABILITY OF BATCHELOR'S VORTEX FOR HIGH SWIRL NUMBERS"

J. Fluid Mech., Vol. 583, 2007, pp. 27-43

Batchelor's vortex has been commonly used in the past as a model for aircraft trailing vortices. Using a temporal stability analysis, new viscous unstable modes have been found for the high swirl numbers of interest in actual large-aircraft vortices. We look here for these unstable viscous modes occurring at large swirl numbers ($q > 1.5$), and large Reynolds numbers ($Re > 1,000$), using a spatial stability analysis, thus characterizing the frequencies at which these modes become convectively unstable for different values of q , Re , and for different intensities of the uniform axial flow. We consider both jet-like and wake-like Batchelor's vortices, and can analyze the stability for Re as high as 100,000,000. We also characterize the frequencies and the swirl numbers for the onset of absolute instabilities of these unstable viscous modes for large q .

"AUTOMATIC EMBEDDING OF POTENTIAL FLOW WAKE SURFACES IN GENERIC MONOLITHIC UNSTRUCTURED MESHES"

Journal of Aircraft, Vol. 50, No. 4, July-August 2013, pp. 1179-1188.

The paper presents two possible ways of modeling wakes within an unstructured two-field potential flow formulation. It aims at avoiding the use of specialized mesh generators featuring the a priori imposition of wake cuts. Thus, by making possible the adoption of widely available general-purpose mesh generators, it gives way to an easier application of a potential formulation to complex configurations. A first approach generates a posteriori wake cuts within generic unstructured meshes, while an alternative method translates the potential discontinuity across the wake into a proper weak constraint on the flow velocity within the grid elements intersected, leaving them unchanged. A steady transonic trim evaluation and a couple of flutter analyses are shown to verify the effectiveness of both strategies, comparing their results with alternative numerical solutions.

Parthasarathy, S. P., Cho, Y. I. and Back, L. H.

"WIDE-FIELD SHADOWGRAPH FLOW VISUALIZATION OF TIP VORTICES GENERATED BY A HELICOPTER ROTOR"

AIAA Paper No. 1985-1557, Cincinnati, OH, July 1985

The vortex trajectory and vortex wake generated by helicopter rotors were visualized using a wide-field shadowgraph technique. Use of a retro-reflective Scotchlite screen made it possible to investigate the flow field generated by full-scale tail rotors. Tip vortex trajectories were visible in shadowgraphs for a range for tip Mach number of 0.38 - 0.60. The effect of the angle of attack was substantial. At an angle of attack greater than 8 degrees, the visibility of the vortex core was significant even at relatively low tip Mach numbers. The theoretical analysis of the visibility was carried out for a rotating blade.

This analysis demonstrated that the visibility decreases with increasing dimensionless core radius and increases with increasing tip Mach number. Based on this investigation, it is concluded that the wide-field shadowgraph flow visualization technique should be feasible to study the flow field generated by a large main rotor in a wind tunnel and in an outdoor full-scale test stand. Of note is that the shadowgraph technique could easily be used with other on-going tests such as aerodynamic performance study, noise measurements, velocity measurements with LDV or hot-wire anemometer, local pressure measurement on the rotor surface, etc.

"OBSTACLE-INDUCED SPIRAL VORTEX BREAKDOWN"

Experiments in Fluids, Vol. 55, 2014, pp. 1784-1 to 1784-11.

An experimental investigation on vortex breakdown dynamics is performed. An adverse pressure gradient is created along the axis of a wing-tip vortex by introducing a sphere downstream of an elliptical hydrofoil. The instrumentation involves high-speed visualizations with air bubbles used as tracers and 2D Laser Doppler Velocimeter (LDV). Two key parameters are identified and varied to control the onset of vortex breakdown: the swirl number, defined as the maximum azimuthal velocity divided by the free-stream velocity, and the adverse pressure gradient. They were controlled through the incidence angle of the elliptical hydrofoil, the free-stream velocity, and the sphere diameter. A single helical breakdown of the vortex was systematically observed over a wide range of experimental parameters. The helical breakdown coiled around the sphere in the direction opposite to the vortex but rotated along the vortex direction. We have observed that the location of vortex breakdown moved upstream as the swirl number or the sphere diameter was increased. LDV measurements were corrected using a reconstruction procedure considering the so-called vortex wandering and the size of the LDV measurement volume. This allows us to investigate the spatio-temporal linear stability properties of the flow and demonstrate that the flow transition from columnar to single helical shape is due to a transition from convective to absolute instability.

Pate, D. J. and German, B. J.

"SUPERPOSITION OF SPANWISE CIRCULATION DISTRIBUTIONS: ACCURACY ASSESSMENT AND APPLICATION IN WING DESIGN"

Journal of Aircraft, Vol. 51, No. 5, September-October 2014, pp. 1439-1454.

Superposition of spanwise lift distributions is a familiar concept from lifting-line theory. However, even for linear potential flows, superposition is not rigorously applicable for aerodynamic models and wing geometries in which the shape of the wake vortex system changes with angle of attack. Nonetheless, the influence of these wake effects could generally be expected to be small, insofar as downstream vortices have a weaker influence than the vortex system in the near field of the wing. In this paper, the theoretical framework for lift distribution superposition is first examined. Next, empirical studies conducted with a panel code are presented that show that superposition remains a

very good approximation for a wide range of wing geometries and operating conditions. A method for correcting the small errors in induced drag predictions that result from the application of superposition is also provided. Finally, an application for wing design in which an additional and a design distribution are superposed to produce lift distributions at other operating conditions is presented. This formulation reveals insights into the influence of the design distribution and the planform characteristics, and it supports computationally inexpensive optimization of wing twist.

Paterson, O., Wang, B. and Mao, X.

"COHERENT STRUCTURES IN THE BREAKDOWN BUBBLE OF A VORTEX FLOW"

AIAA Journal, Vol. 56, No. 5, May 2018, pp. 1812-1817.

Helical structures downstream of the breakdown bubble of the Grabowski vortex profile at Reynolds numbers of Re less than or equal to 500 have been extensively studied through stability analyses in the literature. However, the low-frequency coherent structures inside the bubble, which have been observed in experiments, were not predicted by the stability approach. In the present work, asymptotic stabilities of the Grabowski vortex flow at Re less than or equal to 1000 are carried out to compare against previous works, and then the linear optimal inflow perturbation and the corresponding outcome are studied to unveil the dynamics inside the bubble. It is found that low-frequency inflow perturbations penetrate the bubble and are amplified to coherent structures, whereas high-frequency perturbations are convected around the border of the bubble. These linearized results agree well with previous experimental observations and are validated by direct numerical simulations.

"CONTROLLING WAKE TURBULENCE"

Physical Review Letters, Vol. 88, No. 5, February 2002, pp. 054502-1 - 054502-4. (Erratum, p. 129901-1.)

This Letter introduces a control strategy for taming the wake turbulence behind a cylinder. An angular momentum injection scheme is proposed to synchronize the vertical velocity field. We show that the base suction, wake formation length, absolute instability, and the Karman vortex street are effectively controlled by the angular momentum injection. A control equation is designed to implement the injection. The Navier-Stokes equations, along with the control equation, are solved. The occurrence of a new recirculation free zone is identified.

Patterson Jr, J. C.

"WINGTIP VORTEX TURBINE"

US Patent 4,917,332, April 1990.

A means for extracting rotational energy from the vortex created at aircraft wing tips which consists of a turbine with blades located in the crossflow of the vortex and attached downstream of the wingtip. The turbine has blades attached to a core. When the aircraft is in motion, rotation of core transmits energy to a centrally attached shaft. The rotational energy thus generated may be put to use within the airfoil or aircraft fuselage.

"EXPLORATORY WIND-TUNNEL INVESTIGATION OF A WINGTIP-MOUNTED VORTEX TURBINE FOR VORTEX ENERGY RECOVERY"

NASA TP-2468, June 1985, Langley Research Center, Hampton, VA.

An exploratory investigation has been conducted at the Langley Research Center to determine the possibility of recovering, with a turbine-type device, part of the energy loss associated with the lift-induced vortex system. Tests were conducted on a semispan model with an unswept, untapered wing, with and without a wingtip-mounted vortex turbine. Three sets of turbine blades were tested to determine the effect of airfoil section shape and planform. The tests were conducted at a Mach number of 0.70 over an angle-of-attack range of 0 to 4 degrees at a Reynolds number of 3,820,000 based on the wing reference chord of 13 in.

Patterson, Jr., J. C.

"A CONTROLLED METHOD TO OBTAIN A VISUAL HISTORY OF THE LIFT INDUCED WING TIP VORTEX"

LWP-983, August 1971, NASA Langley Research Center, Hampton, VA

Tests were performed in the towing tank facility of the Langley Loads Division. This method of flow visualization is particularly applicable to the study of lift-induced wing tip vortices and has made possible the ability to record the entire life span of the vortex. To accomplish this, a vertical screen of smoke is produced perpendicular to the flight path and allowed to become stationary. The wing panel is then passed through the screen of smoke producing the circular vortex motion which may be recorded by high-speed motion pictures.

Patterson, Jr., J. C.

"LIFT-INDUCED WING-TIP VORTEX ATTENUATION"

AIAA Paper No. 1974-0038, Washington, DC, January 1974

It has been shown by a new static airflow visualization method that a drogue device properly positioned downstream of the wing tip causes vortex breakdown. This same result has been obtained by mounting a jet engine simulator at the wing tip and directing the high-energy jet blast downstream

into the vortex. These configurations, among others, are now under intensive investigation in the new Langley Vortex Research Facility. In this facility a balance mounted vortex generating model is propelled along the 1800-foot track while a second model trailed at 160 feet (scale distance of 1 mile) measures the far-field rolling moment induced by the vortex of the generating model.

Patterson, Jr., J. C.

"VORTEX ATTENUATION OBTAINED IN THE LANGLEY VORTEX RESEARCH FACILITY"

J. Aircraft, Vol. 12, No. 9, September 1975, pp. 745-749

It has been shown by a new static airflow visualization method that a drogue device properly positioned downstream of the wing tip causes vortex breakdown. This same result has been obtained by mounting a jet engine simulator at the wing tip and directing the high-energy jet blast downstream into the vortex. These configurations, among others, are now under intensive investigation in the new Langley Vortex Research Facility. In this facility, a balance mounted vortex generating model is propelled along a 1800-foot track while a second model trailed at 160 feet (scale distance of 1 mile) measures the far-field rolling moment induced by the vortex of the generating model.

Patterson, Jr., J. C.

"UNDERWING COMPRESSION VORTEX ATTENUATION DEVICE"

U.S. Patent 5,230,485, July 1993

A vortex attenuation device is presented which dissipates a lift-induced vortex generated by a lifting aircraft wing. The device consists of a positive pressure gradient producing means in the form of a compression panel attached to the lower surface of the wing and facing perpendicular to the airflow across the wing. The panel is located between the midpoint of the local wing cord and the trailing edge in the chord-wise direction and at a point which is approximately 55 percent of the wing span as measured from the fuselage center line in the spanwise direction. When deployed in flight, this panel produces a positive pressure gradient aligned with the final roll-up of the total vortex system which interrupts the axial flow in the vortex core and causes the vortex to collapse.

Patterson, Jr., J. C. and Flechner, S. C.

"AN EXPLORATORY WIND TUNNEL INVESTIGATION OF THE WAKE EFFECT OF A PANEL TIP-MOUNTED FAN-JET ENGINE ON THE LIFT-INDUCED VORTEX"

NASA TN D-5729, May 1970, NASA Langley Research Center, Hampton, VA

An investigation has been conducted in the Langley 8-foot transonic pressure tunnel to determine the effectiveness of a tip-mounted powered-model high-bypass fan-jet engine in reducing the tip vorticity of an unswept symmetrical panel. The effects of end plates, a body of revolution, and a flow-through nacelle on panel-tip vorticity were also determined for comparison.

Patterson, Jr., J. C. and Jordon, Jr., F. L.

"THRUST-AUGMENTED VORTEX ATTENUATION"

Proceedings Wake Vortex Minimization Symposium, NASA, SP-409, 1977, pp. 251-270

An experimental investigation has been conducted in the Langley Vortex Research Facility to determine the vortex attenuating effect of engine thrust. Tests were made using a 0.03-scale model of the Boeing 747 transport aircraft as a vortex-generating model. A Learjet-class probe model was used to measure the vortex-induced rolling moment at a scale separation distance of 1.63 km (0.88 n. mi.). These tests were conducted at a lift coefficient of 1.4 at a model velocity of 30.48 m/s. The data presented in this paper indicate that engine thrust is effective as a vortex attenuating device when the engines are operated at high thrust levels and are positioned to direct the high-energy engine wake into the core of the vortex. The greatest thrust vortex-attenuation is obtained by operating the inboard engine thrust reversers at one-quarter thrust and the outboard engines at maximum forward thrust.

"A STATIC-AIR FLOW VISUALIZATION METHOD TO OBTAIN A TIME HISTORY OF THE LIFT-INDUCED VORTEX AND CIRCULATION"

NASA TM X-72769, September 1975, NASA Langley Research Center, Hampton, VA.

An investigation of a recently proposed method of flow visualization has been conducted at Langley Research Center. This method of flow visualization is particularly applicable to the study of lift-induced wing tip vortices through which it is possible to record the entire life span of the vortex. To accomplish this, a vertical screen of smoke is produced perpendicular to the flight path and allowed to become stationary. A model is then driven through the screen of smoke producing the circular vortex motion made visible as the smoke is induced along the path taken by the flow and is recorded by high-speed motion pictures.

"AN INVESTIGATION OF THE INCREASE IN VORTEX INDUCED ROLLING MOMENT ASSOCIATED WITH LANDING GEAR WAKE"

NASA TM X-72786, November 1975, NASA Langley Research Center, Hampton, VA

As part of a NASA-wide program now underway to attempt to reduce the hazard associated with the lift-induced vortex system of large aircraft, a flight test has been conducted at Flight Research Center to verify the results found in the ground base facilities of the effect of span load variation as well as the vortex attenuation of the high energy jet engine exhaust through proper thrust programming. During these flight tests a large increase in vortex strength was experienced because of extending the landing gear. Tests in the Langley Vortex Research Facility indicate that the wake produced by the landing gear

may possibly form an aerodynamic endplate or reflection plane at the inboard edge of each inboard flap which increases the effective aspect ratio of the flap and thereby increases the strength of the flap outer edge vortex.

"GROUND DEVELOPMENT AND FLIGHT CORRELATION OF THE VORTEX ATTENUATING SPLINE DEVICE"

Proceedings Wake Vortex Minimization Symposium, NASA, SP-409, 1977, pp. 271-304

The data presented in this report indicate that the wing-mounted spline is a effective vortex-attenuating device. A comparison of the vortex-induced rolling moment results at a separation scale distance of 0.70 km (0.38 n. mi.) obtained in the Langley Vortex Research Facility with those measured in full-scale flight indicate good agreement for the unattenuated vortex configuration. The comparison also indicates that the spline effectiveness in flight was greater than in the ground facility test. The results of an applications study show that, for the heavy commercial jet aircraft studied, use of the splines does result in some degradation of the climb gradient and rate of climb, but the aircraft should meet certification requirements.

"RECENT RESULTS ON THE EFFECT OF CROSS SECTION ON HYDROFOIL TIP VORTEX OCCURRENCE AT HIGH REYNOLDS NUMBERS"

Cavitation and Multiphase Flow Forum, ASME Vol. 153, 1993, Washigton, DC, pp. 81-86.

Critical cavitation numbers and velocity, axial and tangential, profiles of the tip vortex issued from a 3.8 area ratio elliptical hydrofoil with a NACA0020 cross section at high Reynolds numbers were obtained in the GTH. They are compared with those of a NACA16020 hydrofoil having the same planform. It is shown that for equal experimental conditions, the NACA0020 foil display much larger desinence cavitation numbers as well as larger tangential and axial velocities. The data analysis demonstrates that the modification of the velocity field at the tip of the foil around the vortex, because of the change of the cross section is mainly responsible for most of the observed changes.

"INFLUENCE OF VORTEX DYNAMICS AND ATMOSPHERIC TURBULENCE ON THE EARLY EVOLUTION OF A CONTRAIL"

Atmospheric Chemistry and Physics, Vol. 10, 2010, pp. 3933-3952.

This study describes three-dimensional numerical simulations of the evolution of an aircraft contrail during the first 30 min following the emission of exhausts. The wake is modeled as a vortex pair descending in a stratified atmosphere where turbulent fluctuations are sustained in the late dissipation regime. The focus of the study is laid on the interactions between vortex dynamics, atmospheric

turbulence and contrail microphysics, and their role in determining the growth and the distribution of ice crystals. The atmospheric turbulence is synthesized using a methodology developed to force anisotropic turbulent fluctuations. The results show the feasibility of three-dimensional simulations of the early development of a contrail in supersaturated conditions before its transition into a contrail-cirrus. It is shown that in case of strongly supersaturated and shear-free atmosphere the optical depth is maintained as the contrail spreads by turbulent diffusion in the late dissipation regime.

"EXPERIMENTAL STUDY OF THE DEVELOPMENT OF LONGITUDINAL VORTEX PAIRS EMBEDDED IN A TURBULENT BOUNDARY LAYER"

AIAA Journal, Vol. 26, No. 7, July 1988, pp. 816-823

The mean streamwise development of pairs of longitudinal vortices and arrays of longitudinal vortices embedded in an otherwise two-dimensional turbulent boundary layer is studied. Planes of closely spaced measurements of the three components of mean velocity were obtained at several streamwise locations, and the vorticity and circulation were calculated. It was found that the rate of vorticity spreading in a vortex was greatly increased by proximity of other vortices. Vortices remaining close to the wall produced significant levels of spanwise skin friction and, thus, a greater rate of streamwise circulation decrease.

"EFFECT OF THE CALM-ATMOSPHERE STRATIFICATION ON THE EVOLUTION OF AN AIRCRAFT VORTEX WAKE"

In: Investigation of Vortex Wake Evolution and Flight Safety - Collection of Papers, Trudy TsAGI, Vol. 2622, Publishing Dept. of TsAGI, Moscow, Russia, 1996, pp. 81-89

The process of the entry of a pair of laminar rectilinear vortices into an atmospheric layer with stable stratification is investigated using the numerical solution of the two-dimensional time-dependent Navier-Stokes equations in the Boussinesq approximation. The solution is obtained on a uniform 200 x 200 grid using an explicit finite difference scheme at a flow Reynolds number of $Re = 1,000,000$ for a lapse rate temperature anomaly of 2K per 100 m rise. The calculations have shown that at the initial stage of the submersion of the vortex pair into the stratified layer a deceleration of its descent is observed; during the further descent into the layer the vortices approach one another and their descent rate increases. [In Russian.]

"EVOLUTION OF VORTEX PAIR BEHIND AN AIRCRAFT IN AN ATMOSPHERIC LAYER WITH SIDE SHEAR WIND"

In: Investigation of Vortex Wake Evolution and Flight Safety Problems - Collection of Papers, Trudy TsAGI, Vol. 2627, Publishing Dept. of TsAGI, Moscow, Russia, 1997, pp. 93-101

A numerical modeling of evolution of a vortex pair in atmospheric layer with side shear wind has been performed. Computational method is based on finite difference solution of the Reynolds averaged two-dimensional unsteady Navier-Stokes equations, with longitudinal component of vorticity and stream function being used as dependent variables. For the system closure the second order differential model of turbulence proposed by Donaldson is used. It was assumed that temperature variation with height corresponds to adiabatic atmosphere (no stratification occurs) and side wind velocity linearly varies with height, i.e., the vortex pair is immersed in a homogeneous field of background vorticity. Flow field parameters (longitudinal component of vorticity and Reynolds stress tensor components) are presented for different moments of time and two values of vertical gradient of side wind velocity. Time dependence of circulation of both the vortices is presented. It is shown that at the peripheral region of the vortex having the same sign of vorticity as that of the background one turbulent pulsation intensity is increased which results in increasing the diffusion of the vortex. The other vortex with the same sign of vorticity as that of the background vorticity varies though slightly.

Pavlenko, A. A.

"INFLUENCE OF THE CALM ATMOSPHERIC STRATIFICATION ON THE EVOLUTION OF THE VORTEX WAKE BEHIND AN AIRCRAFT"

International Science and Technology Center, Moscow, Annual Report, Project 201-95, 1996, pp. 33-40

The process of entrance of a pair of laminar rectilinear vortices into an atmospheric layer with stable stratification is modeled by solving numerically the two-dimensional time-dependent Navier-Stokes equations in Boussinesq's approximation. The solution is obtained on an 200x200 uniform grid using an explicit finite-difference scheme at a flow Reynolds number of $Re=1,000,000$ and a temperature anomaly gradient of 2K per 100m height increment. The computations have shown that at the initial phase of immersion of the vortex pair into the stratified layer, a retardation of their descent is observed, then vortices bring together and the rate of their descent becomes higher.

"RUNWAY OCCUPANCY TIME AS ELEMENT OF RUNWAY CAPACITY"

Promet - Traffic & Transportation, Vol. 18, No. 4, 2006, pp. 293-299.

A great many factors determine airside capacity. In the first group are those factors correlated with characteristics of maneuvering areas such as number, layout and location of runways and taxiways. In the following group there are elements correlated with flight operations such as arrival, departure, touch and go operations and the factors related to the aircraft such as weight, separation and wake vortex separation criteria. In the last group there are all other elements such as meteorological conditions and restrictions, ecological conditions, air traffic control skills and equipment, etc. This

paper presents a detailed description of runway occupancy time in arriving and departing flight operations and indications for possible improvements.

Pavlov, V., Buisine, D. and Decossin, S.

"INSTABILITY AND FEATURES OF VORTEX SHEET EVOLUTION"

Comptes Rendus Mecanique, Vol. 330, Issue 11, November 2002, pp. 757-762

The instability and the features of vortex sheet evolution are studied. We consider the self-organization of localized vortices (in two-dimensional flows) into clusters-like and spiral-like structures and show that quasi-final states do not 'forget' conditions of their initial origin. We discuss the physical significance of the obtained results.

"ON THE EFFECT OF SPANWISE CIRCULATION DISTRIBUTION ON THE VORTEX WAKE INTENSITY"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 191- 194

This paper considers a possibility to reduce the aircraft vortex wake intensity through redistributing its spanwise circulation, but maintaining the total lift and flight speed.

Peace, A. J. and Riley, N.

"A VISCOUS VORTEX PAIR IN GROUND EFFECT"

J. Fluid Mech., Vol. 129, April 1983, pp. 409-426

We calculate the flow induced by a vortex pair in a viscous fluid, which is otherwise at rest, in the presence of a plane boundary. This may be either a no-slip or a stress-free boundary. The phenomenon of rebound of the vortices from the boundary occurs for either type of boundary, and an explanation for this is offered in terms of viscous effects.

Peebles, J. L.

"EXPERIMENTAL INVESTIGATION OF THE VORTEX STRUCTURE OF A PROTOTYPE V-22 BLADE TIP"

MS Thesis, University of Texas, Arlington, TX, August 1997

The aerodynamic characteristics of an advanced helicopter rotor blade tip were experimentally determined using test conditions typically encountered by rotor tips ($M=0.80$ with $Re=9,800,000$). In the first phase of the test, stagnation pressure surveys of the airfoil wake were performed at two downstream chord stations (0.1 chord and 1.0 chord) and two angles of attack (0 and 3 degrees) using

a wake rake. This yielded preliminary qualitative data in the form of pressure deficits in the wake of the airfoil. Quantitative data about the flow field in the wake were then obtained using a five-hole probe. Data from the probe were used to determine the velocity components in the vicinity of the pressure deficits previously identified. Finally, the lift, drag, and pitching moment coefficients were calculated using data obtained with a five-component sidewall balance.

"COMPUTATION OF AIR-VORTICES BASED ON GPU TECHNOLOGY -- OPTIMIZING AND PARALLELIZING A MODEL FOR WAKE-VORTEX PREDICTION USING OPENCL"

MS Thesis, July 2013, Royal Institute of Technology, Stockholm, Sweden.

This thesis details the refinement and numerical solution of a preexisting model for predicting the strengths and positions of so-called wake-vortices that are generated from the lift of heavy aircraft. The ultimate objective is to implement a numerical scheme for the model that is fast enough to allow for probabilistic methods, such as Monte Carlo simulations, to deal with the inherent uncertainty in input parameters for wake-vortex predictions. The differential equation system of the wake-vortex model is stated clearly, which has not been done before. The refinement consists in reducing the number of necessary state variables in the differential equation system. A numerical algorithm based on the mathematical properties of the model is implemented and different ways of optimizing the computations are considered, e.g. through parallelization. Finally, a study will be made trying to assess the validity of the results through analyses of the accuracy and of the model's sensitivity to small input parameter variations.

"INTERACTION VORTEX - BOUNDARY LAYER: NUMERICAL STUDY OF WALL MECHANISMS"

Proceedings of 3rd International Workshop on Vortex Flows and Related Numerical Methods, ESAIM, Vol. 7, 1999, pp. 325-334

The interactions between a coherent vortex structure and a flat plate boundary layer are investigated. The unsteady numerical method used associates the Vortex-In-Cell algorithm for the convection step to the Random Walk algorithm for the diffusion one. The boundary layer is discretized by many vortices, 100,000. An appropriate choice of discretization parameters leads to a good solution for the flat plate and exhibits a minimal numerical dissipation. Interactions are studied for different Reynolds numbers, for positive and negative vortices. The Lighthill's mechanism of production of vorticity is observed. In the case of a negative vortex, a recirculation zone appears and a secondary structure with positive vorticity is created inside the boundary layer. The ejection of this structure induces the rebound of the main vortex.

"OFFSHORE WIND PROFILING USING LIGHT DETECTION AND RANGING MEASUREMENTS"

Wind Energy, Vol. 12, 2009, pp. 105-124.

The advantages and limitations of the ZephIR, a continuous-wave, focused light detection and ranging (LiDAR) wind profiler, to observe offshore winds and turbulence characteristics were tested during a 6-month campaign at the transformer/platform of Horns Rev, the world's largest wind farm. The LiDAR system is a ground-based sensing technique which avoids the use of high and costly meteorological masts. Three different inflow conditions were selected to perform LiDAR wind profiling. Comparisons of LiDAR mean wind speeds against cup anemometers from different masts showed high correlations for the open sea sectors and good agreement with their longitudinal turbulence characteristics. Cup anemometer mean wind speed profiles were extended with LiDAR profiles up to 161 m on each inflow sector. The extension resulted in a good profile match for the three surrounding masts. These extended profiles, averaged over all observed stabilities and surface roughness lengths, were compared to the logarithmic profile. The observed deviations were relatively small. Offshore wind farm wakes were also observed from LiDAR measurements where the wind speed deficits were detected at all LiDAR heights. Profile-derived friction velocities and roughness lengths were compared to Charnock's sea roughness model. These average values were found to be close to the model, although the scatter of the individual estimations of sea roughness length was large.

"EXPERIMENTAL STUDY OF VORTEX DYNAMICS DURING BLADE-VORTEX INTERACTIONS"

AIAA Paper 2014-1284, January 2014, National Harbor, MD.

This paper describes the first-phase work of a comprehensive study on vortex dynamics during parallel blade-vortex interaction (BVI). Study of the vortex behavior sheds light on the fundamental interaction mechanism of BVI, and provides important validation data for computational investigations. Evidence has been found in previous studies that the vortex behavior during BVI varies with Reynolds number, but the effects are not clear. In the current study, the relation between Reynolds number and vortex behavior was investigated extensively. The influence of other factors on vortex behavior, such as vortex strength, is also discussed. A pneumatic vortex generation system has been built, which can produce vortices with good repeatability in location, size and strength. The experiment is performed in a low-speed wind tunnel using a planar particle image velocimetry (PIV) technique to characterize the vortex and record BVI incidence. Results indicate that the vortex behavior during BVI strongly depends on the separation distance (h/c) between the vortex and the airfoil. A decrease in vortex strength during BVI is generally observed for h/c less than 0.3. The PIV results also reveal the relation between Reynolds number and the vortex strength variation during the interaction.

"FLOW FIELD MEASUREMENT AROUND VORTEX CAVITATION"

Experiments in Fluids, Vol. 56, 2015, pp. 206-1 to 206-13.

Models for the center frequency of cavitating-vortex induced pressure-fluctuations, in a flow around propellers, require knowledge of the vortex strength and vapor cavity size. For this purpose, stereoscopic particle image velocimetry (PIV) measurements were taken downstream of a fixed half-wing model. A high spatial resolution is required and was obtained via correlation averaging. This reduces the interrogation area size by a factor of 2-8, with respect to conventional PIV measurements. Vortex wandering was accounted for by selecting PIV images for a given vortex position, yielding sufficient data to obtain statistically converged and accurate results, both with and without a vapor-filled vortex core. Based on these results, the low-order Proctor model was applied to describe the tip vortex velocity outside the viscous core, and the cavity size as a function of cavitation number. The flow field around the vortex cavity shows, in comparison with a flow field without cavitation, a region of retarded flow. This layer around the cavity interface is like the viscous core of a vortex without cavitation.

Pereira, J. C. F. and Sereno, J.

"UNCERTAINTY QUANTIFICATION OF A 2D VORTEX PAIR IN GROUND EFFECT"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

Stochastic 2D unsteady Navier-Stokes calculations of a vortex pair evolution under ground effect are reported. The numerical procedure is based on the polynomial chaos, representation of the stochastic process. The results include the uncertainty quantification of the 2D velocity field, originated from random perturbations characterized by a uniform Beta pdf and a coefficient of variability equal to 10 percent in the initial vortex circulation and initial vortex position of one of the vortices. The coupled system of equations resulting from the application of the Polynomial Chaos Method of random variables to the NS's requires several modes in the expansion series yielding at least the solution of 8 systems of momentum and continuity equations comprising 24 strongly coupled differential equations. The ensemble of possible solutions (events) will form large clouds of vorticity related to clustered groups of events. This 'mean vorticity' is not a physical quantity but it contains all possible solutions and corresponds to the most probable set of outcomes. The level of variability of the random input chosen is low, nevertheless, it was amplified up 9 times its initial value.

Perez, A. M., Lopez, G. O. D. and Escobar, J. A.

"COMPUTATIONAL STUDY OF THE WAKE OF A QUADCOPTER PROPELLER IN HOVER"

AIAA Paper 2017-3961, June 2017, Denver, CO.

Quadcopter is the main platform for Unmanned Aerial Vehicle (UAV), the use of this technology is growing fast in different industries such as agriculture, mining and oil and gas. Computational Fluid Dynamics (CFD) plays an important role in understanding the aerodynamics of UAVs. In the present paper, the Spalart-Allmaras and k- ω turbulence models were used to simulate a propeller used in a quadcopter in hover. Both models predicted the wake generated by the propeller, as well as thrust and moment coefficients. For validation, numerical results of thrust and torque were compared to experimental measurements based on flying tests. The wake, forces, torque, pressure, and velocity fields predicted by the two turbulence models are similar; the main difference found was in the turbulent viscosity field in the far wake. Both models overestimate thrust and torque around 18 percent, this difference could be due to the interaction of the wakes and with the fuselage that is not included in the present study.

Perez-Batlle, M., Marcos, M. and Pastor, E.

"EFFECTS OF EN-ROUTE WAKE VORTEX ON RPAS OPERATIONS"

Sixth SESAR Innovation Days, November 2016, Delft, The Netherlands.

Compared with common airliners, High/Medium Altitude Long Endurance (HALE/MALE) RPAS are lighter and have larger wingspan. Therefore, RPAS will be extremely sensitive to vortex interactions with larger airliners, not only during departures and arrivals, but also at medium and high altitudes during the enroute phase. The extent of this sensitivity shall be investigated to determine safe levels of separation and come up with feasible maneuvers to avoid the effect of wake vortex under the

assumption that the RPAS may become unrecoverable by the autopilot. For this reason, the objective of this paper is to model the generation of en-route vortex and quantify its impact into the airworthiness of a potentially conflicting RPAS. To accomplish this objective, a wake vortex generation and encounter model will be created as a first step to define the airliner-RPAS separation requirements due to the airliner's vortex. Then, vortex separation requirements will be compared to those usually employed for separation assurance. Conclusion will show that some current separation standards are not conservative enough when the RPAS faces an airliner wake vortex.

Perez-Saborid, M., Herrada, M. A., Gomez-Barea, A. and Barrero, A.

"DOWNSTREAM EVOLUTION OF UNCONFINED VORTICES: MECHANICAL AND THERMAL ASPECTS"

J. Fluid Mech., Vol. 471, 2002, pp. 51-70

We present a numerical study of the downstream evolution (mechanical and thermal) of vortex-jet cores whose velocity and temperature fields far from the axis match a family of inviscid and non-conducting vortices. The far-velocity field is rotational, except for a particular case which corresponds to the well-known Long's vortex. The evolution of the vortex core depends on both the conditions at a certain upstream station, characterized by the dimensionless value of the velocity at the axis, and a dimensionless swirling parameter L defined as the ratio of the values of the azimuthal and axial velocities outside the vortex core. This numerical study, based on the quasi-cylindrical approximation (QC) of the Navier-Stokes equations, determines the conditions under which the vortex evolution proceeds smoothly, eventually reaching an asymptotic self-similar behavior as described in the literature, or breaks in a non-slender solution (vortex breakdown). In particular, the critical value L beyond which vortex breakdown occurs downstream is a function of a dimensionless parameter a characterizing the axial momentum of the vortex jet at an initial upstream station. It is found numerically that for very large values of L , this vortex breakdown criterion tends to an asymptote which is precisely the value predicted by the self-similar analysis, and beyond which a self-similar structure of the vortex core does not exist. In addition, the computation of the total temperature field provides useful information on the physical mechanisms responsible for the thermal separation phenomenon observed in Ranque-Hilsch tubes and other swirling jet devices. In particular, the mechanical work of viscous forces which gives rise to an intense loss of kinetic energy during the initial stages of the evolution has been identified as the physical mechanism responsible for thermal separation.

"WAKE MODELLING FOR AERIAL REFUELLING USING AERODYNAMIC ADJOINTS"

AIAA Paper 2018-1758, January 2018, Kissimmee, FL.

The modelling of aircraft wakes is of interest for a variety of applications including air-to-air refueling and formation flight, both of which are operational practices that can result in fuel savings. However, aircraft flying in proximity often experience disruptions during flight due to wake turbulence, downwash, and aerodynamic coupling between aircraft. To predict the effect of a tanker aircraft's wake

on the flight dynamics of a refueling aircraft, a coupled vortex lattice method was developed and combined with sensitivity analysis that used an adjoint-based method to quickly predict the change in pitching moment caused by changes in the relative vertical position between the two aircraft. The results from this analysis were compared to existing computational data. Results showed good agreement with trends demonstrated by the existing data in terms of the effect of the tanker aircraft on the lift coefficient and pitching moment coefficient of the refueling aircraft. Differences between models in terms of the value of the tanker's effect on the refueling aircraft were noted. It was thought that these differences were caused by dissimilarities in the tanker models used. The adjoint-based sensitivities were shown to be accurate compared to a finite-difference based approach, but were calculated approximately five times faster. A survey of $d(C_{subm})/dz$ at various points behind a Hercules tanker was presented.

Peristy, L. H., Perez, R. E. and Jansen, P. W.

"WAKE MODELLING WITH EMBEDDED LATERAL AND DIRECTIONAL STABILITY SENSITIVITY ANALYSIS FOR AERIAL REFUELLING OR FORMATION FLIGHT"

AIAA Paper 2019-0583, January 2019, San Diego, CA.

Air-to-air refueling and formation flight are two operational practices that can result in fuel savings. However, aircraft flying in proximity can experience disturbances in terms of aerodynamic forces and moments due to wake turbulence, downwash, and aerodynamic coupling between aircraft. To predict the effect of an aircraft wake on the lateral and directional stability of a trailing aircraft, a coupled vortex lattice method was developed and combined with sensitivity analysis that uses an adjoint-based method to quickly predict the change in rolling moment and yawing moment caused by changes in the relative vertical and lateral position between the two aircraft. A combination of wind-tunnel and flight test data were used as test cases to validate the aerodynamic prediction model and adjoint derived sensitivities. Results showed good agreement with existing data. Regions of static stability were found using the adjoint based sensitivity analysis. These areas of stability were limited to areas where the lateral offset between aircraft was no greater than 40 % of the wingspan. The adjoint-based sensitivities were shown to be accurate when compared to a finite-difference based approach, but were calculated approximately four times faster.

Perkins, E. W. and Canning, T. N.

"INVESTIGATION OF DOWNWASH AND WAKE CHARACTERISTICS AT A MACH NUMBER OF 1.53. I - RECTANGULAR WING"

NACA RM-A8L16, March 1949, Ames Aeronautical Laboratory, Moffett Field, CA.

The results of an experimental investigation of the downwash and wake characteristics behind a rectangular plan-form wing in a supersonic stream are presented. The aspect ratio of the wing was 3.5, and the airfoil section was a 5-percent-thick, symmetrical, double wedge with maximum thickness at 50-percent chord. The tests were made at a Mach number of 1.53 and a Reynolds number, based on

the wing chord length, of approximately 1.25 million. A comparison has been made between the downwash angles predicted by the linear theory and the measured downwash angles predicted by the linear theory and the measured downwash angles. The experimental trends of the variation of downwash angle with angle of attack at zero lift in the spanwise, streamwise, and vertical directions were like those predicted by the linear theory, but in most instances the experimental values were slightly greater than those given by theory. The comparison also showed that the displacement of the vortex sheet and the resulting influence on the downwash distribution must be considered in calculating downwash angles at finite angles of attack. For the low-aspect-ratio wing used in this investigation, the distortion of the vortex sheet behind the wing-tip region had a considerable influence on the position of the wake and on the downwash distribution within a large portion of the induced flow field. In the region outboard of approximately the 30-percent semispan station, the distortion of the vortex sheet decreased the displacement of the sheet considerably from the value calculated by the linear theory.

Perkins, E. W. and Canning, T. N.

"INVESTIGATION OF DOWNWASH AND WAKE CHARACTERISTICS AT A MACH NUMBER OF 1.53. II - TRIANGULAR WING"

RM No. A9D20, June 1949, NACA, Ames Aeronautical Laboratory, Moffett Field, CA.

The results of an experimental investigation of the downwash and wake characteristics behind a triangular plan-form wing in a supersonic stream are presented. The leading-edge sweep angle and aspect ratio were 63 deg and 2.04, respectively. The wing had a 5-percent-thick, symmetrical, double-wedge airfoil section with maximum thickness at 50-percent chord. The tests were made at a Mach number of 1.53 and a Reynolds number, based on the mean aerodynamic chord, of approximately 2 million. Measurements were made of the variation of downwash angle with angle of attack at several positions within the induced flow field. Additional surveys were made to determine the position and extent of the friction wake. These experimental results were analyzed and compared with the characteristics calculated by means of the linear theory. Within that part of the induced flow field where the theory predicts downwash for positive angles of attack of the wing, the experimental values of the variation of the downwash angle with angle of attack through zero lift were found to be in good agreement with the theoretical predictions. Within the remainder of the induced flow field, the agreement was only fair. At angles of attack, appreciably different from zero, the measured downwash angles at the survey points depart markedly from the values predicted by the theory. The reasons for this departure differ in the positive and negative angle-of-attack ranges since the points at which the downwash angles were measured were at a fixed distance above the chord plane of the wing, and the downwash field, at any finite angle of attack, was not symmetric with respect to the extended chord plane. In the positive angle-of-attack range, the departure was primarily the result of the presence of a strong vortex in the induced flow field which was not predicted by the linear theory. In the negative angle-of-attack range, this departure may be attributed to the fact that the displacement of the vortex sheet from the free-stream direction was not as great as predicted by theory. The general characteristics of the friction wake were similar to those observed in subsonic flow. With increasing

distance behind the wing, the wake expanded slowly, decreased in intensity, and with the wing at positive angles of attack, moved downward relative to the free-stream direction.

Perkins, E. W. and Canning, T. N.

"INVESTIGATION OF DOWNWASH AND WAKE CHARACTERISTICS AT A MACH NUMBER OF 1.53. III - SWEPT WINGS"

NACA RM-A9K02, February 1950, Ames Aeronautical Laboratory, Moffett Field, CA.

The results of an experimental investigation of the downwash and wake characteristics behind two highly swept wings in a supersonic stream are presented. The leading-edge sweep angles of the two wings were 63 degrees and 63 degrees 45 minutes, the aspect ratios were 3.50 and 1.66, and the corresponding taper ratios were 0.25 and 1.00. The Mach number of the tests was 1.53 and the Reynolds numbers based on the mean aerodynamic chords were 1.4 million for the tapered wing and 2.6 million for the untapered wing. Measurements were made of the variation of downwash angle with angle of attack at several positions within the induced flow field. Additional surveys were made to determine the position and extent of the friction wake. The experimental downwash results were compared with the characteristics calculated by means of the linear theory. Agreement between the experimental and theoretical values of the rate of change of downwash angle with angle of attack at zero lift was good only at isolated points. In general, the experimental values for the tapered wing were much less than the theoretical. At most of the survey points the rate of change of downwash angle with angle of attack for the tapered wing did not exceed, at any angle of attack, the corresponding theoretical values of the rate of change of downwash at zero lift. The differences between the experimental results for the untapered wing and the theoretical calculations are believed to result from differences between the actual load distribution and that calculated by theory. The general characteristics of the friction wake were like those observed in subsonic flow. With increasing distance downstream from the trailing edge, the wake expanded and, with the wing at positive angles of attack, moved downward relative to the free-stream direction. In general, the maximum pitot-pressure loss at the wake center line decreased with increasing distance behind the trailing edge.

Perkins, S.

"DANGEROUS WAKE"

Science News, Vol. 161, June 2002, p. 387

A new mathematical analysis of an aeronautical hazard known as wake turbulence might eventually lead to improved air safety and increase the number of flights at major airports, scientists say. Using a mathematical model, Saffman and Hill examined how such vortices behave when they encounter wind shear, a natural phenomenon in which adjacent layers of air move at different speeds or in different directions. The researchers found that when the rotation that results opposes an aircraft-trailing vortex, it can cause the vortex to dissipate more quickly than usual. However, when the wind shear

rotates in the same direction as a vortex, the swirl persists longer than it does in the absence of wind shear.

Pern, N. J.

"WAKE VORTEX MITIGATION USING AN ADAPTIVE AIRFOIL"

MS Thesis, 1999, University of Kentucky, Lexington, Kentucky.

In this research, the concept of adaptive airfoils for wake vortex control is explored. Adaptive airfoils are a new area of interest in the field of aerodynamics and aerospace applications. Only recently has this idea become a major concern in the field. There are several concepts of adaptive airfoils in the current literature, but adaptive airfoil development is still in the infancy stage. Previous work done in this area will be briefly outlined and discussed. The idea of fabricating an adaptive airfoil with smart materials will be discussed thoroughly, as well as the potential problems and the future work required in adaptive airfoil development. The specific problem of wake vortex mitigation with adaptive airfoil technology will be addressed.

Pern, N. J. and Jacob, J. D.

"WAKE VORTEX MITIGATION USING ADAPTIVE AIRFOILS: THE PIEZOELECTRIC ARC AIRFOIL"

AIAA Paper No. 1999--524, Reno, NV, January 1999

The development of the vortex wake from a pair of adaptive circular arc airfoils is discussed. A piezo-ceramic actuator with a steel substrate serves as an adaptive airfoil. The baseline (zero potential) radius of curvature R is varied by changing the voltage applied across the arc airfoil. A maximum input voltage varies $R \pm 2\%$ resulting in a maximum change in lift coefficient of approximately 7%. This allows a simple method to examine the effect of unsteady lift coefficient on vortex development and wake mitigation. The application to wake mitigation is explored and preliminary experimental results are discussed. The wing-tip vortex is observed up to 12 chord-lengths downstream for varying frequency.

"A STATISTICAL ANALYSIS OF APPROACH WINDS AT CAPACITY-RESTRICTED AIRPORTS"

ATC-296, November 2000, MIT Lincoln Lab., Lexington, MA

A study was conducted on six major U.S. airports with closely-spaced parallel (CSP) runways that become capacity-restricted during times of lowered cloud ceilings and visibilities. These airports were SFO, BOS, EWR, PHL, SEA, and STL. Efforts are underway to develop a feasible system for simultaneous CSP approaches, which would increase the capacity at these airports during restrictive weather

conditions. When considering any new procedure, the wind conditions on approach are needed to understand the impact of wake turbulence transport. Wind observations from aircraft that are equipped with Meteorological Data Collection and Reporting System (MDCRS) capabilities were used to conduct a statistical analysis on wind characteristics at each airport. Data from January 1997 through December 1999 were used in each analysis. Data analysis techniques and the statistical results are presented in this report. This information is expected to support procedure and benefits assessment models.

Perras, G. H. and Dasey, T. J.

"A STATISTICAL ANALYSIS OF APPROACH WINDS AT CAPACITY-RESTRICTED AIRPORTS"

19th Digital Avionics Systems Conference, Philadelphia, PA, Vol. 1, Oct. 2000, pp. 3.E.4-1 - 3.E.4-7

Since ambient wind speed and direction are the most important factors when considering the possibility of a lateral wake vortex encounter, wind behavior around airports with closely-spaced parallel (CSP) runways needs to be well understood before simultaneous approaches during restrictive weather could ever be used in an operational setting. This paper presents a statistical analysis of wind behavior for several major airports with CSP runways by using aircraft wind observations. Specifically, speed and direction characteristics of headwinds and crosswinds are examined, as well as correlations between the two wind components with respect to each other and with respect to altitude. The resulting data should prove useful for Monte Carlo simulations of new CSP approach procedures.

"TURBULENCE CLIMATOLOGY AT DALLAS/FT. WORTH (DFW) AIRPORT - IMPLICATIONS FOR A DEPARTURE WAKE VORTEX SPACING SYSTEM"

NASA/L-4, November 2000, MIT Lincoln Lab., Lexington, MA

Potential adaptive wake vortex spacing systems may need to rely on wake vortex decay rather than wake vortex transport in reducing wake separations. A wake vortex takeoff-spacing system, in particular, will need to rely on wake decay. Ambient turbulence is the primary influence on wake decay away from the ground. This study evaluated 18 months of ambient turbulence measurements at Dallas/Ft. Worth (DFW) Airport. The measurements show minor variation in the turbulence levels at various times of the year or times of the day for time periods when a departure system could be used. Arrival system operation was also examined, and a slightly lower overall turbulence level was found as compared to departure system benefit periods. The Sarpkaya model, a validated model of wake vortex behavior, was applied to various turbulence levels and compared to the DFW turbulence statistics. The results show that wake vortices from Heavy aircraft on takeoff should dissipate within one minute for most of the time and will rarely last two minutes. These results will need to be verified by wake vortex measurements on departure.

Perry, R. B.

"REDUCED SPACING OPERATIONS OVERVIEW"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 5-10

Within NASA's Terminal Area Productivity program, the Reduced Spacing Operations sub element, based at NASA Langley Research Center, is performing research in three airborne areas to enhance airport terminal area capacity throughput. Wake vortex research is underway to build and demonstrate an Aircraft Vortex Spacing System (AVOSS) which will dynamically adjust the spacing between arriving aircraft while preserving or enhancing the current safety level. The design of AVOSS utilizes weather state predictions and real time wake vortex sensing to support both wake vortex transport and demise predictions. Airborne information for Lateral Spacing research is examining instrument approaches to closely spaced parallel runways using cockpit traffic displays and alerting cues. Flight Management System/Center TRACON Automation Center research is addressing the data link of applicable information between the ground and cockpit to enhance the operational efficiency of both.

Perry, R. B.

"NASA AIRCRAFT VORTEX SPACING SYSTEM (AVOSS) RESEARCH"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 25-26

The National Aeronautics and Space Administration (NASA) is addressing airport capacity enhancements during instrument meteorological conditions through the Terminal Area Productivity (TAP) program. Within TAP, the Reduced Spacing Operations (RSO) subelement at Langley Research Center is developing the Aircraft Vortex Spacing System (AVOSS) for use in establishing aircraft arrival scheduling based on dynamic wake vortex spacing criteria. The goal of AVOSS research underway is to develop and demonstrate an engineering model of a dynamic, weather dependent aircraft vortex spacing system, with required lead time and stability considerations, by the year 2000. In today's ATC system, AVOSS could inform ATC controllers when a fixed reduced separation becomes safe to apply to 'large' and 'heavy' aircraft categories. With appropriate integration into the Center/TRACON Automation System (CTAS), AVOSS could provide dynamic spacing tailored to actual generator/follower aircraft pairs rather than a few broad aircraft categories. NASA Langley Research Center recently integrated all the major AVOSS components during the initial field deployment of AVOSS at the Dallas/Fort Worth (DFW) International Airport, and is currently implementing a real-time AVOSS computational capability at NASA Langley to support ongoing real-time meteorological and wake vortex measurements from DFW.

Perry, R. B., Hinton, D. A. and Stuever, R. A.

"NASA WAKE VORTEX RESEARCH FOR AIRCRAFT SPACING"

AIAA Paper No. 1997-0057, Reno, NV, January 1997

The National Aeronautics and Space Administration (NASA) is addressing airport capacity enhancements during instrument meteorological conditions through the Terminal Area Productivity (TAP) program. Within TAP, the Reduced Spacing Operations (RSO) subelement at the NASA Langley Research Center is developing an Aircraft Vortex Spacing System (AVOSS). AVOSS will integrate the output of several inter-related areas to produce weather dependent, dynamic wake vortex spacing criteria. These areas include current and predicted weather conditions, models of wake vortex transport and decay in these weather conditions, real-time feedback of wake vortex behavior from sensors, and operationally acceptable aircraft/wake interaction criteria. In today's ATC system, the AVOSS could inform ATC controllers when a fixed reduced separation becomes safe to apply to 'large' and 'heavy' aircraft categories. With appropriate integration into the Center/TRACON Automation System (CTAS), AVOSS dynamic spacing could be tailored to actual generator/follower aircraft pairs rather than a few broad aircraft categories.

"TRACKING WEATHER'S FLIGHT PATH"

IEEE Spectrum, September 2000, pp. 38-45

Smoother, safer flying is in the forecast for all kinds of weather, thanks to aviation weather technologies now in development. In tackling the problem of turbulence generated behind an aircraft, the wake vortex, the concern is efficiency as well as passenger safety and comfort.

Pete, K. R., Smith, S. T. and Vicroy, D. D.

"MODEL VALIDATION OF WAKE-VORTEX/AIRCRAFT ENCOUNTERS"

AIAA Paper No. 2000-3979, Denver, CO, August 2000

Wake-vortex effects on a 10% scale model of the B737-100 aircraft are calculated using both strip theory and vortex-lattice methods. The results are then compared to data taken in the 30' x 60' wind tunnel at NASA Langley Research Center (LaRC). The accuracy of the models for a reduced geometry, such as with the horizontal stabilizer and the vertical tail removed, is also investigated. Using a 10% error in the circulation strength and comparing the model's results with the experiment illustrates the sensitivity of the models to the vortex circulation strength. It was determined that both strip theory and the vortex lattice method give accurate results when all the geometrical information is used. When the horizontal stabilizer and vertical tail were removed there were difficulties modeling the side force coefficient and pitching moment. With the removal of only the vertical tail unacceptable errors occurred when modeling the side force coefficient and yawing moment. Lift could not be accurately modeled with either the full geometry or the reduced geometry.

"ONE-YEAR OPERATIONAL MEASUREMENTS WITH A SONIC ANEMOMETER-THERMOMETER AND A DOPPLER SODAR"

Journal of Atmospheric and Oceanic Technology, Vol. 15, February 1998, pp. 18-28.

A Doppler sodar and an ultrasonic anemometer-thermometer, which are operated continuously at a nuclear research center in Germany, are described. Mean values and second moments including turbulent surface fluxes recorded over 1 yr are analyzed to assess their credibility. Particularly, the effects of rain on the data quality and the statistical bias caused by a reduced data availability -- typical for remote sensing measurements -- are investigated. Mean profiles of the vertical wind variance for different classes of Monin-Obukhov length, the mean vertical wind component versus wind direction, and the annual variation of 24-h averages of the surface heat flux are presented.

Peterson, C. W., Wolfe, W. P. and Payne, J. L.

"EXPERIMENTS AND COMPUTATIONS OF ROLL TORQUE INDUCED BY VORTEX-FIN INTERACTION"

AIAA Paper No. 2004-1069, Reno, NV, January 2004

An experiment was conducted in Arnold Engineering Development Center's 16-ft transonic wind tunnel to measure dependency of vortex-induced counter torque upon J (the ratio of spin motor jet dynamic pressure to freestream dynamic pressure), Mach number, Reynolds number, angle of attack and roll orientation, spin motor nozzle configuration, and fin cant angle. Counter torque data and Laser Vapor Screen images confirm that J is the dominant parameter for correlating counter torque produced by a given vehicle configuration, flight condition, angle of attack and roll orientation. At $M = 0.8$ (with no shock waves in the flow), we observed a monotonic variation of the counter torque coefficient with J that is independent of Reynolds number but dependent on angle of attack and the orientation of the fins with respect to the spin motor nozzle azimuthal location. At $M = 0.95$ and 1.1 , measured values of counter torque coefficient were strongly influenced by changes in Reynolds number, suggesting that shock-boundary layer interaction may be present.

"CORRELATION OF WIND TUNNEL AND FLIGHT TEST RESULTS OF A FULL-SCALE HINGELESS ROTOR"

Aeromechanics Specialists Conference, American Helicopter Society, January 1994, San Francisco, CA, pp. 2.2-1 - 2.2-16.

Correlation of wind tunnel results of a full-scale four-bladed hingeless rotor system with flight test measurements is presented. The results presented are from a recently completed full-scale rotor test in the NASA Ames 40- by 80-Foot Wind Tunnel and a recently completed flight test of a BO-105 helicopter at the DLR, Braunschweig, Germany. Rotor hub and blade loads are shown over a range of

advance ratios from 0.1 to 0.34 for rotor thrust coefficient = 0.07. Good correlation of measured blade root flap bending moments in the wind tunnel with flight test measurements is shown when the rotor is trimmed to measured flight hub pitching and rolling moments. Analytical results using the CAMRAD/JA (Comprehensive Analytical Model of Rotorcraft Aerodynamics and Dynamics, Johnson Aeronautics) analysis shows good correlation when the analysis is trimmed to isolated rotor once-per-revolution root flap moments.

"VORTEX STRETCHING IN A LAMINAR BOUNDARY LAYER FLOW"

Experiments in Fluids, Vol. 22, 1997, pp. 351-353.

A new technique to produce controlled stretched vortices is presented. The initial vorticity comes from a laminar boundary layer flow and the stretching is parallel to the initial vorticity. This low velocity flow enables direct observations of the formation and destabilization of vortices. Visualizations are combined with quasi-instantaneous measurements of a full velocity profile obtained with an ultrasonic pulsed Doppler velocimeter. Several modes of destabilization are observed and include pairing of two vortices, hairpin deformation, and vortex breakdown into a coil shape.

"INVESTIGATIONS OF TRANSONIC TRAILING EDGE FLOWS"

Proceedings of the Second Conf., Soc. for Computer Simulation, San Diego, CA, January 1986, pp. 199-210

An experimental study of several of the trailing edge and wake turbulence properties for a NACA 64A010 airfoil section was completed. The experiments were conducted at the Ohio State University Aeronautical and Astronautical Research Laboratory in the 6-inch x 22-inch transonic wind tunnel facility. The data were obtained at a free stream Mach number of 0.80 and a flow Reynolds number (based on chord length) of 5 million. The principal diagnostic tool was a dual-component laser Doppler velocimeter. The experimental data included surface static pressures, chordwise and vertical mean velocities, RMS turbulence intensities, local flow angles, and a determination of turbulence kinetic energy in the wake at chordwise locations between the transonic shock wave and the trailing edge, in the near wake just downstream of the trailing edge and in the far wake. At the two angles of attack tested (0 and 2 degrees), the turbulence intensities and turbulence kinetic energy were observed to decay in the streamwise direction. In the far wake, for the non-lifting case, the turbulence intensities were nearly isotropic. For the two-degree case, the horizontal component of the turbulence intensity was observed to be substantially higher than the vertical component.

Petry, H. J.

"AN OBJECT-ORIENTED SIMULATION OF THE C-17 WINGTIP VORTICES IN THE AIRDROP ENVIRONMENT"

M.S. Thesis, March 1997, Air Force Inst. of Tech., Wright-Patterson AFB, OH

This thesis effort focuses on the development of an object-oriented simulation of C-17 personnel airdrop operations and provides a tool for risk assessment of jumper and wingtip vortex interaction. Using the initial modeling efforts of the Wright Laboratory, this model expands those efforts to include random aircraft, wind and jumper movement within the simulation using MODSIM 3 as its language. Once the model was built, verified, and calibrated, it helped perform a preliminary analysis of jumper risk with varying element spacing and no crosswind. The results of the simulation provided 15 data points with which linear and logistic regression provided an estimation of the marginal rate of change of jumper/vortex encounter rate. Using the third order model shows that the encounter rate levels off around 24,000 feet spacing between element leaders at 12%, and stays as high as 11% at 32,000 feet before dropping to 0.4% at 34,000 feet. Further research and model improvements may bring the encounter rate down at the more distant spacing but that is left for post thesis analysis efforts.

Pfouts, R. A.

"A COMPARISON BETWEEN SIMULATED AND MEASURED FREE-FLIGHT VORTEX ENCOUNTER BEHAVIOR IN THE NASA LANGLEY FULL-SCALE WIND TUNNEL"

M.S. Thesis, August 1997, Old Dominion University, Norfolk, VA

An examination of the use of static measurements in simulating dynamic aircraft-wake encounters is presented. By comparing dynamic aircraft-wake vortex encounter measurements obtained in free-flight wind tunnel tests to data obtained from computer-simulated encounters based on static wind tunnel data, a determination is made concerning the validity of static vortex models in a dynamic flight environment. The development and testing of specialized elements of a flight simulation code are presented and dynamic free-flight measurements and predicted results are compared. This study shows that static modeling provides reasonable estimates for lateral encounter trajectories when the following aircraft model is farther than one-half its span from the vortex axis. When closer to the vortex axis, dynamic interactions occur between the aircraft model and the vortex that cause the simulator to overpredict the magnitude of vertical and roll accelerations. Although these dynamics interactions are not negligible and their effects cannot be fully estimated by static measurements, reasonable agreement exists between the simulations and the free-flight experiments which justify the use of static models for preliminary estimates of the effects of wake vortex encounters on in-flight operations.

Phillips, E. H.

"NTSB CRASH PROBE FOCUSES ON RUDDER"

Aviation Week & Space Technology, Vol. 142, No. 5, 30 January 1995, pp. 30-31

The U.S. National Transportation Safety Board is increasingly certain that the rudder control system of a Boeing 737-300 contributed to the crash of USAir Flight 427 last September near Aliquippa, Pa. However, tests conducted by Boeing engineers indicate the main rudder power control unit on USAir

Flight 427 was operating normally when the aircraft crashed. The result of a battery of tests and reviews of various possibilities indicated that wake turbulence combined with uncommanded rudder movement may have doomed Flight 427. Simulator tests indicate that a yaw rate of only 2.5 deg/sec is sufficient to cause an initial upset like that recorded by Flight 427. Pilot experts suspect that the rudder was deflected to the left about 15-17 deg throughout the descent.

Phillips, E. H.

"NASA/FAA TO STUDY WAKE VORTEX BEHAVIOR"

Aviation Week & Space Technology, Vol. 141, No. 18, 31 October 1994, p. 70

NASA and the FAA will begin benchmark tests this week at Memphis International Airport to determine if airport capacity can be increased by predicting the behavior and decay of wake vortices. If programs can be developed to accurately and reliably predict the direction and speed of an active vortex as well as when it will decay and cease to be a safety concern, airport capacity could be increased by as much as 12-15%.

Phillips, E. H.

"FAA PROGRAM TARGETS WAKE VORTEX THREAT"

Aviation Week and Space Technology, Vol. 140, No. 7, 14 February 1994, pp. 32, 36

The FAA plans to launch a new, internationally based wake vortex research program this year with the eventual goal of safely reducing aircraft separation standards and increasing airport capacity. The overall goal of the agency's program is to 'provide a scientific understanding of wake vortices' and develop technologies and guidelines to help pilots and air traffic controllers reduce vortex hazards in the airport and en route environments, the plan said.

Phillips, E. H.

"757 WAKE HAZARD CALLED OVERSTATED"

Aviation Week & Space Technology, Vol. 140, No. 6, 7 February 1994, pp. 24-25

The 757's wake signature is no greater than that of other aircraft in its class and requires no change in separation standards, according to FAA and NOAA officials. A report on Boeing 757 wake vortex strength has been 'misinterpreted' and 'no reason' exists to warrant increasing separation standards for aircraft trailing the transports on final approach.

Phillips, E. H.

"VORTEX TESTS MAY YIELD CLUES TO USAIR CRASH"

Aviation Week & Space Technology, Vol. 143, No. 14, 2 October 1995, p. 33.

Still searching for clues in the unsolved mystery of USAir Flight 427, the National Transportation Safety Board is completing wake vortex flight tests that may help investigators learn what caused the Boeing 737-300 to crash near Pittsburgh in September 1994. Initial data indicates that the wake turbulence generated by a 727-200 is more intense than existing computer models predict, and that the vortices are about 50% closer together.

Phillips, N. and Knowles, K.

"POSITIVE AND NEGATIVE SPANWISE FLOW DEVELOPMENT ON AN INSECT-LIKE ROTATING WING"

Journal of Aircraft, Vol. 50, No. 5, September-October 2013, pp. 1321-1332.

This paper presents an experimental investigation of the spanwise flow development on an impulsively started rotating rectangular wing at 45 deg angle of attack. Reynolds numbers of 500 and 15,000 were studied, which correspond to insect and flapping-wing micro-air-vehicle scales, respectively. Stereoscopic particle image velocimetry flowfield measurements were taken at various spanwise locations and sweep angles (angle of rotation from start) on a motor-driven rectangular wing immersed in a seeded water tank. At both Reynolds numbers, the development of the flow was characterized by the formation of strong positive (root-to-tip) and negative (tip-to-root) spanwise flows, which lost strength toward the tip and root, respectively. The negative spanwise flow appeared to be created by the tip vortex, which accelerated fluid from beyond the tip to the root and turned a portion of the positive spanwise flow back on itself, inducing a secondary vortex inboard of the tip vortex and rotating in the opposite sense. Peak positive and negative spanwise flows in both cases were on the order of the wingtip speed. The extent of negative spanwise flow formation on rectangular wings versus tapered wings, as observed in other studies, suggests that perhaps the formation of negative spanwise flow is dependent on wing geometry and the size of the tip vortex.

Phillips, W. F. and Hunsaker, D. F.

"DESIGNING WING TWIST OR PLANFORM DISTRIBUTIONS FOR SPECIFIED LIFT DISTRIBUTIONS"

Journal of Aircraft, Vol. 56, No. 2, March-April 2019, pp. 847-849.

Prandtl's classical lifting-line equation can be used to relate the chord-length distribution, twist distribution, and section-lift distribution for an unswept finite wing. This note presents a general analytic solution such that, given a specified section-lift distribution and either the chord-length distribution or the twist distribution, the third of these distributions can be obtained. If the section-lift distribution and wing planform are specified, the required twist distribution can be found. On the other hand, if the section-lift distribution and wing twist distribution are specified, the required planform can be found. Example solutions are also presented for a case of special interest when designing wings for minimum induced drag. The analytic relations presented in this paper can be used for general wing design and may be particularly useful in the design of morphing wings that can alter

the wing twist distribution and/or planform during flight to obtain optimum lift distributions for various flight phases.

"ESTIMATING THE LOW-SPEED DOWNWASH ANGLE ON AN AFT TAIL"

AIAA Paper No. 2002-0830, Reno, NV, January 2002

A closed-form analytic solution for the downwash induced on an aft tail by the main wing of an airplane is presented. This infinite series solution is based on Prandtl's classical lifting-line theory and accounts for the effects of wing planform shape as well as tail position and vortex rollup. The results obtained from the present analysis reduce to the known solution for an elliptic wing. Results for a tapered wing are also presented. This infinite series solution applies only to a main wing with no sweep or dihedral. However, an approximate correction is presented, which can be used with some caution for swept wings. Results obtained from this analytic solution are compared with other methods and experimental data.

Phillips, W. F., Anderson, E.A., Jenkins, J. C. and Sunouchi, S.

"ESTIMATING THE LOW-SPEED DOWNWASH ANGLE ON AN AFT TAIL"

Journal of Aircraft, Vol. 39, No. 4, July-August 2002, pp. 600-608

A closed-form analytic solution for the downwash induced on an aft tail by the main wing of an airplane is presented. This infinite series solution is based on Prandtl's classical lifting-line theory and accounts for the effects of wing planform shape, as well as tail position and vortex rollup. The results obtained from the present analysis reduce to the known solution for an elliptic wing. Results for a tapered wing are also presented. This infinite series solution applies only to a main wing with no sweep or dihedral. However, an approximate correction is presented, which can be used with some caution for swept wings. Results obtained from this analytic solution are compared with other methods and experimental data.

Phillips, W. R. C.

"TURBULENT PREDICTION AND MEASUREMENT IN A TURBULENT TRAILING VORTEX"

MERLTN 74-5, June 1974, McGill University, Montreal, Canada

The second order closure theory of Launder, Reece and Rodi is used to model the Reynolds stresses in a turbulent trailing vortex. The results are compared with data of a turbulent trailing vortex and are predicted well by the theory.

Phillips, W. R. C.

"THE TURBULENT TRAILING VORTEX DURING ROLL-UP"

J. Fluid Mech., Vol. 105, April 1981, pp. 451-467

The turbulent trailing vortex forming from a rolling-up vortex sheet is considered. The merged region is seen to rapidly attain a state of equilibrium and similarity variables are used to describe it. The detailed distributions of circulation and Reynolds stresses are seen to depend to some extent upon the initial spanwise distribution of circulation on the wing. It is found that two modes of decay of peak tangential velocity are possible depending upon the separation of the vortices.

Phillips, W. R. C.

"THE BOUNDARY LAYER BENEATH A RANKINE-LIKE VORTEX"

Proc. Royal Soc. London, Vol. 411, Series A, May 1987, pp. 177-192

In high lift situations trailing vortices spring from the suction surface of the wing tip, rather like a mini tornado. To simulate this situation, laser doppler anemometry is used to study the flow that results when a Rankine-like vortex rotates normal to a stationary horizontal disc. Measurements are made both in the boundary layer on the surface and in the vortex, which is observed to undergo various types of vortex breakdown.

Phillips, W. R. C.

"ON VORTEX BOUNDARY LAYERS"

Proceedings Royal Society of London, Series A, Vol. 400, August 1985, pp. 253-261.

Flow visualization is used to study the flow that results when a potential vortex rotates normal to a stationary horizontal disc. Close to the disc the vortex is observed to undergo a massive disruption, either of the axisymmetric or helical form. On some occasions the sense of the helix was observed to be opposite that of the outer flow as would be the case with vortex breakdown, while on other occasions it took the same sense as the outer flow.

Phillips, W. R. C. and Graham, J. A. H.

"REYNOLDS-STRESS MEASUREMENTS IN A TURBULENT TRAILING VORTEX"

J. Fluid Mech., Vol. 147, October 1984, pp. 353-371

Measurements of a turbulent trailing vortex in zero pressure gradient are described. These include mean velocities and all the components of the Reynolds-stress tensor. The measurements were made using linearized hot wires at stations 45, 78, and 109 chord lengths downstream of the wing. Axisymmetric jets or wakes were added coaxially to the vortex while the total circulation was held

constant, and their effect studied. It was found that increasing the flow force hastens the radial dispersion of vorticity; this is seen to be concurrent with higher turbulent intensities and Reynolds shear stresses. With the flux of excess axial momentum effectively zero, thereby approximating a turbulent line vortex, no discernable downstream change was observed in the velocity field and very little in the turbulence field. A balance of terms in the mean-momentum equations is presented and discussed. It is seen that, although the radial velocity is numerically much smaller than the axial velocity, terms that contain it, both in axial- and tangential-momentum equations, cannot be ignored, unless the magnitude of the flow force (divided by the fluid density) is much less than the square of the total circulation.

Pichugina, Y. L., Banta, R. M., Brewer, W. A., Lundquist, J. K., Kelley, N. D., Hardesty, R. M., Alvarez, R. J., Mirocha, J. D., Sandberg, S. P. and Weickmann, A. M.

"WIND TURBINE WAKE STUDY BY THE NOAA HIGH-RESOLUTION DOPPLER LIDAR"

16th Coherent Laser Conference, June 2011, Long Beach, CA.

The assessment of the velocity deficit and turbulence associated with operational turbines is a major issue for wind farm design and optimization of the spacing between turbines. The significant velocity deficit and turbulence generated by upstream turbines can reduce the power production and produce harmful vibrations in downstream turbines, which can lead to excess maintenance costs. The complexity of wake effects depends on many factors, both hardware (turbine size, rotor speed, and blade geometry, etc.) and meteorological (prevalent wind direction at the site, wind velocity, wind gradients, boundary layer stability, turbulence characteristics, etc.). A critical issue in addressing these problems is a lack of high-quality measurements, quantitatively characterizing the structure and intensity of turbine-generated wakes and the velocity deficits accompanying them. In this study we use the High-Resolution Doppler Lidar (HRDL), at the Earth System Research Laboratory of NOAA. Over the last decade, HRDL has been used to study flows associated with wind energy, and has a documented capability to observe wakes of obstacles on land, such as trees and buildings, and in water, such as oil platforms and moving ships. This paper will demonstrate HRDL's capability to perform turbine wake measurements. It will present results on wind flow conditions at the experimental site and wind-turbine wake characteristics, such as velocity deficits and downstream extent of wakes.

Picot, J., Paoli, R., Thouron, O. and Cariolle, D.

"LARGE-EDDY SIMULATION OF CONTRAIL EVOLUTION IN THE VORTEX PHASE AND IN INTERACTION WITH ATMOSPHERIC TURBULENCE"

Atmospheric Chemistry and Physics, Vol. 15, July 2015, pp. 7369-7389.

In this work, the evolution of contrails in the vortex and dissipation regimes is studied by means of fully three-dimensional large-eddy simulation (LES) coupled to a Lagrangian particle tracking method to treat the ice phase. In this paper, fine-scale atmospheric turbulence is generated and sustained by means of a stochastic forcing that mimics the properties of stably stratified turbulent flows as those

occurring in the upper troposphere and lower stratosphere. The initial flow field is composed of the turbulent background flow and a wake flow obtained from separate LES of the jet regime. Atmospheric turbulence is the main driver of the wake instability and the structure of the resulting wake is sensitive to the intensity of the perturbations, primarily in the vertical direction. A stronger turbulence accelerates the onset of the instability, which results in shorter contrail descent and more effective mixing in the interior of the plume. However, the self-induced turbulence that is produced in the wake after the vortex breakup dominates over background turbulence until the end of the vortex regime and controls the mixing with ambient air. This results in mean microphysical characteristics such as ice mass and optical depth that are slightly affected by the intensity of atmospheric turbulence. However, the background humidity and temperature have a first-order effect on the survival of ice crystals and particle size distribution, which is in line with recent studies.

"ON THE VORTEX PAIR QUICKLY FORMED BY SOME AEROFOILS"

J. Royal Aeronautical Society, Vol. 27, No. 154, October 1923, pp. 488-500

A study was made on the structure of a vortex in turbulent flow to determine the effect of eddies, if employed in airfoil theory. This study was done because eddies were so commonly found in real flow pass other bodies.

Pierrehumbert, R. T.

"A FAMILY OF STEADY, TRANSLATING VORTEX PAIRS WITH DISTRIBUTED VORTICITY"

J. Fluid Mech., Vol. 99, Pt. 1, July 1980, pp. 129-14.

An efficient relaxation method is developed for computing the properties of a family of vortex pairs with distributed vorticity, propagating without change of shape through a homogeneous, inviscid fluid. The numerical results indicate that a steady state exists even when the gap between vortices is arbitrarily small, and that as the gap closes the steady state approaches a limiting vortex pair with a cusp on the axis of symmetry. Comparison is made with an approximate theory due to Saffman, and agreement is found to be good until the vortices are almost touching. The energy of members of the family is computed, and possible means of experimental production are discussed.

"VORTICITY CONFINEMENT APPLIED TO TURBULENT WING TIP VORTICES FOR WAKE-INTEGRAL DRAG PREDICTION"

AIAA Paper 2013-2574, June 2013, San Diego, CA.

In the current study the vorticity confinement approach was applied to tip vortices shed by edges of stationary wings to predict induced drag by far-field integration in Trefftz plane. The vorticity

confinement parameter was evaluated first by application to convection of vortices in uniform flow and then to tip vortices shed by finite-aspect ratio rectangular wing in subsonic flight. Dependence of vorticity confinement parameter on the flight Mach number and the angle of attack was evaluated. The aerodynamic drag results with application of vorticity confinement are much closer to analytic lifting line theory compared to integration over surface of wing. While the viscous profile drag is more accurately evaluated by surface integration, the induced drag needs to be evaluated in the far field by applying vorticity confinement to prevent its numerical diffusion by upwind schemes. To apply vorticity confinement to viscous and turbulent flows, it is shown that vorticity confinement does not affect the physical rate of dissipation in viscous/turbulent flows at time scales corresponding to convection of vortices from the wing to Trefftz plane of integration. To account for turbulent effects on tip vortices, vorticity confinement was applied in combination with Spalart-Allmaras, k-e, and six Reynolds stresses models of turbulence.

"LOCALIZATION OF THE ACOUSTIC SOURCES OF THE A-340 WITH A LARGE PHASED MICROPHONE ARRAY DURING FLIGHT TESTS"

AIAA Paper No. 2002-2506, June 2002, Breckenridge, CO

Flyover measurements with a phased array of microphones extending over an area of 16 m by 16 m are reported. The 161-microphone array was made possible by combining hardware from ONERA and DLR. In this investigation of the airframe noise of an Airbus A340, the flyover altitudes were between 90 m and 165 m. The data reduction methods for moving objects of DLR and ONERA are compared. Some source maps are shown and discussed. It is demonstrated that nested arrays must be used for a study over a wide frequency range, and that comparisons of the noise maps between different arrays provide valuable information about the noise sources. The ONERA method is shown to be a powerful data reduction method based on a small number of microphones while the DLR method results in alias-free maps at the expense of a much larger number of microphones.

"WAKE VORTEX INCIDENTS REPORTED IN THE UK 1972-1976"

CAA Paper 77012, June 1977, Civil Aviation Authority, London, England

The CAA wake vortex incident reporting scheme was formally initiated in July 1972; reports had previously been collected on an informal basis and reasonably complete information is available on incidents occurring from January 1972 onwards. Pilots who believe their aircraft to have encountered a wake vortex are asked to complete a detailed questionnaire. Whenever possible, the reports are supplemented by spacing data supplied by the air traffic controllers and by meteorological data; this extra information is received as a matter of course when incidents are reported in the neighborhood of London Heathrow airport. In some cases it has been possible to examine flight data recordings from

aircraft involved in reported incidents. An examination is made of the rate of occurrence of incidents before and after the change in separation standards introduced in March 1974.

Pilie, R. J. and Jiusto, J. E.

"A LABORATORY STUDY OF CONTRAILS"

Journal of Meteorology, Vol. 15, April 1958, pp. 149-154.

Contrails were produced for laboratory study by burning aircraft fuels under controlled conditions of ambient temperature and humidity at pressure altitudes between 1000 and 300 mb. Observed critical formation temperatures differ from Appleman's theoretical data in a manner similar to that obtained on project CLOUD TRAIL flights. Laboratory experiments with these trails proved that the initial phase of the condensed moisture is liquid and produced strong evidence that, contrary to general belief, the final phase is sometimes liquid. Additional evidence was obtained indicating that Appleman's criterion for a barely visible trail (0.004 g per cubic meter of condensed moisture) is very nearly correct for ideal conditions of observation such as used in the laboratory, but is probably small by an order of magnitude or more for adverse conditions. By modifying Appleman's theory to allow for the production of a visible quantity of liquid water under adverse viewing conditions, agreement is reached with project CLOUD TRAIL data. Also presented is a simple interpretation of the theory which substantially reduces the labor required to compute critical temperatures for contrail formation.

Pinsker, W. J. G.

"THE HAZARD OF VORTEX WAKE ENCOUNTERS IN THE CRUISE"

TR 79063, June 1979, Royal Aircraft Establishment, Farnborough, England

Records are shown of encounters with vortex wakes of civil aircraft in enroute flight. These are of sufficient severity and frequency to constitute a potential airworthiness hazard. The principal concern is with airframe loads but one case is also documented of a major upset in roll.

Pinton, J.-F. and Brillant, G.

"SOUND AND VORTICITY INTERACTIONS: TRANSMISSION AND SCATTERING"

Theoretical and Computational Fluid Dynamics, Vol. 18, 2005, pp. 413-433

We review several aspects of the propagation of sound in vortical flows. We restrict ourselves to isothermal, humidity-free flows at low Mach number M . Since vorticity plays a major role in vortex-flow interactions we focus on vortical flows. We consider two main canonical situations. The first concerns the transmission of sound. We analyze the evolution of acoustic wavefronts as they propagate across a single vortex. The second situation addresses the scattering of sound waves by nonstationary vortices. We study the evolution of the acoustic pressure emitted in the far field, at an angle with the initial direction of propagation. In this geometry one performs direct spectroscopy of

the flow vorticity field. In each case, we review theoretical results and compare with experimental measurements and numerical simulations when available. We also briefly report how the following new acoustic techniques have recently been used to study complex or turbulent flows: time-resolved acoustic spectroscopy, speckle interferometry and Lagrangian particle tracking.

Pirozzoli, S.

"DYNAMICS OF RING VORTICES IMPINGING ON PLANAR SHOCK WAVES"

Physics of Fluids, Vol. 16, No. 5, May 2004, pp. 1171-1185

In the present paper the encounter of vortex rings with planar shock waves is studied in a three-dimensional environment, with the objective to assess the influence of shock and vortex strength and vortex orientation on the dynamics of the process. The study relies on numerical simulations performed by means of a state-of-the-art hybrid compact/WENO (weighted essentially nonoscillatory) shock-capturing algorithm to solve the Euler equations of gas dynamics. The study focuses on the characterization of the interaction in terms of the evolution of the geometrical parameters of the vortex and the mean flow properties such as kinetic energy and enstrophy. The vortex is compressed as it passes through the shock, and its characteristic dimensions decrease; at the same time its axis is deflected and the ring follows a complex dynamic evolution, even though a nearly steady state is reached for the global quantities. In particular, it has been found that the total vortex kinetic energy is generally nonincreasing after the interaction, while the enstrophy always increases. A simple theory is developed here to shed some light onto the physical phenomena involved, which is found to compare reasonably well with the results of the computations. Some final comments are made regarding the extension of the results reported in the present study to the analysis of shock-compressed turbulence.

Pirrung, G. R., Hansen, M. H. and Madsen, H. A.

"IMPROVEMENT OF A NEAR WAKE MODEL FOR TRAILING VORTICITY"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012083-1 - 012083-10.

A near wake model, originally proposed by Beddoes, is further developed. The purpose of the model is to account for the radially dependent time constants of the fast aerodynamic response and to provide a tip loss correction. It is based on lifting line theory and models the downwash due to roughly the first 90 degrees of rotation. This restriction of the model to the near wake allows for using a computationally efficient indicial function algorithm. The aim of this study is to improve the accuracy of the downwash close to the root and tip of the blade and to decrease the sensitivity of the model to temporal discretization, both regarding numerical stability and quality of the results. The modified near wake model is coupled to an aerodynamics model, which consists of a blade element momentum model with dynamic inflow for the far wake and a 2D shed vorticity model that simulates the unsteady buildup of both lift and circulation in the attached flow region. The near wake model is validated

against the test case of a finite wing with constant elliptical bound circulation. An unsteady simulation of the NREL 5 MW rotor shows the functionality of the coupled model.

"TOOLS FOR DYNAMIC ADJUSTMENT OF AIRCRAFT SEPARATIONS IN WAKE VORTICES"

ICAS Paper 2010-10.2.2, Sept. 2010, Nice, France.

To avoid the risk induced by wake vortices, minimum separation standards between aircraft in the arrival and departure flow have been defined which, nowadays seem to be overly conservative. The aim in the medium / long term of the work presented in this paper is to develop tools for aircraft guidance in the wake turbulence using predictive modelling of the vortices and measurements performed on board or transmitted from outside. Thus, this will enable to perform simulation tests on new operation procedures authorizing more throughput and to give some specifications for new sensors. The proposed avoidance tools are based on the frame of potential field methods, using flatness properties of the flight mechanic model of the aircraft in order to build feasible trajectories.

Plank, V. G. and Spatola, A. A.

"CLOUD MODIFICATION BY HELICOPTER WAKES"

Journal of Applied Meteorology, Vol. 8, August 1969, pp. 566-578.

Helicopter wake effects on stratus and stratocumulus clouds are described. Holes and troughs were created in such clouds with dimensions several hundred feet across. The velocities and penetration distances of the downwash flow beneath the HH-53B helicopter employed in the experiments were investigated by the release of a 'tracing agent' from the helicopter and by hovering at various altitudes above the water surface of a Florida bayou. The downwash velocities were as large as 100 ft/sec, near the rotor, and the downwash extended some 1300 ft beneath the helicopter (under near dry adiabatic conditions). A suggestion is made that helicopters might be employed operationally to clear radiation-type ground fog from airfield runways. The cloud clearing capabilities of the HH-53B helicopter are discussed in support of this suggestion, by reference to observational data and to the theory of Hohler.

Plascott, R. H.

"MEASUREMENTS OF THE PATHS OF THE VORTEX CORES SHED FROM THE WINGS OF A TYPICAL GUIDED-MISSILE MODEL AT $M = 1.57$ "

R. & M. No. 3016, March 1954, Aeronautical Research Council, Great Britain

The paths of the cores of the vortex sheets shed from the wings of a typical guided-missile model, having cruciform rectangular wings mounted on a long cone-cylinder body, have been traced in their movement downstream over a range of incidence and yaw from 5 to 20 deg and 0 to 20 deg respectively at $M = 1.57$. The measurements have shown that: (a) the cores of the vortex sheets

remain close to the plane parallel to the free stream containing the line of the mid-chords of the wings from which the vortex sheets are shed; (b) the movement of the fully rolled-up cores in this plane can, for practical purposes, be attributed entirely to the flow induced by the other wing; (c) estimates of the paths of the vortex cores based on slender-body theory do not agree at all well in the regions investigated owing to the presence of strong shock waves and rapid expansions. Estimates of the paths of the vortex cores based on a semi-empirical analysis have shown reasonable agreement, however, and it is considered that approximations similar to those made in these estimates for this configuration would give reliable values for other configurations in the regions near the wings; well downstream of this region a slender-body theory analysis would probably be satisfactory; (d) slender-body theory gives a reasonable estimate of the spacing of the cores of the fully rolled-up sheets at the zero yaw condition. Estimates of the characteristics of four rear surfaces using this vortex spacing have shown satisfactory agreement with experiment; and (e) further tests to check these conclusions on a large range of missiles seem desirable.

"LINEAR MULTIVARIABLE REGRESSION MODELS FOR PREDICTION OF EDDY DISSIPATION RATE FROM AVAILABLE METEOROLOGICAL DATA"

NASA/CR-2005-213504, July 2005, Hampton, VA

Linear multivariable regression models for predicting day and night Eddy Dissipation Rate (EDR) from available meteorological data sources are defined and validated. Model definition is based on a combination of 1997-2000 Dallas/Fort Worth (DFW) data sources. EDR from Aircraft Vortex Spacing System (AVOSS) deployment data, and regression variables primarily from corresponding Automated Surface Observation System (ASOS) data. Model validation is accomplished through EDR predictions on a similar combination of 1994-1995 Memphis (MEM) AVOSS and ASOS data, supplemented with testing using complementary DFW data train and test subsets. Model forms include an intercept plus a single term of fixed optimal power for each of these regression variables; 30-minute forward averaged mean and variance of near-surface wind speed and temperature, variance of wind direction, and a discrete cloud cover metric. Optimal powers are determined by maximizing explained variation during single variable least squares regression. Intercept and term coefficients are then determined by multivariable least squares regression using wind speed variance weighting. Distinct day and night models, regressing on EDR and the natural log of EDR respectively, yield best performance and avoid model discontinuity over day/night data boundaries. Existing AVOSS vortex prediction algorithms may use model predicted EDR from airport specific ASOS data to generate local weather dependent estimates of aircraft wake vortex transport and decay to assess the performance of future wake spacing system concepts. Model-ready, full year 1999 ASOS data for DFW and 11 additional airport sites is prepared for this purpose.

Plougonven, R. and Zhang, F.

"GRAVITY WAVES GENERATED BY JETS AND FRONTS AND THEIR RELEVANCE FOR CLEAR-AIR TURBULENCE"

In *Aviation Turbulence*, edited by R. Sharman and T. Lane, Chapter 19, 2016, Springer International Publishing Switzerland, pp. 385-406.

Jets and fronts are known from observations and modeling studies to be an important source of gravity waves, primarily waves with low intrinsic frequencies. Waves in the jet-exit regions have recurrently been documented and are now rather well understood. Nonetheless, other waves (e.g., involving convection) are also present in the jet/front regions, and there is no simple model available yet to quantitatively predict excited waves from the knowledge of the large-scale flow. Only a handful of case studies have analyzed how jet-generated gravity waves contribute to the occurrence of clear-air turbulence (CAT) in the vicinity of the upper tropospheric jet. They have confirmed that the modulation of vertical shear and stability by strong, low-frequency gravity waves produces localized bands of turbulence. Further studies would be required to discriminate between this and other mechanisms (convectively generated gravity waves, inertial instability) that lead to CAT in the vicinity of jet streaks.

Poisson-Quinton, P. and Werle, H.

"WATER TUNNEL VISUALIZATION OF VORTEX FLOW"

Astronautics and Aeronautics, Vol. 5, June 1967, pp. 64-66

The complexities and subtleties of vortex flow about the wings, fins and fuselage of slender aircraft and missiles have been revealed elegantly by a small water-tunnel. Visualization of the vortices is obtained (1) by colored emissions that show the streamlines near the model and (2) by air-bubbles showing the flow in a thin lighted section either normal or parallel to the flow.

Polentz, P. P.

"COMPARISON OF THE AERODYNAMIC CHARACTERISTICS OF THE NACA 0010 AND 0010-64 AIRFOIL SECTIONS AT HIGH SUBSONIC MACH NUMBERS"

NACA RM A9G19, October 1949, Ames Aeronautical Laboratory, Moffett Field, CA.

A wind-tunnel investigation has been conducted to determine the lift, drag, and pitching-moment characteristics of the NACA 0010 and 0010-64 airfoil sections at Mach numbers up to 0.91 and Reynolds numbers between 1,000,000 and 1,900,000. The results are compared to illustrate the effects of varying the chordwise location of maximum thickness from 30-percent to 40-percent chord on the principal high-speed characteristics of the sections. A virtually unchanged Mach number for lift divergence, a decrease in lift-curve slope of approximately 10 percent, and a reduced maximum lift coefficient at Mach numbers below 0.70 were associated with the more rearward location of maximum thickness. The Mach number for drag divergence was increased about 0.05 at lift coefficients up to 0.4,

but the rate of drag rise above the Mach number for drag divergence was not appreciably changed. Pitching moment was affected to a negligible degree.

Polhamus, E. C.

"CHARTS FOR PREDICTING THE SUBSONIC VORTEX-LIFT CHARACTERISTICS OF ARROW, DELTA, AND DIAMOND WINGS"

NASA TN D-6243, April 1971, NASA Langley Research Center, Hampton, VA.

The leading-edge-suction analogy method of predicting the aerodynamic characteristics of slender delta wings has been extended to cover arrow- and diamond-wing planforms. Charts for use in calculating the potential- and vortex-flow terms for the lift and drag are presented, and a subsonic compressibility correction procedure based on the Prandtl-Glauert transformation is outlined.

"GROUND BASED LARGE SCALE WAKE VORTEX INVESTIGATIONS BY MEANS OF PARTICLE IMAGE VELOCIMETRY: A FEASIBILITY STUDY"

Advanced In-Flight Measurement Techniques, Research Topics in Aerospace, edited by F. Boden et al, Chapter 17, 2013, Springer-Verlag Berlin Heidelberg, pp. 291-304.

The investigation of aircraft wake vortices is a fundamental challenge in aerospace research. The enhanced safety and efficiency given by better prediction and detection of these complex vortex systems is significant. Within Advanced In-Flight Measurement techniques several non-intrusive optical methods were considered to visualize and measure the wake vortex of a landing aircraft. The main objective of the herewith presented campaign was the application of the Particle Image Velocimetry (PIV) to the investigation of these vortex flows. This report describes the first steps and approaches for the implementation of a large-scale PIV measurement system for the determination of wing wake vortices of a landing aircraft. Many issues have to be addressed before the flyover test could be carried out. During the realization phase of this experiment several steps were considered and discarded, a prototype of a seeding generator based on helium filled soap bubbles was designed and preliminary studies have been carried out exclusively for the investigation of the laser light sheet behavior when propagating over large distances. This report presents a summary of all the considerations and pretests for this application.

Politz, C., Over, B. and Kirmse, T.

"THE APPLICATION OF BACKGROUND ORIENTED SCHLIEREN METHOD TO AIRCRAFT WAKE VORTEX INVESTIGATIONS"

Advanced In-Flight Measurement Techniques, Research Topics in Aerospace, edited by F. Boden et al, Chapter 19, 2013, Springer-Verlag Berlin Heidelberg, pp. 321-329.

Vortex wakes of conventional aircraft and their propagating nature close to the ground have a great impact on the safety and efficiency of the traffic flow on an airport. The development of a measurement technique which helps detecting e.g. the density gradients in the air due to the wake vortices and understanding the nature of such a flow structure in its natural environment can improve the predictability of this hazardous phenomenon. Therefore, the practical aspects of the implementation of an advanced Schlieren technique on an airport are described in this chapter. Two experiments based on slightly different setups and locations relatively to the runway were conducted to access the feasibility of the Background Oriented Schlieren method for the detection and investigation of aircraft wake vortices. The evaluation of the obtained data indicated a sufficient ability of this technique to detect strong density gradient but on the other hand, turned out to be less efficient when dealing with the peculiarities of a large-scale outdoor experiment.

"CFD STUDY OF BLUFF BODY WAKE FROM A HANGAR WITH COMPARISON TO EXPERIMENTAL DATA"

AIAA Paper No. 2011-3351, June 2011, Honolulu, Hawaii.

The Cobalt V5.0 CFD solver was applied to the prediction of bluff body wake from a model scale hangar configuration at a Reynolds number of 1,600,000. Results were compared against 144th scale surface pressure coefficient and surface oil flow wind tunnel data. Baseline CFD predictions applied a monotone integrated large eddy simulation turbulence modeling approach. Results from delayed detached eddy simulation are also discussed.

Pomeroy, B. W. and Visser, K. D.

"A COMPUTATIONAL STUDY OF INDUCED DRAG BEHAVIOR FOR SPANWISE CAMBERED WINGS"

AIAA Paper No. 2010-4227, June-July 2010, Chicago, Illinois.

Results from lifting line theory, vortex lattice methods, and Euler techniques suggest that simple spanwise cambering of a planar wing, resulting in a reduced projected span but equivalent arc length and area, reduces the induced drag. Lifting line theory suggested a reduction of induced drag in positive cambered wings by almost 1 percent for certain configurations. Three-dimensional Euler flow solutions were obtained using the TetrUSS package from NASA Langley and suggested a drag reduction of as much as 1.6 percent, or 4.3 drag counts for the current configuration, with upward cambered wings. Viscous solutions were also run on the optimum Euler geometry and indicated reduced improvements of less than 1 count or 0.30 percent. Initial optimization with twist improved the Euler results to 2 percent.

Pomin, H. and Wagner, S.

"NAVIER-STOKES ANALYSIS OF HELICOPTER ROTOR AERODYNAMICS IN HOVER AND FORWARD FLIGHT"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 813-821

Reynolds-averaged compressible Navier-Stokes computations are presented for the hovering 7A model rotor and a low aspect ratio NACA0012 rotor in nonlifting forward flight. For enhanced hover performance prediction, aeroelastic effects are considered by tightly coupling the flow solver with a finite element model of the blade based on Timoshenko beam theory. Good agreement between computed and measured rotor performance is achieved for three collective pitch settings on structured periodic grids featuring noncongruent cell faces along the periodicity planes. Results of a hybrid Navier-Stokes/Euler chimera hover computation are presented, in addition to the periodic grid analysis demonstrating the superiority of the overset grid approach with respect to tip vortex conservation. The unsteady Navier-Stokes computations for the nonlifting forward flight test case show more sensitivity relative to time step size than comparable Euler analyses. Overall correlation of computed and experimental near-tip pressure distributions over blade azimuth is fair, and the strong transonic effects on the advancing blade are adequately captured by the numerical analysis.

Pond, S., Smith, S. D., Hamblin, P. F. and Burling, R. W.

"SPECTRA OF VELOCITY AND TEMPERATURE FLUCTUATIONS IN THE ATMOSPHERIC BOUNDARY LAYER OVER THE SEA"

Journal of the Atmospheric Sciences, Vol. 23, Issue 4, July 1966, pp. 376-386.

Measurements of the spectra of fluctuations in wind velocity over the sea sensed by three basically different instruments are described. One comparison shows good agreement between spectra from a thrust anemometer and cup anemometers. Another comparison shows that greatly improved precision of spectra derived from a hot wire anemometer can be gained by calibrating the low frequency response against spectra from cup anemometers. The measurements confirm Kolmogoroff's prediction of the existence of a universal form of the spectrum at high wave numbers. The shape of a spectrum of temperature fluctuations agree with that found by earlier workers.

Ponta, F. L.

"VORTEX DECAY IN THE KARMAN EDDY STREET"

Physics of Fluids, Vol. 22, 2010, pp. 093601-1 - 093601-11.

In this paper, we analyze the effect of viscosity on the vorticity distribution and its rate of decay in the Karman vortex street behind a circular cylinder. We used direct numerical simulation data, which we compare to well-known experimental measurements. By decomposing the incompressible velocity field in a frame of reference attached to the cylinder into its solenoidal and harmonic components, we identify the eddy structure associated with the formation, shedding, and rearrangement of the vortices into the Karman Street, and study their subsequent decay. This allows us to extend the conclusions of the partially viscous model by Hooker, who made several simplifying hypotheses: initial infinite-length filament-vortex wake, circular Lamb vortices of equal age at subsequent times, and no overlapping of vortex cores. We show that the vortices have elliptical cores with an elliptical ratio that evolves

downstream according to a systematic law. We also find that the vortex cores exhibit a Gaussian vorticity profile and a vorticity versus stream-function scatter plot clearly consistent with the Lamb-vortex model. The peak vorticity in the core decays downstream with a hyperbolic decay rate determined by the amount of circulation contained in the core at the early stages of the street, which is also consistent with Lamb's solution.

Pope, S.B. and Whitelaw, J. H.

"THE CALCULATION OF NEAR-WAKE FLOWS"

Journal of Fluid Mechanics, Vol. 73, part 1, 1976, pp. 9-32.

Calculated flow properties are compared with measurements obtained in two-dimensional isothermal wakes with and without recirculation. The equations of continuity and momentum were solved numerically together with equations which formed a turbulence model. Calculations were made using three turbulence models: the first comprised transport equations for turbulence kinetic energy and the rate of turbulence dissipation; the second and third comprised equations for the rate of turbulence dissipation and two forms of Reynolds-stress equations characterized by different redistribution terms. The results show that, for wakes without recirculation, the turbulence model is less important than the boundary condition assumed in the plane of the trailing edge of the body; though the Reynolds-stress models do, of course, provide a better representation of the individual normal stresses. In the case of wakes with recirculation, both the length of the recirculation region and the rate of spread of the downstream wake are underestimated. The second discrepancy is particularly evident and appears to stem from the form of the dissipation equations. A suggestion for improving the modelling of this equation is provided together with necessary justification.

Poppleton, E. D.

"EFFECT OF AIR INJECTION INTO THE CORE OF A TRAILING VORTEX"

J. Aircraft, Vol. 8, No. 8, August 1971, pp. 672-673

The radial distribution of axial velocity which occurs in the wake of any given aircraft depends on the way the vortex is generated, and the overall axial-momentum balance for the fluid that ultimately constitutes the core of the vortex. The note describes preliminary experiments conducted in the McGill 30-inch blower tunnel to examine the possibility that if air is injected along the axis in the early stages of the formation of the vortex, its subsequent behavior may be modified by thus changing conditions in the nascent core. It was found that the effect of blowing through the jet is effectively to 'age' the vortex prematurely.

Poppleton, E. D.

"THE CONTROL OF WING-TIP VORTICES"

Aero. Tech. Note 7102, August 1971, University of Sydney, Sydney, Australia

A device is proposed for the control of the velocity distribution in the core of a trailing vortex. Preliminary calculations show that the required planform shape does not differ radically from that of a conventional wing, and that there is a considerable reduction in vortex drag.

Poppoff, I. G., Farlow, N. H. and Anderson, L. B.

"STUDIES OF AIRCRAFT WAKE CHEMISTRY AND DISPERSION"

Acta Astronautics, Vol. 1, January-February 1974, pp. 157-178

Use of aerospace technology to study aircraft wakes is reviewed. It is shown how aerospace vehicles can be used to provide data for increased understanding of the atmosphere and of aircraft exhaust trails where knowledge is inadequate to evaluate fully the potential impact of the engine emissions. Models of aircraft near-field exhaust wakes are characterized by jet, vortex, and dispersion regimes. Wake growth in the jet regime is self-determined and rapid, whereas further spreading is inhibited in the vortex regime because of circulating vortex motion. Wake diffusion in the dispersion regimes is initially influenced by aircraft induced turbulence but is dominated later by small-scale atmospheric turbulence. Computed fluid mechanical results show the importance of effects such as wake buoyancy, wind shear, turbulence, and traffic corridor exhaust buildup on dispersion of the wake. In the jet regime the exhaust characteristics and thermochemistry serve to illustrate initial chemical changes involving potential pollutant species.

Porter, C. O.

"THE OPTICAL ENVIRONMENT FROM THE TIP VORTICES OF A HELICOPTER IN DIFFERENT FLIGHT REGIMES"

PhD Thesis, October 2011, Notre Dame University, Notre Dame, IN.

Aero-optical aberrations associated with turbulent compressible flow fields can seriously degrade the performance of an optical system; the effect of these aberrations increases as the wavelength of the transiting light becomes shorter, and so is particularly strong at visible and near-infrared wavelengths. These aero-optical aberrations originate from both spatial- and temporal-variations of the index-of-refraction, and are associated with the low-pressure cores and concomitant reduced density within the vortical structures in certain turbulent flow fields such as free-shear layers and tip vortices. To date, aero-optics research has focused primarily on fixed-wing aircraft traveling at compressible-flow speeds, where compressible shear layers and turbulent boundary layers are the dominant source of aero-optic aberrations. Helicopter platforms operate at much lower Mach numbers and are actually best suited for hover. In this case, the optical aberrations produced from shear-layer or turbulent boundary-layer flows are greatly reduced or eliminated in the case of hover; instead, aero-optic aberrations result primarily from the wake of the rotor that can have tip speeds up to a Mach number of one. The tip vortices shed from the rotor blades have an aberrating effect similar to the vortices in a compressible shear-layer that forms behind a turret on a fixed-wing aircraft. In this dissertation, experimental and numerical results

are presented that both calibrate and validate a scaling relationship derived from Euler's equations and the Lamb-Oseen vortex model. Extended numerical simulations of basic helicopter flowfield features were performed for a medium-sized helicopter both in hover and in forward flight to determine estimates of the spatial- and temporal-degradation of a collimated beam traveling through the rotor-blade wake. The results indicate that the severity of the aberration is highly dependent on the vortex circulation strength and core radius. Even with the most conservative estimates, the far field effects of light propagating through these tip vortices greatly reduces the irradiance delivered on target through both tip/tilt and higher order effects. Finally, the use of adaptive optics to correct for these aberrations is examined for the case of hover.

Porter, C., Rennie, M. and Jumper, E.

"THE AERO-OPTICAL ENVIRONMENT OF A HELICOPTER IN FORWARD FLIGHT"

AIAA Paper No. 2011-3283, June 2011, Honolulu, Hawaii.

The performance of an optical system mounted in a hemispherical turret can be seriously limited at certain viewing angles due to aero-optical aberrations on the outgoing beam. The strength of these aberrations is related to the density fluctuations in the air immediately surrounding the turret and is proportional to the Mach number squared; helicopters are therefore an attractive platform for optical systems due to their low flight speeds. In this case, aero-optical aberrations can still arise, however, from the wake and especially the tip vortices from the helicopter blades. A simplified model of a rotor tip-vortex is used to gain insight into the potential aero-optical environment of a helicopter in forward flight. The simplified model allows for the rapid calculation of aero-optic effects at different forward-flight speeds. The results indicate that the largest aero-optic aberration originates from 'super vortices' that appear along the lateral edge of the helicopter wake. Estimated aberration amplitudes are presented, as well as an estimate of the undisturbed viewing angle of the optical system as a function of forward-flight speed.

Porter, C., Rennie, M. and Jumper, E.

"AERO-OPTIC EFFECTS OF A WINGTIP VORTEX"

AIAA Journal, Vol. 51, No. 7, July 2013, pp. 1533-1541.

For an optical system carried by a helicopter, aero-optic aberrations originate primarily from blade tip vortices that pass through the system field of view. These aberrations result from the reduced pressure and density in the vortex cores, and the associated variations in the index of refraction. As part of an investigation into the full aero-optic environment surrounding a helicopter, this paper describes an investigation into the optical character of a single tip vortex. The Lamb-Oseen vortex model is used to compute realistic velocity fields, which are then used with the energy equation to determine thermodynamic properties. The resulting aero-optic data are used to calibrate a scaling law that is derived from the basic fluid-mechanic equations of motion, and this scaling law is validated against

experimental data. The scaling relationship is then used to make a simple estimate of the vortex-induced aberrations on a fuselage-mounted optical system for a medium-sized helicopter.

Porter, C., Rennie, M. and Jumper, E.

"COMPUTATION OF THE AERO-OPTICAL ENVIRONMENT OF A HELICOPTER USING PRESCRIBED-WAKE METHODS"

AIAA Journal, Vol. 53, No. 3, March 2015, pp. 532-541.

A fast low-order computational approach is presented for estimating the aero-optic effect of the rotor tip vortex system on helicopter-borne optical systems. The approach employs prescribed-wake methods that have been developed by the helicopter design community to rapidly generate realistic approximations to the vortex-wake systems of helicopters in hover and forward flight. With the geometry of the vortex-wake system defined, an experimentally validated computational method that employs the isentropic assumption is then used to compute pressure, temperature, density, and index-of-refraction fields in the selected computational domain. Predictions determined using the computational approach for the spatially and temporally resolved aero-optic aberrations on an optical system mounted on a helicopter in hover and forward flight are presented.

Portnoy, H.

"THE EFFECT OF WAKE THICKNESS ON THE ROLLING-UP PROCESS IN TWO DIMENSIONS"

ICAS 1976, October 1976, Ottawa, Ontario, Canada.

A numerical method is developed for calculating the flow field due to a two-dimensional distribution of vorticity over a given area. A distribution of vorticity over a long thin ellipse is then used to model the flow about the unrolled cross-section of a thick wake far downstream of the wing trailing-edge. The distribution is now allowed to distort under the action of its own induced velocity field, (which is calculated by the aforementioned numerical method), thus simulating roll-up of a wake with thickness. The influence of viscosity is neglected and two different span loadings are studied.

Portnoy, H.

"AERODYNAMIC EFFECTS OF VORTEX SUPPRESSORS"

TAE-221, July 1974, Technion-Israel Inst. of Technology, Haifa, Israel

The effectiveness of various devices in accelerating the dissipation of wing-tip vortices has received considerable attention recently. These devices include jets blown into or near the vortex core, both in the upstream and downstream direction, small cruciform wings, both fixed and rotating, mounted close behind the wing near tip and angled fences or vortex generators mounted on the wing upper and lower surfaces so as to produce swirl opposite to that of the tip vortex. In this report are proposed

mathematical models for representing some of these devices in order to calculate their effects on the wing aerodynamic properties.

Portnoy, H.

"CALCULATION OF THE AERODYNAMIC EFFECTS OF CERTAIN VORTEX SUPPRESSING DEVICES"

AFOSR-TR-75-0713, December 1974, Technion-Israel Inst. of Technology, Haifa, Israel

There has been a recent increase of interest in devices for accelerating the dissipation of wing-tip trailing vortices. A number of experimental programs have been carried out to determine the effectiveness of various devices, such as tip-mounted jets, small windmills, suitably disposed vortex generators and so on, in increasing the rate of vortex decay. Only limited attention seems to have been paid to the effects of these devices on the wing aerodynamic properties and the work that has been done appears to be entirely experimental. It is the purpose of the present paper to propose three simple mathematical models which may be used to assess many of the current suppressors, from the viewpoint of wing property modification.

Portnoy, H.

"THE INITIAL ROLL-UP OF A THICK, TWO-DIMENSIONAL WAKE BEHIND A WING OF FINITE SPAN"

TAE-262, November 1975, Technion-Israel Inst. of Technology, Haifa, Israel.

This work is an attempt to remove the unrealistic features of earlier vortex wake models, namely zero wake thickness and vorticity concentrated on lines, by assuming that the wake vorticity is contained in a layer of finite thickness with some plausible cross-sectional shape. The wake flow is assumed to be two-dimensional and the rolling-up is studied via the time-dependent development of this model so that it deals with the slow rolling-up taking place far behind the wing. The mathematical model of the wake is described and examples of the initial roll-up phase have been calculated for three wakes of different thicknesses and elliptic cross-sections, subjected to uniform downwash (corresponding to elliptic spanwise loading).

"PROCEEDINGS OF THE INTERNATIONAL WAKE VORTEX MEETING, OTTAWA, ONTARIO, 2-4 DECEMBER 1997"

TP 13166, December 1977, Transport Canada, Transport Development Centre, Montreal, Quebec, Canada.

This report is a record of the international meeting on Wake Vortex Prediction, which took place in Ottawa, Ontario, on December 2-4, 1997, and was hosted by Transport Canada. The principal objectives of this meeting were to promote international cooperation in the development of a real-time wake vortex forecasting system and to discuss improved aviation safety and efficiency in relation to

wake vortex modelling, real-time prediction, and meteorological requirements. Experts from Canada, Russia, Belgium, the United States, the United Kingdom, France, and Germany explained their perspectives on the wake vortex issues as well as their proposed solutions. Representatives of airlines, pilots, air navigation service providers, air traffic controllers, airport authorities, governments, and aircraft manufacturers presented their views on the issues.

"APPLICATION OF 3D PARTICLE METHOD TO THE PREDICTION OF AERODYNAMIC SOUND"

ESAIM Proceedings, Vol. 1, 1996, pp. 349-362.

Low-Mach-number aeroacoustic theories are applied to predict far-field sound emission from vortex-dominated flows. The latter are simulated using three-dimensional vortex methods. Both particle schemes and filament-based schemes are used. Comparisons of model predictions with theoretical and experimental results on the interaction of two vortex rings are first discussed. Next, the schemes are used to examine the effect of initial conditions and 3D perturbations on the properties of the far-field acoustic pressure. Finally, a more elaborate wind-turbine model is presented and its application to the evaluation of several turbine-blade designs is summarized.

Potsdam, M. and Pulliam, T.

"TURBULENCE MODELING TREATMENT FOR ROTORCRAFT WAKES"

AHS Aeromechanics Specialist's Meeting, Jan. 2008, San Francisco, CA.

This work investigates the influence of turbulence modeling in the vortical wake of rotorcraft simulations. It is seen that for a range of flight conditions, but especially hover, overall rotor performance prediction can be significantly affected by the wake turbulence model characteristics. The characteristics of some baseline turbulence model formulations (e.g. Baldwin-Barth, Spalart-Allmaras) are observed to produce too much turbulent eddy viscosity if the production is based on the vorticity field of the vortex-dominated rotor wake. Due to the excess production of the turbulent eddy viscosity in the wake, and its subsequent convection and diffusion, the wall-bounded viscous flow is modified. To ameliorate these difficulties, turbulence model modifications in the wake, such as turning off the production source terms, are evaluated. They are shown to improve solution accuracy compared with experimental data for a quarter-scale V-22 isolated rotor in hover, a CH-47 isolated rotor in hover, and a UH-60A in forward flight at high thrust coefficient. The overall effect on rotor performance can be several points in rotor figure of merit or a variation in stall boundary thrust coefficient.

Potts, J. R. and Crowther, W. J.

"VISUALISATION OF THE FLOW OVER A DISC-WING"

9th International Symposium on Flow Visualization, August 2000, Paper 247, Edinburgh, Scotland, UK.

An experimental investigation into the flow characteristics of a disc-wing has been carried out in a low-speed wind tunnel over a flow speed range of 0 to 20 m/s. The disc-wing considered has an axis-symmetric, approximately elliptic cross-section and hollowed out underside cavity. The aim of this research was to gain an understanding of the complex three-dimensional flow structures, to identify regions receptive to flow control technologies such as vortex generators or synthetic (massless) jets. Flow visualization techniques including surface paint and smoke wire methods have been utilized to determine the position and form of surface flow structures.

Pourhashem, H. and Sunil, K.

"BOW SHOCK/VORTEX INTERACTION: EFFECT OF REDUCING THE VORTEX HEIGHT ON STRUCTURE OF THE GENERATED FLOW FIELD"

AIAA Paper 2019-0947, January 2019, San Diego, CA.

The present computational study examines the effect of vortex height on characteristics of bow shock/vortex interaction as a practical technique for improving mixing of fuel and air in Scramjet engines. The bow shock/vortex interaction is induced through placing a vortex generator in the form of a semi-span wing section at an angle of attack upstream of a flat plate with an injection slot. The vortex interacts with the injection induced bow shock, and for a sufficiently strong interaction a supersonic vortex breakdown is expected. The results of the computational study demonstrate that reducing the vortex height leads to the interaction of the vortex with the stronger portion of the bow shock, which results in a vortex breakdown for all examined jet momentum ratios. Results indicate that moving the vortex center close to the plate surface leads to a significant destruction of the vortex core and formation of large subsonic region and a downstream displacement of the primary separation shock due to the Mach number deficit. Additionally, increased mixing of injectant with the supersonic cross flow for all examined cases is observed.

Pourhashem, H., Kalkhoran, I. M. and Sunil, K.

"INTERACTION OF VORTEX WITH BOW SHOCK WAVE: COMPUTATIONAL MODEL, EXPERIMENTAL VALIDATION, ENHANCED MIXING"

AIAA JOURNAL, Vol. 56, No. 8, August 2018, pp. 3071-3085.

A computational model is developed using a delayed detached-eddy simulation to examine the various aspects of shock-wave/vortex interactions, in which the specific case of naturally formed bow shock wave generated during a sonic injection into a supersonic crossflow is considered. The model is validated by comparing with experimental results obtained previously and is deployed to investigate the effects of shock/vortex interaction on mixing characteristics of supersonic flows. A vortex generator, in the form of a semispan wing section, is placed at an angle of attack upstream of an injection location. The resultant vortex interacts with the bow shock, and for a sufficiently strong interaction, there is breakdown of the supersonic vortex. The vortex bursting observed during the computational study is in a very good agreement with a previous physical model. The computational results demonstrate that

the shock/vortex interaction can be an effective method of mixing enhancement because it results in redistribution and increase of vorticity in the flowfield, which enhances the entrainment and eventual mixing of injectant and supersonic crossflow.

Pourhashem, H., Kalkhoran, I. M., Finch, P. and Kumar, S.

"STUDY OF SHOCK WAVE/VORTEX INTERACTION FOR SUPERSONIC MIXING ENHANCEMENT"

AIAA Paper 2017-4648, July 2017, Atlanta, GA.

In the present study, the characteristics of a shock wave/vortex interaction for the enhancement of fuel air mixing in scramjet engines suitable for hypersonic vehicles is investigated. The scheme is based on the previous work developed by Kalkhoran et al. (1998) in the area of shock wave/vortex interaction in which a dramatic supersonic vortex bursting was shown. This study involves positioning a vortex generator, in the form of a semi-span wing section placed at an angle of attack, upstream of an injection slot. The vortex interacts with the naturally formed bow shock due to conventional injection, and for sufficiently strong interaction a supersonic vortex breakdown is expected. Computational investigations are conducted to validate the results of the experimental study using the Reynolds Stress Model (RSM). The results of the present computational investigation are in good agreement with the experimental data, confirming the characteristics of the supersonic vortex breakdown observed during the experimental study. Furthermore, computational results demonstrate the enhanced mixing and shortening of the combustion length for the cases involving the supersonic shock/vortex interaction.

Povitsky, A., Zheng, T. and Vatisstas, G.

"EFFECT OF VORTEX PROFILE ON SOUND GENERATION IN A NON-UNIFORM FLOW"

Lecture Notes in Computer Science, Vol. 2668, 2003, pp. 826-836

The propagation of acoustic waves originating from stretching of intense self-similar vortices in the non-uniform mean flow is studied by numerical modeling using high-order compact approximation. Near-wall stretching of initial vortex by the stagnation flow leads to sound radiation from the generated pressure quadrupole. To mimic unsteady stagnation flows and impingement jets, the stagnation flow has been switched off at some time moment. Subsonic stagnation flow and flow around a cylinder are taken as prototypes of real-world flows with strong gradients of mean pressure and velocity. Compressibility of the background mean flow and the vortex are considered and its effect on amplification of acoustic pressure is discussed. Generation of sound by stretching of vorticity dipole leads to formation of a three-spot wave with maximum acoustic pressure at the centerline. Since aeroacoustic applications require good physical approximations for the viscous nature of tip vortices, several semi-empirical profiles of vortex velocity were considered. The intensity and directivity of acoustic wave patterns appear to be quite different for Taylor and Vatisstas vortices.

Powell, A.

"THEORY OF VORTEX SOUND"

Journal Acoustical Society of America, Vol. 36, No. 1, January 1964, pp. 177-195

Physical arguments are followed by mathematical developments to show how aerodynamic sound is generated as a result of the movement of vortices, or of vorticity, in an unsteady fluid flow. Changes in circulation or area of a vortex ring give rise to a dipole sound field, the former being illustrated by oscillating flow about a fixed sphere, and the latter by a simple model for the aeolian tone attributable to the stretching of vortex rings. Because in a free flow there can be no change of the total vortex strength (circulation times area), there is no net dipole strength, but each moving element of vorticity still causes a local dipole like flow; each element of moving vorticity acts with some equal and opposite movement elsewhere in the flow so that together they form an oblique quadrupole, although the total effect must be reducible to an assembly of lateral quadrupoles. A cardinal result is that the vorticity in a slightly compressible fluid can be considered to induce the whole flow field, both the hydrodynamic part and the acoustic part. With vorticity taken as the common basis, a slightly compressible flow is compared to the corresponding incompressible one, which may be used in the evaluation of the sound-radiation formula. The theory is particularly well-structured to estimate sound from flows described in terms of vorticity: the sound field is determined for two rectilinear vortices spinning about an axis between them, and its basis for similarity methods is demonstrated in application to free shear flow and jet flow.

Powell, A.

"A BASICALLY MONOPOLE SOURCE FORMULATION FOR VORTEX-GENERATED SOUND"

J. Acoustical Society of America, Vol. 97, No. 4, April 1995, pp. 2144-2146.

Lighthill's source term for aerodynamic sound generation can be expressed in terms of the squares of the vorticity and of the principal rates of strain of the sound-generating fluid, in the usual incompressible approximation. These represent local monopole source regions. When there are discrete interacting vortices, the former has the physical interpretation of the sound emission being associated with the occurrence of pressure minima at vortex cores, while the latter may be imagined to be the emission associated with the pressure maxima in regions between colliding vortices. The quadrupole source volume integrals converge rapidly, so the whole source region may be thought of as compact, the poor convergence difficulties associated with the use of the 'incompressible' pressure of previous 'simple source' or 'dilatational' theories being avoided.

Powell, A.

"VORTEX SOUND THEORY: DIRECT PROOF OF EQUIVALENCE OF 'VORTEX FORCE' AND 'VORTICITY-ALONE' FORMULATIONS"

Journal of Acoustical Society of America, Vol. 97, No. 3, March 1995, pp. 1534-1537.

In the theory of vortex sound the far-field compact source strengths are the volume integrals of the time differential of the vortex force. Mohring's method, using a vector Green's function, produces instead the vorticity-alone volume integrals that do not explicitly involve the velocity of the inviscid incompressible sound-generating flow. Direct proofs that these different integral results are in fact exactly equal are offered: given one form, the other can be found with no appeal to acoustical theory whatsoever. The implications of these integral formulations is discussed.

Powell, A.

"WHY DO VORTICES GENERATE SOUND?"

Transactions of the ASME, Vol. 117, June 1995, pp. 252-260

Emphasizing physical pictures with a minimum of analysis, an introductory account is presented as to how vortices generate sound. Based on the observation that a vortex ring induces the same hydrodynamic (incompressible) flow as does a dipole sheet of the same shape, simple physical arguments for sound generation by vorticity are presented, first in terms of moving vortex rings of fixed strength and then of fixed rings of variable strength. These lead to the formal results of the theory of vortex sound, with the source expressed in terms of the vortex force, and of the form introduced by Moehring in terms of vortex moment. The simple 'Contiguous Method' of finding the contiguous acoustic field surrounding an acoustically compact hydrodynamic (incompressible) field is also discussed. Some very simple vortex flows illustrate the various ideas. These are all for acoustically compact, low Mach number flows of an inviscid fluid, except that a simple argument for the effect of viscous dissipation is given and its relevance to the 'dilatation' of a vortex is mentioned.

Powell, A.

"VORTEX SOUND: AN ALTERNATIVE DERIVATION OF MOHRINGS FORMULATION"

Journal Acoustical Society of America., Vol. 97, Issue 1, Jan. 1995, pp. 684-686

By considering that the radial flow velocity at a spherical bounding surface due to a system of vortex rings (as given by the so-called Biot-Savart analogy for incompressible flow), fixed but of variable strength, drives the contiguous acoustic fields, simple physical arguments are presented that yield the results for dipole and quadrupole vortex sound in Mohring's form.

Powell, J. D., Jennings, C. and Holforthy, W.

"USE OF ADS-B AND PERSPECTIVE DISPLAYS TO ENHANCE AIRPORT CAPACITY"

24th Digital Avionics Systems Conference, Vol. 1, Nov. 2005, pp. 4.D.4-1--4.D.4-9

As the growth in air travel continues over the coming decades, there will need to be increases in the capacity of the airspace system, especially airports. Technology associated with GPS, along with changes in procedures between air traffic controllers and pilots, has the capability to provide much of

the required growth without sacrificing safety and without requiring wholesale expansions of airport land areas. The use of GPS to augment radar surveillance through Automatic Dependent Surveillance - Broadcast (ADS-B) provides a substantial improvement in surveillance accuracy and provides every pilot with information on neighboring traffic, information that does not exist now. Wake vortex turbulence of neighboring traffic is one of the limiting factors on parallel runway spacing and the in-trail spacing of aircraft. This paper shows how the impact of wake turbulence can be substantially reduced by the use of ADS-B and appropriate displays. The paper presents results of analyses, pilot simulations, and flight-testing that show the required runway spacing can be reduced from the current 4300 ft. to 750 ft., thus substantially improving landing capacity while minimizing cost and the effect on the environment.

Prasad, N. S.

"RECENT ADVANCES IN WIND LIDAR TECHNOLOGIES FOR CHARACTERIZATION OF WAKE VORTICES"

AIAA Paper 2018-2863, June 2018, Atlanta, GA.

Fast-time wake vortex models have been studied in various details for possible operational and research applications related to air traffic management. The wake vortex Light Detection and Ranging (lidar) technology plays a critical role in validating these numerical wake models. With the advent of lasers, various types of remote sensing techniques and systems began to develop in laboratories across the world. Fundamentally, all these techniques depend upon sensing of wind velocities at a given range coupled with effective algorithms for extraction of wake vortex characteristics. When solid-state lasers appeared on the scene, practical lidar systems were built for field operations. These lidars have enabled wake vortex data collection in airports under various environmental and air craft orientation conditions for analysis and validation of CFD generated fast-time wake vortex models. In this paper, a brief history of wake vortex measurements followed by prominent field campaigns conducted by NASA Langley Research Center will be discussed. In subsequent sections, salient aspects of recently developed novel wind lidar technology will be presented.

Prasad, N. S., Sibell, R., Vettori, S., Higgins, R. and Tracy, A.

"AN ALL-FIBER, MODULAR, COMPACT WIND LIDAR FOR WIND SENSING AND WAKE VORTEX APPLICATIONS"

Proceedings SPIE 9465, Laser Radar Technology and Applications XX, April 2015, Baltimore, MD. Next-Generation Spectroscopic Technologies VIII, June 2015.

This paper discusses an innovative, compact and eye safe coherent lidar system developed for wind and wake vortex sensing applications. With an innovative all-fiber and modular transceiver architecture, the wind lidar system has reduced size, weight, and power requirements, and provides enhanced performance along with operational elegance. This all-fiber architecture is developed around fiber seed laser coupled to uniquely configured fiber amplifier modules. The innovative features of this lidar system, besides its all-fiber architecture, include pulse width agility and user programmable 3D hemispherical scanner unit. Operating at a wavelength of 1.5457 microns and with a

PRF of up to 20 KHz, the lidar transmitter system is designed as a Class I system with dimensions of 30' (W) x 46' (L) x 60' (H). With an operational range exceeding 10 km, the wind lidar is configured to measure wind velocities of greater than 120 m/s with an accuracy of ± 0.2 m/s and allow range resolution of less than 15 m. The dynamical configuration capability of transmitted pulse widths from 50 ns to 400 ns allows high resolution wake vortex measurements. The scanner uses innovative liquid metal slip ring and is built using 3D printer technology with light weight nylon. As such, it provides continuous 360-degree azimuth and 180-degree elevation scan angles with an incremental motion of 0.001 degree. The lidar system is air cooled and requires 110 V for its operation. This compact and modular lidar system is anticipated to provide mobility, reliability, and ease of field deployment for wind and wake vortex measurements. Currently, this wind lidar is undergoing validation tests under various atmospheric conditions. Preliminary results of these field measurements of wind characteristics that were recently carried out in Colorado are discussed.

Prasad, N. S., Tracy, A., Vettori, S., Higgins, R. and Sibell, R.

"INNOVATIVE FIBER-LASER ARCHITECTURE BASED COMPACT WIND LIDAR"

18th Coherent Laser Radar Conference, June 2016, Boulder, CO.

This paper describes an innovative, all-fiber, compact, and eyesafe coherent lidar system developed for wind and wake vortex sensing applications. The all-fiber lidar, with modular architecture, incorporates an integrated 3D scanner that provides user programmable, continuous 360-degree azimuth and 180-degree elevation scan angles. Operating at 1.54 microns, the lidar allows pulse width agility from 50 - 400 ns with a variable PRF of up to 20 KHz. The wind lidar is air cooled with overall dimensions of 30 cm x 46 cm x 60 cm and is designed as a Class I system. This lidar is capable of measuring wind velocities greater than 120 ± 0.2 m/s over ranges greater than 10 km and with a range resolution of less than 15 m. In this paper, the key features of lidar instrumentation and its functionality are discussed followed by results of recent wind forecast measurements on a wind farm.

Premaratne, P. and Hu, H.

"A NOVEL VORTEX METHOD TO INVESTIGATE WIND TUNNEL NEAR-WAKE CHARACTERISTICS"

AIAA Paper 2017-4213, June 2017, Denver, CO.

We utilize vortex methods to identify possible mechanisms which cause vortex filaments to break-up in the wake behind a horizontal axis wind turbine (HAWT). This study was inspired by the flow characteristics observed in PIV measurements from an experiment conducted at the Atmospheric Boundary Layer (ABL) tunnel at ISU using a scaled model of an industry standard HAWT. Measurements revealed the presence of a tip vortex filament and a secondary vortex filament emanating from the mid-span location of the blade. The mid-span vortex has twice the circulation of the tip vortex filament and the vortices break-up at $X/D=0.5$ axial station. Both filaments showed expansion with the wake and a merging effect between the filaments. Our investigation using a vortex-blob based method (2D)

and a filament-based method (3D) captured wake expansion of both filaments as well as the converging behavior, which could result in wake instability.

Premaratne, P. and Hu, H.

"ANALYSIS OF TURBINE WAKE CHARACTERISTICS USING DYNAMIC MODE DECOMPOSITION"

AIAA Paper 2017-4214, June 2017, Denver, CO.

We examine the flow characteristics behind a three-bladed horizontal-axis wind turbine via experiments in a large-scale wind tunnel with a scaled model placed in a typical Atmospheric Boundary Layer (ABL) wind under neutral stability conditions. A high-resolution digital particle image velocimetry (PIV) system was used to study the detailed flow field. Besides analyzing average statistics of the flow quantities such as mean velocity and vorticity distributions in the wake, 'phase-locked' PIV measurements also elucidated further details of the vortex structures in the wake for a frozen position of the blades. Phase-averaged measurements of the near-wake ($0 < X/D < 1.0$) were arranged to resemble a time resolved snapshot series to be analyzed by Dynamic Mode Decomposition (DMD) method, an advanced statistical method capable of detecting dominant spatial and temporal structures buried in a flow field. The DMD method managed to identify the high energy modes that dominate in a series of given regions of interest that encompasses the shear layer. The DMD modes revealed a transition in modal shape from axisymmetric to asymmetric as the vortical structures travel downstream and break-up at a critical $X/D = 0.5$. Axisymmetric mode produced in the DMD analysis agreed satisfactorily with a low order reconstruction obtained from a prior POD analysis. A full field DMD analysis of the shear layer region yielded a spatially and temporally decaying mode which encapsulates both asymmetric and axisymmetric modes observed previously.

"ASSIGNED SPACING GOAL CALCULATION FOR INTERVAL MANAGEMENT PAIRED APPROACH OPERATIONS"

Report MTR190104, December 2018, Mitre Corporation, McLean, VA.

This is a MITRE report entitled 'Assigned Spacing Goal Calculation for Interval Management Paired Approach Operations.'

Priest, A. J., Dobney, D. G. and Hill, R. P.

"MEASUREMENTS IN THE NEAR-WAKE OF A TRANSPORT MODEL TO DETERMINE THE LIFT, DRAG AND DRAG COMPONENTS USING MASKELL'S ANALYSIS"

RAE TR-81012, February 1981, Royal Aircraft Establishment, Farnborough, England.

Extensive measurements have been made on a plane normal to the wake of a swept-wing/fuselage model of airbus type, at $C_{sub-L} = 0.49$ in incompressible flow, using a computer-controlled wake-traverse system incorporating a null-reading five-hole yawmeter probe. The results define the detailed distributions of total pressure defect, flow velocity, flow angles and streamwise vorticity in the viscous wake at that plane. The results have been analyzed within the basic theoretical framework set out by Maskell (1973), allowing the calculation of lift and drag from traverse data, and the resolution of the drag into provisionally-defined components $C_{sub-D sub I}$ and $C_{sub-D sub II}$, respectively relating to the profile drag and vortex drag.

Primeggia, C. and Hodgkins, P. D.

"DEPARTURE EXCLUSION ZONE (DEZ) - A FUTURE CONCEPT TO ENHANCE RUNWAY OPERATIONS USING AIRCRAFT DERIVED DATA"

Fifth NASA Integrated Communications, Navigation, and Surveillance (ICNS) Conference and Workshop, May 2005, Fairfax, VA

This paper highlights a concept for a Departure Exclusion Zone (DEZ) tool. Wake turbulence accidents and incidents have been, and continue to be, a significant contributor to the worldwide safety statistics. The safety concern of wake vortices, particularly when lighter aircraft are following heavy aircrafts, has caused the FAA to enact minimum separation requirements during the arrival and departure phases of flight. The wake-turbulence separation criteria, while necessary, are currently a limiting factor in several airport capacities. This paper examines the technical requirements for a system that relieves the departure constraints enhancing the efficiency of runway operations. The proposed system uses the Flight Management System/autopilot to establish tracks that avoid the wake of the preceding aircraft. Given that an aircraft can provide meteorological (wind, temperature, and air density) and state data (model, speed, weight, etc.), the wake vortices can be calculated with sufficient accuracy to develop individual departure routes (tracks) for each aircraft to avoid the wake of the preceding aircraft. The proposed DEZ system acquires the aircraft data, calculates the exclusion zone for each aircraft and provides the results to the controller's display and to the cockpit.

Pritchett, A. R.

"PILOT PERFORMANCE AT COLLISION AVOIDANCE DURING CLOSELY SPACED PARALLEL APPROACHES"

Air Traffic Control Quarterly, Vol. 7, No. 1, 1999, pp. 47-75.

To examine the issues with collision avoidance during closely spaced parallel approaches, two related studies have been performed. First, the most hazardous relative positions of aircraft on parallel approaches were identified through fast-time simulations of collision trajectories. Second, a part-task flight simulator evaluation of traffic displays, the need for automatic alerts and for autopilot control of the approach was conducted. While a need was identified for alerting systems to command effective avoidance maneuvers, pilots were found to frequently not conform to the commanded avoidance

maneuver, with a resulting decrease in performance. Based on these results, concerns meriting further study are discussed..

"WAKE VORTEX REPORTING SCHEME AND METEOROLOGICAL DATA COLLECTION SYSTEM"

VII/53563/95, October 1995, European Commission, Brussels, Belgium

A feasibility study for implementing Wake Vortex Reporting Systems (WVRS) and meteorological monitoring systems at seven European airports (Paris Orly, Frankfurt, Brussels, London Heathrow, Gatwick, Amsterdam, and Milan) was completed. The intent is to gather a comprehensive range of data on wake vortex incidents and amass data on airport meteorological and wind conditions through a wake vortex reporting scheme and meteorological data capture system at the European airports. The data would be used to validate models and to improve short term windspeed and direction forecasts for use in Wake Vortex Advisory Schemes.

Probst, S., Knopp, T., Francois, D. G. and Grabe, C.

"SCALE-RESOLVING SIMULATIONS OF THE STREAMWISE VORTEX DOWNSTREAM OF A DELTA WING"

AIAA Paper 2019-0331, January 2019, San Diego, CA.

This paper investigates simulation strategies to accurately predict the streamwise evolution of the longitudinal vortex that is generated at the leading edge of a delta wing. For this purpose, different hybrid RANS/LES approaches are assessed by comparison with experimental reference data. As test case a new wind tunnel experiment is considered, which provides detailed data of the vortex evolution downstream of the delta-wing trailing edge using stereoscopic particle image velocimetry. Since in this work the vortex development in the wake is of primary interest, the flow around the delta wing is modeled with RANS, whereas a scale-resolving LES is only applied in its wake. This approach reduces the computational effort compared to pure LES and enables a systematic study of different grid designs and suitable positions of the RANS/LES interface. The results show the importance of applying synthetic turbulence to trigger the generation of resolved structures at the RANS/LES interface.

Proctor, F. and Hamilton, D. W.

"WAKE VORTEX TRANSPORT AND DECAY FROM THE PERSPECTIVE OF PARALLEL RUNWAYS"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001.

For aircraft approaching/departing a single runway, safe aircraft separations may be determined from the time interval needed for a wake vortex to either dissipate or transport out of the flight corridor. For parallel runways, predictions for safe conditions are more complex since crosswinds can transport wake vortices into adjacent flight corridors. During instrument meteorological conditions (IMC), capacity is

decreased for airports with parallel runways, since operations may be reduced or shut down along one of the runways due to the uncertain position of the laterally-drifting wakes. Potential encounters with wake vortices generated from adjacent corridors can be avoided by ensuring that runways are built with adequate lateral separation. However, since this is not always feasible and many parallel runways are in place, capacity improvements must benefit from predictions of wake vortex position and lifetime. Important environmental parameters for predicting wake vortex transport and demise for parallel runway systems are the vertical profile of ambient crosswind and intensity of ambient turbulence. A system designed to predict vortex spacing for parallel runways, at minimum, should be able to predict if wake vortices from adjacent runways can reach the flight corridor before vortex demise. This will require an understanding of how vortices interact with the ground, crosswind shear, and ambient turbulence. We are investigating these interactions with the LES Terminal Area Simulation System (TASS) and will present results at the conference. Our results show that for optimal conditions of strong crosswinds and weak ambient turbulence, wake vortices may drift laterally up to distances of 27 effective spans for out of ground effect and 17 effective spans for in ground effect.

"NUMERICAL STUDY OF A LONG-LIVED, ISOLATED WAKE VORTEX IN GROUND EFFECT"

AIAA Paper 2014-2469, June 2014, Atlanta, GA.

This paper examines a case observed during the 1990 Idaho Falls Test program, in which a wake vortex having an unusually long lifetime was observed while in ground effect. A numerical simulation is performed with a Large Eddy Simulation model to understand the response of the environment in affecting this event. In the simulation, it was found that one of the vortices decayed quickly, whereas the remaining vortex persisted beyond typical vortex lifetimes found in ground effect. This unusual behavior was found to be related to the first and second vertical derivatives of the ambient crosswind.

"TWO DIMENSIONAL PARAMETRIC STUDIES OF WAKE VORTEX INTERACTION WITH THE ATMOSPHERE"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 93-108.

Results from parametric runs using two-dimensional TASS are presented. First, a set of experiments are presented that examine the sensitivity of the aircraft initiation height for an 'in ground effect' case with weak crosswind. Interaction between the ground and the wake vortex produces an oscillatory rebound whose phase and amplitude are a function of the generation height. A second set of experiments are presented which examine the influence on crosswind shear. Shear layers, such as may be found between the nocturnal stable layer and the residual layer, can act to deflect vortices upward. Further investigation reveals that the second derivative of the crosswind can differentially reduce the descent speed of each member of a vortex pair, causing tilting of the vortex pair. If sufficiently large, the second derivative of crosswind can deflect the vortex pair upwards, with the sign of the second

derivative determining which of the two vortices rises to a higher altitude. Linear shear, on the other hand, caused no change in the descent speed of the vortices; thus having no effect on the orientation of the vortices. Observed and model data from an actual case are presented in support of the conclusion regarding the influence of shear on rising vortices.

"NASA LANGLEY'S NUMERICAL MODELLING EFFORT TO UNDERSTAND THE INTERACTION OF AIRCRAFT WAKE VORTICES WITH THEIR ENVIRONMENT"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 63-64.

Numerical modelling of aircraft wake vortices and the turbulent atmospheric boundary layer are being used at NASA Langley to help understand and quantify wake vortex transport and decay. A large-eddy simulation model which includes a meteorological framework is applied to study the interaction of wake vortices with environments characterized by crosswind shear, stratification, humidity, and atmospheric turbulence. Results from the numerical simulations, along with field measurements are being used to assist in the development of algorithms for an operational wake-vortex aircraft spacing system. The 2-D model is found to be generally valid for studying wake vortex transport (both out of and in ground effect), while the 3-D approach is necessary for realistic treatment of decay. The numerical results with confirming lidar data observed during the Memphis airport field deployments, show that wake vortices decay from the outside with very minimal expansion of the core. Also presented will be 2-D results that show that transport of wake vortices are unaffected when imbedded in uniform rain or fog, but their transport can be strongly affected by the vertical change in ambient crosswind shear. The latter can reduce the rate of vortex descent and in some cases may cause one of the members of the vortex pair to rise.

Proctor, F. H.

"THE NASA-LANGLEY WAKE VORTEX MODELLING EFFORT IN SUPPORT OF AN OPERATIONAL AIRCRAFT SPACING SYSTEM"

AIAA Paper No. 1998-0589, Reno, NV, January 1998

Two numerical modelling efforts, one using a large eddy simulation model and the other a numerical weather prediction model, are underway in support of NASA's Terminal Area Productivity program. The large-eddy simulation model (LES) has a meteorological framework and permits the interaction of wake vortices with environments characterized by crosswind shear, stratification, humidity, and atmospheric turbulence. Results from numerical simulations are being used to assist in the development of algorithms for an operational wake-vortex aircraft spacing system. A mesoscale weather forecast model is being adapted for providing operational forecast of winds, temperature, and turbulence parameters to be used in the terminal area. The 2-D model is found to be generally valid for studying wake vortex transport, while the 3-D approach is necessary for realistic treatment of decay via

interaction of wake vortices and atmospheric boundary layer turbulence. Presented are results showing that wake vortex transport is unaffected by uniform fog or rain, but wake vortex transport can be strongly affected by nonlinear vertical change in the ambient crosswind. Both simulation and observations show that atmospheric vortices decay from the outside with minimal expansion of the core. Vortex decay and the onset of three-dimensional instabilities are found to be enhanced by the presence of ambient turbulence.

"NASA LANGLEY'S NUMERICAL MODELLING EFFORT TO UNDERSTAND THE INTERACTION OF AIRCRAFT WAKE VORTICES WITH THEIR ENVIRONMENT"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

Numerical modelling of aircraft wake vortices and the turbulent atmospheric boundary layer are being used at NASA Langley to help understand and quantify wake vortex transport and decay. A Large-Eddy simulation model which includes a meteorological framework is applied to study the interaction of wake vortices with environments characterized by crosswind shear, stratification, humidity, and atmospheric turbulence. Results from the numerical simulations, along with field measurements are being used to assist in the development of algorithms for an operational wake-vortex aircraft spacing system. Described are the goals and modelling approach, as well as achievements obtained to date. Simulation results and comparisons with field data will be presented. The numerical results with confirming lidar data observed during the Memphis airport field deployments, show that wake vortices decay from the outside with very minimal expansion of the core. This contrasts with previous numerical modelling studies which have reported either the wake vortex decays from the inside with a significant expansion of the core, or very little decay occurs until sinusoidal instabilities take place.

Proctor, F. H.

"NUMERICAL SIMULATION OF WAKE VORTICES MEASURED DURING THE IDAHO FALLS AND MEMPHIS FIELD PROGRAMS"

AIAA Paper No. 1996-2496, New Orleans, LA, June 1996

A numerical large-eddy simulation model is under modification and testing for application to aircraft wake vortices. The model, having a meteorological framework, permits the interaction of wake vortices with environments characterized by crosswind shear, stratification, and humidity. As part of the validation process, model results are compared with measured field data from the 1990 Idaho Falls and the 1994-1995 Memphis field experiments. Cases are selected that represent different aircraft and a cross section of meteorological environments. Also included is one case with wake vortex generation in ground effect. The model simulations are initialized with the appropriate meteorological conditions and a post roll-up vortex system. No ambient turbulence is assumed in our initial set of experiments, although turbulence can be self-generated by the interaction of the model wakes with the ground and environment.

Proctor, F. H.

"THE LARC WAKE VORTEX MODELLING EFFORT"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 75-92

The purpose of the modelling effort at NASA Langley, including goals, is outlined in this presentation. Included is a description of the numerical model that is used for the NASA wake vortex modelling effort and the approach that is taken to achieve the stated goals. Also shown are: 1) a demonstration of using the model in a fog environment; 2) preliminary results from a 3-D simulation in a nonturbulent and thermally-stable environment with comparison to a comparable 2-D simulation of the same event; and 3) several validation cases from the Idaho-Falls and Memphis field studies where results from the 2-D version of the model are compared with Lidar and tower data.

Proctor, F. H.

"INTERACTION OF AIRCRAFT WAKES FROM LATERALLY SPACED AIRCRAFT"

AIAA Paper 2009-0343, Jan. 2009, Orlando, FL

Large Eddy Simulations are used to examine wake interactions from aircraft on closely spaced parallel paths. Two sets of experiments are conducted, with the first set for in ground effect (IGE). The initial wake field for each aircraft represents a rolled-up vortex pair generated by a B-747. Parametric sets include wake interactions from aircraft pairs with lateral separations of 400, 500, 600, and 750 ft. The simulation of a wake from a single aircraft is used as baseline. The study shows that the wake vortices from either a pair or a formation of B-747's that fly with very close lateral spacing, last longer than those from an isolated B-747. For OGE, the inner vortices between the pair of aircraft, ascend, link and quickly dissipate, leaving the outer vortices to decay and descend slowly. For the IGE scenario, the inner vortices ascend and last longer, while the outer vortices decay from ground interaction at a rate similar to that expected from an isolated aircraft. Both OGE and IGE scenarios produce longer-lasting wakes for aircraft with separations less than 600 ft. The results are significant because concepts to increase airport capacity have been proposed that assume either aircraft formations and/or aircraft pairs landing on very closely spaced runways.

Proctor, F. H. and Ahmad, N. N.

"CROSSWIND SHEAR GRADIENT AFFECT ON WAKE VORTICES"

AIAA Paper No. 2011-3038, June 2011, Honolulu, Hawaii.

Parametric simulations with a Large Eddy Simulation (LES) model are used to explore the influence of crosswind shear on aircraft wake vortices. Previous studies based on field measurements, laboratory experiments, as well as LES, have shown that the vertical gradient of crosswind shear, i.e. the second

vertical derivative of the environmental crosswind, can influence wake vortex transport. The presence of nonlinear vertical shear of the crosswind velocity can reduce the descent rate, causing a wake vortex pair to tilt and change in its lateral separation. The LES parametric studies confirm that the vertical gradient of crosswind shear does influence vortex trajectories. The parametric results also show that vortex decay from the effects of shear is complex since the crosswind shear, along with the vertical gradient of crosswind shear, can affect whether the lateral separation between wake vortices is increased or decreased. If the separation is decreased, the vortex linking time is decreased, and a more rapid decay of wake vortex circulation occurs. If the separation is increased, the time to link is increased, and at least one of the vortices of the vortex pair may have a longer life time than in the case without shear. In some cases, the wake vortices may never link.

"EVALUATION OF FAST-TIME WAKE VORTEX PREDICTION MODELS"

AIAA Paper 2009-0344, Jan. 2009, Orlando, FL

Current fast-time wake models are reviewed and three basic types are defined. Predictions from several of the fast-time models are compared. Previous statistical evaluations of the APA-Sarpkaya and D2P fast-time models are discussed. Root Mean Square errors between fast-time model predictions and Lidar wake measurements are examined for a 24 hr period at Denver International Airport. Shortcomings in current methodology for evaluating wake errors are also discussed.

Proctor, F. H. and Han, J.

"NUMERICAL STUDY OF WAKE VORTEX INTERACTION WITH THE GROUND USING THE TERMINAL AREA SIMULATION SYSTEM"

AIAA Paper No. 1999-0754, Reno, NV, January 1999

A sensitivity study for the 'in-ground effect' on aircraft wake vortices has been conducted using a validated large eddy simulation model. The numerical results are compared with observed data and show good agreement for vortex decay and lateral transport. The vortex decay rate is strongly influenced by the ground, but appears somewhat insensitive to ambient turbulence. In addition, the results show that the ground can affect the trajectory and descent-rate of a wake-vortex pair at elevations up to about $3B$ (where B is the initial vortex separation). However, the ground does not influence the average circulation of the vortices until the cores descend to within about $0.6B$ after which time the ground greatly enhances their rate of demise. Vortex rebound occurs in the simulations, but is more subtle than shown in previous numerical studies.

"NUMERICAL SIMULATION OF AIRCRAFT TRAILING VORTICES"

9th Conf. On Aviation, Range and Aerospace Meteorology, Paper 7.12, AMS, Orlando, FL, September 2000.

The National Aeronautics and Space Administration (NASA) under its Terminal Area Productivity program is investigating new technologies that will allow increased airport capacity while maintaining the present standards for safety. As an element of this program, the Aircraft Vortex Spacing System is being demonstrated in July 2000 at Dallas Ft.-Worth Airport. This system allows reduced aircraft separations, thus increasing the arrival and departure rates, while ensuring that wake vortices do not endanger trailing aircraft. The system uses predictions of wake vortex position and strength based on input from the current weather state. This prediction is accomplished by a semi-empirical model developed from theory, field observations, and relationships derived from numerical wake vortex simulations. Numerical experiments with a Large Eddy Simulation (LES) model are being conducted to provide guidance for the enhancement of these prediction algorithms. This paper summarizes many of the previous investigations with the model and presents some new results regarding the onset of wake vortex decay.

"THREE-PHASED WAKE VORTEX DECAY"

AIAA Paper No. 2010-7991, Toronto, Canada, August 2010.

A detailed parametric study is conducted that examines vortex decay within turbulent and stratified atmospheres. The study uses a large eddy simulation model to simulate the out-of-ground effect behavior of wake vortices due to their interaction with atmospheric turbulence and thermal stratification. This paper presents results from a parametric investigation and suggests improvements for existing fast-time wake prediction models. This paper also describes a three-phased decay for wake vortices. The third phase is characterized by a relatively slow rate of circulation decay. and is associated with the ring-vortex stage that occurs following vortex linking. The three-phased decay is most prevalent for wakes imbedded within environments having low-turbulence and near-neutral stratification.

"WAKE VORTEX TRANSPORT AND DECAY IN GROUND EFFECT: VORTEX LINKING WITH THE GROUND"

AIAA Paper No. 2000-0757, Reno, NV, January 2000

Numerical simulations are carried out with a three-dimensional Large-Eddy Simulation (LES) model to explore the sensitivity of vortex decay and transport in ground effect (IGE). The vortex decay rates are found to be strongly enhanced following maximum descent into ground effect. The nondimensional decay rate is found to be insensitive to the initial values of circulation, height, and vortex separation. The information gained from these simulations is used to construct a simple decay relationship. This relationship compares well with observed data from an IGE case study. Similarly, a relationship for lateral drift due to ground effect is constructed from the LES data. In the second part of this paper,

vortex linking with the ground is investigated. Our numerical simulations of wake vortices for IGE show that a vortex may link with its image beneath the ground, if the intensity of the ambient turbulence is moderate to high. This linking with the ground (which is observed in real cases) gives the appearance of a vortex tube that bends to become vertically oriented and which terminates at the ground. From the simulations conducted, the linking time for IGE appears to be similar to the linking time for vortices in the free atmosphere; i.e., a function of ambient turbulence intensity.

"TASS DRIVEN ALGORITHMS FOR WAKE PREDICTION"

AIAA Paper No. 2006-1073, Reno, NV, January 2006

The TASS Driven Algorithms for Wake Prediction (TDAWP) is a simple set of algorithms engineered from results of three-dimensional large eddy simulations of wake vortices. The model consists of two equations, one for the prediction of vortex transport and a second for wake vortex decay. The model is designed for real-time predictions of wake vortex position and strength, and is dependent upon, weather conditions. A detailed description of TDAWP, including validation with field data, is included.

"SIMULATIONS OF WAKE VORTEX DECAY IN THE ATMOSPHERE"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

As part of a NASA program to increase airport capacity, a numerical large-eddy simulation model has been used to investigate wake vortex behavior in the atmosphere. The primary objective of the numerical studies has been to quantify vortex transport and decay in relation to atmospheric variables. The studies have shown that the rate of vortex decay increases with increasing levels of ambient turbulence (as quantified by the eddy dissipation rate). However, near the ground, the decay rate is independent of the ambient turbulence level. Here, vortex decay is dominated by frictional interaction with the ground. Results also show that the time of vortex linking was primarily influenced by ambient turbulence. This was true even for cases of vortex linking with the ground. Vortex descent was found to be influenced by crosswind shear, large atmospheric eddies, and stratification. Results show that unexpected stalls during vortex descent can be attributed to either crosswind shear or vertical transport due to large planetary boundary layer eddies. Our studies, which assume high-Reynolds number flow with resolved turbulence, have reached different conclusions than those published using laminar models. For example, in cases of the free atmosphere with no crosswind, we find that 1) vortex separation is nearly constant, 2) vortex cores remain tight as the vortex decays, 3) the time of vortex linking is independent of the level of stratification, and 4) wake vortices dissipate once their descent is stalled due to stable stratification.

"METEOROLOGY AND WAKE VORTEX INFLUENCE ON AMERICAN AIRLINES FL-587 ACCIDENT"

NASA-TM-2004-213018, January 2004, NASA, Hampton, VA

The atmospheric environment surrounding the crash of American Airlines Flight 587 is investigated. Examined are evidence for any unusual atmospheric conditions and the potential for encounters with aircraft wake vortices. Computer simulations are carried out with two different vortex prediction models and a Large Eddy Simulation model. Wind models are proposed for studying aircraft and pilot response to the wake vortex encounter.

"TWO DIMENSIONAL WAKE VORTEX SIMULATIONS IN THE ATMOSPHERE: PRELIMINARY SENSITIVITY STUDIES"

AIAA Paper No. 1997-0056, Reno, NV, January 1997

A numerical large-eddy simulation model is currently being used to quantify aircraft wake vortex behavior with meteorological observables. The model, having a meteorological framework, permits the interaction of wake vortices with environments characterized by crosswind shear, stratification, and humidity. The addition of grid-scale turbulence as an initial condition appeared to have little consequence. Results show that conventional nondimensionalizations work very well for vortex pairs embedded in stably stratified flows. However, this result is based on simple environments with constant Brunt-Vaisala frequency. Results presented here also show that crosswind profiles exert important and complex interactions on the trajectories of wake vortices. Nonlinear crosswind profiles tended to arrest the descent of wake vortex pairs. The member of the vortex pair with vorticity of same sign as the vertical change in the ambient along-track vorticity may be deflected upwards.

"NEAR-FIELD VORTEX-WAKE/PLUME INTERACTION AT LOW SPEED"

Proceedings of FEDSM 98, 1998 ASME Fluids Engineering Division Summer Meeting, FEDSM98-4991, June 1998, Washington, DC.

A combined experimental and analytical study of nearfield vortex-wake/plume interaction in a subsonic flow has been initiated and preliminary results are presented. An engineering model is developed to examine the sensitivity of the various parameters leading to the onset of interaction. The utility of the model is illustrated and the associated strengths, envisioned limitations and possible refinements are discussed. Finally, comparisons are made with flow visualization experiments and good qualitative agreement has been found.

Prosser, C. P. and Wiler, C. D.

"RPV FLYING QUALITIES DESIGN CRITERIA"

AFFDL-TR-76-125, December 1976, Rockwell International Corporation Missiles Systems Division, Wright-Patterson AFB, OH.

The concept and philosophy for the organization of an RPV Flying Qualities Design Criteria are presented in a preliminary framework of criteria with supporting background and rationale. This report completes Phase II 6f a four-phase AFFPL/FGC program for the development of an RPV Flying Qualities Specification. The performance-oriented criteria are developed in hierarchical fashion from mission requirements, through total system requirements, to subsystem requirements. The criteria encompass automatic and manual controls, command and data link, controls and displays as well as vehicle stability and control. The material was based on an RPV literature search and review, and an evaluation of existing military specifications for piloted aircraft, such as MIL-F-8785B, MIL-F-83300, MIL-F-9490D (USAF), and MIL-C-18244A (Navy).

Proudian, A. P., Balser, M.

"AIRCRAFT VORTEX DETECTION SYSTEM"

US Patent 3,671,927, June 1972.

A system for detection and measurement of aircraft wing tip vortices. An acoustic radar with transmitter and receiver spaced from each other in a plane perpendicular to the flight path for illuminating the vortex and picking up scattering of the transmitter signal produced by the vortex, using Doppler frequency spectrum analysis with the maximum and minimum frequencies providing a measure of vortex intensity. A plurality of receivers operating with a common transmitter providing coverage of an area of interest along a flight path.

Pruis, M. J. and Delisi, D. D

"CORRELATION OF THE TEMPORAL VARIABILITY IN THE CROSSWIND AND THE OBSERVATION LIFETIME OF VORTICES MEASURED WITH A PULSED LIDAR"

AIAA Paper No. 2011-3199, June 2011, Honolulu, Hawaii.

The length of time over which a vortex pair behind a generating aircraft is observed with a pulsed lidar is compared with the observed temporal variability of the local crosswind. Multiple aircraft types and a broad range of atmospheric conditions are examined. It is found that the observed variability of the crosswind is a strong predictor of the observation lifetime. The magnitude of the variability of the crosswind varies as a function of time, measurement sites and altitude, but the relationship between the observation lifetime and temporal crosswind variability appears to be robust in the out-of-ground effect region. The focus of this paper is on results from a 2006 measurement campaign at Denver International Airport; however, the methodology is applicable at other airports. We compare these results with EDR estimates obtained using tower measurements and describe a new methodology for estimating EDR using the velocity estimates obtained from the same pulsed lidar that is used to track the vortices.

Pruis, M. J. and Delisi, D. P

"COMPARISON OF ENSEMBLE PREDICTIONS OF A NEW PROBABILISTIC FAST-TIME WAKE VORTEX MODEL AND LIDAR OBSERVED VORTEX CIRCULATION INTENSITIES AND TRAJECTORIES"

AIAA Paper No. 2011-3036, June 2011, Honolulu, Hawaii.

Lidar observations of wake vortex circulation intensity and trajectories are compared to the predictions of a new probabilistic fast-time wake vortex model. The new probabilistic model utilizes several different deterministic fast-time vortex models and produces ensemble model predictions of wake vortex behavior. Multiple numerical predictions are conducted in the form of a Monte Carlo analysis with slightly different initial conditions that are all plausible given the past or current set of observations and measurements. The probabilistic model predictions attempt to account for the two primary sources of uncertainty in fast-time wake vortex models: the errors introduced by sensitivity to the initial aircraft parameters and environmental conditions; and errors introduced because of imperfections in the model assumptions and simplifications. There three main findings of the study. First, the new probabilistic fast-time wake vortex prediction model reproduces observed vortex behavior and predicts approximately the same mean and spread as the observations. Second, uncertainties in the generator aircraft parameters are as important as uncertainties in the atmospheric conditions in generating estimated spread in the model predictions. And third, the spread between the different deterministic fast-time wake vortex models overlaps when plausible uncertainties in initial conditions are used. While development and validation of the new probabilistic fast-time wake vortex model is on-going, it appears that it will develop into a useful tool to help assess deterministic fast-time model performance, to assist in planning future wake vortex field observation campaigns, and eventually to examine current or proposed wake separation standards.

Pruis, M. J. and Delisi, D. P.

"ASSESSMENT OF FAST-TIME WAKE VORTEX PREDICTION MODELS USING PULSED AND CONTINUOUS WAVE LIDAR OBSERVATIONS AT SEVERAL DIFFERENT AIRPORTS"

AIAA Paper No. 2011-3035, June 2011, Honolulu, Hawaii.

Seven fast-time numerical wake vortex prediction models are reviewed, compared against each other, and evaluated against observations obtained using pulsed and continuous wave lidar at several different airports. Assessment of the models is performed as a function of wake age, aircraft size, generator height, and environmental conditions. The purpose of this study is to assess the relative strengths and weaknesses and ranges of applicability of different fast-time wake vortex prediction models. An important finding of this study is that, over a large range of environmental conditions, the fast-time wake vortex models predict similar behavior in vortex trajectories and circulation intensity. Furthermore, evaluation of the models with lidar observations indicates that in this same range of environmental conditions, the models agree reasonably well with observations of wake vortex evolution. The largest spread in the model predictions occur when the ambient turbulence is weak. Importantly, these conditions correlate with the long-lasting wake vortex observations. Increasing stratification also increases the model spread. Unfortunately, there is a paucity of available high quality, in situ observations of environmental conditions coincident with wake vortex measurements. The lack of high-quality data leads to ambiguity in ranking model performance. Assessment would be improved by a better quantification of the errors and uncertainties in the lidar observations, atmospheric conditions, and aircraft parameters; and with more landings in different glide slope regions with high quality, in situ observations of environmental conditions.

Pruis, M. J., Delisi, D. P. and Ahmad, N. N.

"COMPARISONS OF CROSSWIND VELOCITY PROFILE ESTIMATES USED IN FAST-TIME WAKE VORTEX PREDICTION MODELS"

AIAA Paper No. 2011-1002, January 2011, Orlando, FL.

Five methods for estimating crosswind profiles used in fast-time wake vortex prediction models are compared in this study. Previous investigations have shown that temporal and spatial variations in the crosswind vertical profile have a large impact on the transport and time evolution of the trailing vortex pair. The most important crosswind parameters are the magnitude of the crosswind and the gradient in the crosswind shear. It is known that pulsed and continuous wave lidar measurements can provide good estimates of the wind profile in the vicinity of airports. In this study comparisons are made between estimates of the crosswind profiles from a priori information on the trajectory of the vortex pair as well as crosswind profiles derived from different sensors and a regional numerical weather prediction model.

Pruis, M. J., Delisi, D. P. and Jacob, D.

"EFFECT OF ATMOSPHERIC SHEETS AND LAYERS NEAR THE GROUND ON WAKE VORTEX TRANSPORT AND DECAY"

AIAA Paper 2015-3315, June 2015, Dallas, TX.

Sheets and layers in the atmospheric boundary layer are common and develop during nighttime stably stratified shear flows. The eddy dissipation rates in the layers are found to be 3 to 4 orders of

magnitude less than the sheets between the layers, a difference large enough to potentially modify the rate at which vortices decay. The sheets are also found to be the boundaries separating regions of vorticity. Thus depending on what layer the aircraft vortex is horizontally advected within, the ambient vorticity of the region may reinforce or oppose the vorticity of the wake vortex. The vertical crosswind shear that is correlated with the presence of sheets and layers will also tend to tilt the port and starboard vortices with respect to one another, and thus it is not uncommon for the vortices to be horizontally advected at heights that are different from one another. We believe that because of the combination of these processes, vortices may sometimes be observed propagating in a layer of reduced turbulence for a longer than expected amount of time. In this paper, we will describe data collected at Memphis International Airport and show examples of vortices descending through atmospheric sheets and layers.

Pruis, M. J., Delisi, D. P. and Jacob, D.

"OBSERVATIONS OF WAKE VORTICES FROM UPWARD LOOKING PULSED DOPPLER LIDAR DATA"

AIAA Paper 2015-3177, June 2015, Dallas, TX.

NASA collected a large dataset of wake vortex and weather observations at Memphis International Airport from the spring of 2013 through early 2015. During this field experiment, there were several time intervals where special data acquisitions were obtained. One of these special data acquisitions is upward looking vertical stare data obtained using NASA's Halo Photonics StreamLine pulsed Doppler lidar. The upward looking stare data was collected in regions where wake vortices generated behind aircraft would drift with the ambient crosswind past the lidar. Samples of data from both arriving and departing aircraft were obtained. These observations were collected as experiments of opportunity, however from the preliminary analysis of the data, we believe it will be possible to obtain estimates of the core radius of the vortices, the distance between the vortex cores, and the tangential velocity profile of the vortices from this type of data product. In this paper, we will discuss the field set-up for these observations, review the data processing techniques and discuss the potential for these types of observations to estimate wake parameters that are currently not well constrained, yet very important, for development of wake hazard metrics.

Pruis, M. J., Delisi, D. P. and Jacob, D.

"OBSERVATIONS OF SMALL-SCALE ATMOSPHERIC VARIABILITY AND THE IMPORTANCE OF ACCURATE WEATHER INFORMATION IN DETERMINISTIC AND PROBABILISTIC FAST-TIME WAKE VORTEX MODELING"

AIAA Paper 2014-2468, June 2014, Atlanta, GA.

NASA has an on-going field experiment at Memphis International Airport to measure wake turbulence generated by aircraft in the near-ground effect region. This new data will be used in the validation and improvement of fast-time numerical wake vortex models, and provide an important data set to be used in the further development of probabilistic wake vortex estimation algorithms. An important component of this field program is to obtain high-quality estimates of important weather conditions in,

or near, the region where the wake vortices are generated and tracked, and at a frequency such that the scales of variability important in the evolution of wake vortices is observed. In this paper we will describe the intercomparisons of the estimates derived from multiple sensors for the important weather parameters of atmospheric turbulence and wind speed and direction. Using the results of this intercomparison, we will provide some guidance on what uncertainties may be applicable and useful when utilizing different sources for the estimation of the meteorological condition in probabilistic fast-time wake vortex simulations.

Pruis, M. J., Delisi, D. P., Ahmad, N. N. and Proctor, F. H.

"ATMOSPHERIC TURBULENCE ESTIMATES FROM A PULSED LIDAR"

AIAA Paper 2013-0512, January 2013, Grapevine, TX.

Estimates of the eddy dissipation rate (EDR) were obtained from measurements made by a coherent pulsed lidar and compared with estimates from mesoscale model simulations and measurements from an in situ sonic anemometer at the Denver International Airport and with EDR estimates from the last observation time of the trailing vortex pair. The estimates of EDR from the lidar were obtained using two different methodologies. The two methodologies show consistent estimates of the vertical profiles. Comparison of EDR derived from the Weather Research and Forecast (WRF) mesoscale model with the in situ lidar estimates show good agreement during the daytime convective boundary layer, but the WRF simulations tend to overestimate EDR during the nighttime. The EDR estimates from a sonic anemometer located at 7.3 meters above ground level are approximately one order of magnitude greater than both the WRF and lidar estimates -- which are from greater heights -- during the daytime convective boundary layer and substantially greater during the nighttime stable boundary layer. The consistency of the EDR estimates from different methods suggests a reasonable ability to estimate, from pulsed lidar measurements, the EDR near and below the altitude of an aircraft in an airport terminal area.

"FAST-TIME WAKE VORTEX MODEL PREDICTIONS COMPARED WITH OBSERVATIONS BEHIND LANDING AIRCRAFT NEAR THE GROUND"

AIAA Paper 2015-3316, June 2015, Dallas, TX.

NASA has recently collected a large dataset of wake vortex and weather observations at Memphis International Airport. The wake data consists primarily of vortices generated between one and two wingspans above the ground. Most of the landings in the dataset include field observations of all the required environmental and aircraft data needed for input into fast-time wake vortex prediction models: including vertical profiles of wind speed, air temperature and eddy dissipation rate, as well as the aircraft weights. Prior to the collection of this data set there was only a small amount of data that could be used in the evaluation of the skill of fast-time wake vortex prediction models when the vortices were generated within a couple wingspans of ground surface. This new data set significantly

increases the amount of data available for the assessment of the models in this important region. Comparison of three fast-time model predictions with the new Memphis data indicates there are several areas where the models can be improved in the in-ground effect region; specifically better parameterization of the effect of turbulence, and inclusion of the effect of headwind.

Pruis, M. J., Delisi, D. P., Jacob, D. and Lai, D. Y.

"SUMMARY OF NASA WAKE AND WEATHER DATA COLLECTION AT MEMPHIS INTERNATIONAL AIRPORT: 2013-2015"

AIAA Paper 2016-3274, June 2016, Washington, DC.

NASA has collected a large dataset of wake vortex and weather observations at Memphis International Airport. The wake data consists primarily of vortices generated between one and two wingspans above the ground. Most of the landings in the dataset include all the required environmental and aircraft data needed for input into fast-time wake vortex prediction models; including vertical profiles of wind speed, air temperature and eddy dissipation rate, as well as the aircraft weights and approach speed. Prior to the collection of this data set there was only a small amount of data that could be used in the evaluation of the skill of fast-time wake vortex prediction models when the vortices were generated within a couple wingspans of the ground surface. This new data set significantly increases the amount of data available for the assessment of the models in this important region. In this paper, we will describe the new data set including how the environmental data was collected and analyzed, and show example results comparing wake vortex behavior for different atmospheric conditions and aircraft types.

Pruyn, R. and Goland, L.

"AN INVESTIGATION OF VTOL OPERATIONAL PROBLEMS DUE TO DOWNWASH EFFECTS"

Report 179T80-2, June 1961, Kellett Aircraft, Willow Grove, PA.

Operational problems of VTOL type aircraft caused by downwash effects have been investigated utilizing a 3500-horsepower engine and a 15-foot diameter propeller mounted on a 20-ton crane. Results are presented for various propeller disc loadings up to 60 pounds per square foot, for several types of terrain and for various propeller heights and orientation above the terrain. The effects on pilot vision, ground personnel, equipment, aircraft and on aircraft concealment are presented. The effects of downwash were found to be a major operational problem which could limit the operational utility of VTOL aircraft.

Pruzan, D. A.

"EVALUATION OF AN ULTRASONIC VORTEX DETECTION SYSTEM"

AIAA Paper No. 2005-1413, Reno, NV, January 2005

Nielsen Engineering and Research (NEAR) has developed a prototype ultrasonic vortex detection system for measuring axial vorticity in a turbine engine test cell. To detect the presence of vorticity, acoustic signals are propagated around the inside perimeter of the test cell's bell mouth. An ultrasonic transmitter, flush-mounted with the bell mouth wall, generates an acoustic pulse which travels around the bell mouth along a path nominally perpendicular to the freestream direction. The propagation time for this signal to get to the receiver is then measured. The transmitter and receiver functions are then switched, and the time-of-flight for propagation in the opposite direction is measured. If there is no axial vorticity present, the two measured time-of-flight values will be the same. If the two measurements differ, then there is vorticity in the flow, and the associated circulation value can be directly computed from the time-of-flight measurements and knowledge of the local speed of sound. To demonstrate the feasibility of this approach, a prototype of the ultrasonic vortex detection system was fabricated and installed into a 10-inch diameter, low-speed wind tunnel. Measurements of vorticity were made with the tunnel empty, and with a low-aspect ratio wing present to generate axial vorticity. The latter measurements compare well with predicted wing tip vorticity values from NEAR's MISDL numerical code.

"INTERACTION OF WAKE VORTICES WITH THE GROUND"

Aerospace Science and Technology, Vol. 4, March 2000, pp. 239-247

The aim of this study is to describe wake vortices near the ground, including rebound. A calculation code solving the incompressible Navier-Stokes equations has been developed; it allows us to compute unsteady two-dimensional flows and steady three-dimensional flows having a preferential direction. The two-dimensional version of the code allows the capture of the rebound of the vortices near the wall as well as the creation of secondary vortices. In the three-dimensional case, the results are compared with experiments. The importance of the axial velocity is also analyzed.

Pulla, D.

"THE UNSTEADY WAKE GOVERNED BY A ROTOR IN GROUND EFFECT"

American Physical Society, 57th Annual Meeting Division of Fluid Mechanics, Nov. 2005, Chicago, IL.

Helicopters flying close to the ground encounter many handling qualities problems. Large unsteady forces near the main and tail rotors are believed to be a major cause of these problems. We investigate the structure of the unsteady wake generated by multibladed rotors in ground effect. A vortex lattice method with a free wake model is used to simulate the tip-vortex and the method of images is used to model the ground and the blades are modeled using the lifting surface method. The rotor wake is advanced in time until periodicity is attained. Unsteadiness in the form of instantaneous velocities is studied at different planes on the advancing and retreating sides of the tail rotor to identify the plane with the maximum unsteadiness. The root-mean-square of the deviation of the instantaneous velocity from the time averaged velocity over a given period is used to quantify the unsteadiness.

Pulla, D. and Conlisk, A. T.

"THE LONG TIME STRUCTURE OF THE ROTOR WAKE IN GROUND EFFECT"

AIAA Paper No. 2005-1408, Reno, NV, January 2005

The form of the rotor wake in the presence of a ground has been investigated using a vortex model of the rotor wake. Both hover and forward flight have been considered and the presence of the ground is modelled using the method of images. A lifting-line theory is used to model the rotor blade and a time-stepping vortex method has been used to obtain the evolution of tip-vortex. A numerical scheme has been designed to compute up to a hundred rotor revolutions. Our results show that periodicity is obtained after about thirty rotor revolutions near the blade as well as near the ground although this value depends to some extent on the advance ratio. Unsteadiness near the tail rotor has been studied by computing the deviation of the downwash and y -velocities from the mean at a hypothetical tail rotor and on its advancing and retreating sides.

Pulla, D. P.

"A STUDY OF HELICOPTER AERODYNAMICS IN GROUND EFFECT"

PhD Thesis, May 2006, Ohio State University, Columbus, OH.

The flow around a helicopter is very complex; it becomes much more complex when it comes close to the ground. The presence of the ground changes the aerodynamic characteristics of the rotor and the flow environment becomes much more complex compared with that of flight out-of-ground effect and hence the behavior of the rotor wake in the vicinity of the ground is challenging to predict. Under in-ground-effect conditions, the wake collides with the ground and causes a significant perturbation to the flow near the blade. Significant interactions between the main rotor wake and the ground have been associated with the formation and passage of the ground vortex in forward flight. The presence of a ground vortex affects the handling qualities of the helicopter. The aim of this research is to capture the physics of the flow features and dynamics of ground effect flows around a rotorcraft, provide an understanding of the rotor wake/vortices near the ground, and generate rigorous models to accurately predict handling qualities, loads and moments acting on the rotor and the power requirements. The wake structure after periodicity is reached is obtained for hover and different forward flight speeds. Also, the nature of the flowfield, as well as the formation of the ground vortex, is understood by obtaining the velocity contours on a longitudinal plane containing the rotor blade after periodicity is obtained. The unsteadiness in the velocities is quantified by obtaining the RMS deviation in velocities on different planes containing the tail rotor around the rotor disk simulating the various kinds of flight. Thrust and power requirements on the rotor disk have been predicted and have been successfully validated by comparison with experimental results obtained from Georgia Institute of Technology.

Pulla, D. P., Godavarty, V., Burgraff, O. R. and Conlisk, A. T.

"INVISCID MODEL OF THE FORMATION OF A ROTOR TIP VORTEX"

AIAA Journal, Vol. 44, No. 7, July 2006, pp. 1653-1661.

The roll up of trailing vortex filaments shed from a finite-length rotor blade in hover has been computed and analyzed. It is shown that the formation of the tip vortex is a strong function of the aspect ratio of the blade, angle of attack, and number of blades. The amount of trailing circulation associated with the tip vortex develops downstream and approaches an asymptotic constant that is less than that the total amount of trailing circulation. The results for the vertical and horizontal velocity profiles downstream of the blade are compared with the results for an infinite blade and with the experimental results of McAlister et al, (McAlister, K., Tung, C., and Heineck, J. T., 'Devices That Alter the Tip Vortex of a Rotor' NASA TM-2001-209625, Aeroflightdynamics Directorate, TR-01-A-003, Feb. 2001). The velocity profiles across the tip vortex compare extremely well with experiment.

Pulla, P., Bhattacharyya, S. and Conlisk, A. T.

"THE STRUCTURE OF THE ROTOR WAKE IN GROUND EFFECT"

American Physical Society, Fluid Dynamics 56th Annual Meeting, Nov. 2003, East Rutherford, NJ.

The form of the rotor wake in the presence of a ground has been investigated. Both hover and forward flight have been considered. The presence of the ground is modeled using the method of images. Lifting-line and lifting surface methods have been used to model the blade and results for the two methods are compared. A time-stepping vortex method has been used to obtain the evolution of tip-vortex. The agreement of the computed results with experimental data in hover is encouraging. The wake geometry for both single and two bladed rotors has been calculated for different ground to rotor separation distances and for several forward flight speeds. The individual vortex lines comprising the tip vortices form the ground vortex on the upstream side of the rotor at low forward flight speeds. The results show that the vortex core shifts downstream as the forward speed of the rotor increases.

Pullin, D. I. and Phillips, W. R. C.

"ON A GENERALIZATION OF KADEN'S PROBLEM"

Journal of Fluid Mechanics, Vol. 104, March 1981, pp. 45-53.

Kaden's problem of the roll-up of an initially planar semi-infinite vortex sheet is extended to include sheets exhibiting a general power law circulation distribution resulting in both power law and logarithmic-like velocity field singularities. Both single and double branched spirals are considered.

"VORTEX DYNAMICS IN TURBULENCE"

Ann. Rev. Fluid Mechanics, Vol. 30, 1998, pp. 31-51

We survey attempts to construct vortex models of the inertial-range and fine-scale range of high Reynolds number turbulence. An emphasis is placed on models capable of quantitative predictions or post-dictions.

Purser, P. E., Spearman, M. L. and Bates, W. R.

"PRELIMINARY INVESTIGATION AT LOW SPEED OF DOWNWASH CHARACTERISTICS OF SMALL-SCALE SWEPTBACK WINGS"

NACA Technical Note, 1378, July 1947, Langley Memorial Aeronautical Laboratory, Langley Field, VA.

A preliminary investigation has been made at low speed of the downwash behind various small-scale sweptback wings. The wing configurations for which data were obtained covered aspect ratios from 2.5 to 4.0, sweepback angles from 32.5 to 40 degrees, and ratios of root chord to tip chord from 0.62 to 2.06. The data showed that for the higher tails and shorter tail lengths behind each of the wings in the wing-tail combinations tested, fairly large variations occurred in the rate of change of downwash angle with angle of attack de/da at high angles of attack with resulting large changes in the longitudinal stability of the wing-tail combinations. In general, lowering the tail to a position near the extended chord line of the wing and increasing the tail length caused improvement of the stability as characterized by decreases in de/da and by decreases in the variation of de/da with angle of attack. Increasing the wing aspect ratio caused a reduction in de/da and improved the tail contribution to the stability. Increasing the ratio of wing root chord to tip chord caused increases in the rate of change of downwash angle with angle of attack for the low lift range. The use of trailing-edge flaps caused a slight increase in de/da and caused an increment of downwash angle at low angles of attack about the same as would be expected for unswept wings. Leading-edge slats reduced the variation of de/da at high lift coefficients and generally resulted in improvement of the stability. Values of downwash angle computed from design charts for unswept wings given in NACA Reports No. 648 and 711 agreed fairly well with experimental data at low lift coefficients provided the computations were based on the aspect ratio and span of an unswept wing having the same panels as the sweptback wing.

Purvis, J. W.

"ANALYTICAL PREDICTION OF VORTEX LIFT"

J. Aircraft, Vol. 18, No. 4, April 1981, pp. 225-230

General integral expressions are derived for the nonlinear lift and pitching moment of arbitrary wing planforms in subsonic flow. The analysis uses the suction analogy and an assumed pressure distribution based on classical linear theory results. The potential flow lift constant and certain wing geometric parameters are the only unknowns in the integral expressions. Results of the analysis are compared with experimental data and other numerical methods for several representative wings, including ogee and double-delta planforms. The present method is shown to be as accurate as other numerical schemes for predicting total lift, induced drag, and pitching moment.

Puttinger, S., Mehrle, A. and Gittler, P.

"NUMERICAL OPTIMIZATION AND EXPERIMENTAL INVESTIGATIONS ON THE PRINCIPLE OF THE VORTEX DIFFUSER"

AIAA Paper No. 2009-3610, June 2009, San Antonio, Texas.

The present work deals with numerical optimization of and experimental studies on aft mounted wing tip devices, so called vortex diffusers. The purpose of most kinds of wing tip devices is to reduce the induced drag by converting vortex energy into thrust. To obtain an optimal design for the vortex diffuser, the parameterized diffuser blade shape is optimized with respect to axial thrust within the framework of lifting line theory. Finite airfoil performance is accounted for by applying lift and drag coefficients from wind tunnel data. The so gained optimal design for the vortex diffuser blades is realized on a small-scale model, and wind tunnel tests are carried out to investigate drag reduction of the vortex diffuser for comparison with numerical results. Furthermore, the goal is to gain some experience and data for preparation of real flight testing on a UAV. Experiments clearly show that the vortex diffuser can reduce drag in high lift / high angle of attack configurations. Wind tunnel tests, however, also demonstrate some problems for practical design of the vortex diffuser.

Qiao, W. and Michel, U.

"A STUDY ON THE VORTEX SHEDDING NOISE FROM THE WAKE OF AIRCRAFT WINGS"

AIAA Paper No. 2000-1973, Lahaina, HI, June 2000

An important airframe noise source -vortex shedding noise- was first identified by U. Michel et al (1998) based on the fly-over measurements with a planar microphone array. In this paper, the detail results from the planar microphone array measurements about this new airframe noise source on different aircraft were presented. The position of this source on airframe, the frequency features and the directional features of this source were described. It is found that the narrow-band frequency spectrum of this source is dominated by a tone. The frequency of the tone increases with the increase in airspeed. The directivity of the tone has an increasing sound pressure level to the forward arc, and a decreasing sound pressure level to the rear arc. The difference of the sound pressure level from emission angle of 60 degrees to 120 degrees is about 5-8 dB. It is proposed that vortex shedding from the wake of aircraft wing results to this noise surface.

Qiao, Z. D., Yang, A. M. and Zhu, B.

"NUMERICAL SIMULATION OF NAVIER-STOKES EQUATIONS FOR HELICOPTER ROTOR IN FORWARD FLIGHT USING MOVING CHIMERA GRIDS"

ICAS 2002 Paper 2002-R53, Sopt. 2002, Toronto, Canada.

At present dual time methods with explicit inner iteration scheme have been adopted by the most of unsteady flow simulations based on Euler equations or Navier-Stokes equations. A disadvantage of the methods is that the computation efficiency is not enough to calculate the complex unsteady flows. In

this paper a full implicit dual time method with implicit pseudo-time scheme by using moving chimera grids is developed for computation of complex unsteady flows. In the method a highly efficient implicit LU-SSOR method is adopted for the inner interaction computation. The numerical tests of the unsteady flow simulation based on Navier-Stokes equations for forward flight of rotary wings show that the computation results agree with experiment and the method is very efficient for computation of complex unsteady flows.

Qu, Q., Huang, L., Liu, P. and Agarwal, R. K.

"NEAR-FIELD WINGTIP VORTEX CHARACTERISTICS OF A RECTANGULAR WING IN GROUND EFFECT"

AIAA Paper 2016-1781, January 2016, San Diego, CA.

The aerodynamics and near-field wingtip vortex characteristics of a rectangular wing with NACA4412 section in ground effect (GE) are studied in this paper. The steady compressible Reynolds-Averaged Navier-Stokes (RANS) equations with the Spalart-Allmaras (SA) turbulence model are discretized using the finite volume method. Based on the pressure and lift variations in GE, a 3D rectangular wing can be divided into two parts along the span-wise direction: the quasi-2D inner part of the wing (away from wing tip) in which the lift increases monotonously, and the second part near the wingtip in which the lift decreases. In GE, the wingtip vortex moves outward along the span-wise direction due to the ground mirror effect, and rebounds in the vertical direction due to the induction from the secondary vortex generated from the ground boundary layer. In GE, the strength of the near-field wingtip vortex along the flow direction depends not only on the initial vortex strength and the shear layer developing from the trailing edge of the wing, but also due to the generation of secondary vortex in the ground boundary layer, and the interaction between the wingtip vortex and the secondary vortex.

"DETACHED EDDY SIMULATION OF FAR-FIELD WAKE VORTEX IN STATIC AND MUTATIONAL GROUND EFFECTS"

AIAA Paper 2017-3039, June 2017, Denver, CO.

Far-field wake vortex can increase the risk in take-off and landing of a fighter aircraft especially on the deck of an aircraft carrier. The development and decay of a far-field wake vortex in static and mutational ground effect is studied using the detached eddy simulation (DES). Without loss of generality, in this study the vortex is modeled as an Oseen vortex. In the quiescent air, the Oseen vortex moves closer to the ground or moves over the platform. The vortex decay in unbounded flow field is slower due to viscous effects. It is shown by numerical simulation that the vortex decay in static ground effect is very quick due to both the secondary vortex generation and the interaction between the primary vortex and the secondary vortex.

Quackenbush, T. R. and Wachspress, D. A.

"REVIEW AND ASSESSMENT OF SELECTED ISSUES IN HOVERING ROTOR TIP VORTEX DYNAMICS"

Proceedings of the ARO Rotorcraft Wake Prediction Basic Research Workshop, March 2009, Georgia Institute of Technology, Atlanta, GA, p. 50.

This discussion will briefly outline previously developed (though still relevant) methods of analysis of vortex instabilities in hovering rotor wakes, derived from the linearized dynamics of self-preserving wake solutions. The behavior of OGE rotor wakes will be discussed and the relationship of computed measures of wake instabilities to prior analytical and experimental results from other investigators will be noted. The ability of current methods to capture noteworthy behaviors in the wakes of IGE hovering rotors will also be described, including the appearance of long-period pulsations in wake-induced velocity and vortex bundling.

Quackenbush, T. R., Batcho, P. F., Bilanin, A. J. and Carpenter, B. F.

"DESIGN, FABRICATION, AND TEST PLANNING FOR AN SMA-ACTUATED VORTEX WAKE CONTROL SYSTEM"

Proc. SPIE, Vol. 3326, June 1998, pp. 259-27.

This paper describes ongoing design and fabrication work on a vortex wake control system for submarines that employs SMA-actuated devices. Previous work has described the theoretical basis and feasibility studies for this system, which is based on a novel wake control scheme known as vortex leveraging. The critical item in the realization of this system is a Smart Vortex Leveraging Tab (SVLT), whose design and fabrication is the principal focus of this work. This paper outlines the background of the effort and the design principles involved, but will chiefly deal with three closely interrelated topics; the hydrodynamic design requirements and control surface layout for the vortex leveraging system; the detail design and fabrication techniques being used in the construction of a prototype SVLT; and the test planning and experiment design process currently underway for test of both the overall vortex leveraging concept and SVLT device itself.

Quackenbush, T. R., Bilanin, A. J. and Carpenter, B. F.

"TEST RESULTS FOR AN SMA-ACTUATED VORTEX WAKE CONTROL SYSTEM"

Proceedings SPIE, Industrial and Commercial Applications of Smart Structures Technologies, Vol. 3674, March 1999, Newport Beach, CA, pp. 84-94.

This paper describes recent test results obtained on a prototype SMA-actuated foil that serves as a key element in a vortex wake control scheme for lifting surfaces. Previous papers have described the theoretical basis and feasibility studies for this scheme -- which is based on a novel wake control concept known as vortex leveraging -- as well as prior work on device design, test planning, and fabrication. The critical item in the realization of this scheme is a Smart Vortex Leveraging Tab (SVLT), a device designed to provide perturbations in the vortex system downstream of lifting surfaces at frequencies and amplitudes carefully selected to accelerate overall wake breakup. The paper

summarizes the background of the effort, but focuses on the detailed design and fabrication techniques used in the construction of a prototype SVLT and the results of water tunnel tests of a near full-scale prototype device.

Quackenbush, T. R., Bilanin, A. J. and McKillip, R. M.

"VORTEX WAKE CONTROL VIA SMART STRUCTURES TECHNOLOGY"

Proc. SPIE, Vol. 2721, May 1996, pp. 78-92

Control of trailing vortex wakes is an important challenge for both military and civilian applications. This paper summarizes an assessment of the feasibility of mitigating adverse vortex wake effects using control surfaces actuated via Shape Memory Alloy (SMA) technology. The assessment involved a combined computational/design analysis that identified methods for introducing small secondary vortices to promote the deintensification of vortex wakes of submarines and aircraft. Computational analyses of wake breakup using this 'vortex leveraging' strategy were undertaken, and showed dramatic increases in the dissipation rate of concentrated vortex wakes. This paper briefly summarizes these results and describes the preliminary design of actuation mechanisms for the deflectable surfaces that effect the required time-varying wake perturbations. These surfaces, which build on the high-force, high-deflection capabilities of SMA materials, are shown to be well suited for the very low frequency actuation requirements of the wake deintensification mission. The paper outlines the assessment of device performance capabilities and describes the sizing studies undertaken for full-scale Vortex Leveraging Tabs (VLTs) designed for use in hydrodynamic and aerodynamic applications. Results obtained to date indicate that the proposed VLTs can accelerate wake breakup by over a factor of three and can be implemented using deflectable surfaces actuated using SMAs.

Quackenbush, T. R., Bilanin, A. J., Batcho, P. F., McKillip, R. M. and Carpenter, B. F.

"IMPLEMENTATION OF VORTEX WAKE CONTROL USING SMA-ACTUATED DEVICES"

Proc. SPIE, Vol. 3044, May 1997, pp. 134-146

Mitigation of the undesirable effects of trailing vortex wakes has been a long-standing priority for both reduction of submarine wake signature and alleviation of aircraft vortex wake hazard. A recent study established the feasibility of using relatively weak, secondary vortices with carefully selected unsteady amplitude and phasing to accelerate the breakup of the primary vortex system of a lifting surface, a technique denoted 'vortex leveraging'. This paper will summarize progress on the development of SMA-actuated devices for implementing vortex leveraging for hydrodynamic applications. The methods being applied to the hydrodynamic design of these deformable Smart Vortex Leveraging Tabs (SVLTs) will be described, and the results of a preliminary assessment of SVLT performance in achieving wake breakup will be presented. Also, previous work on the design and testing of deformable control surfaces actuated via embedded SMA agonist wires will be reviewed and the design process being employed in the present applications will be discussed. Finally, the plans for

near-term computational and experimental work to validate the use of SMA-driven devices for the wake mitigation task will be briefly outlined.

Quackenbush, T. R., Boschitsch, A. H. and Bilanin, A. J.

"COMPUTATIONAL AND EXPERIMENTAL STUDIES IN MULTIPAIR WAKE VORTEX INSTABILITIES"

AIAA Paper 2013-3190, June 2013, San Diego, CA.

Control of trailing vortex wakes of lifting surfaces such as aircraft wings and submarine control planes is an important challenge for both military and civil applications. This paper summarizes the development and testing of a method for mitigating adverse vortex wake effects using active control of auxiliary aerodynamic surfaces mounted on the primary lifting wing. The governing concept involves a method for introducing small, secondary vortices of periodic, time-varying strength to promote the deintensification of the primary vortex wake system. Computational analyses of wake breakup using this 'vortex leveraging' strategy have shown up to an order of magnitude increase in the dissipation rate of concentrated vortex pair wakes relative to natural mechanisms. The work described here was among the first efforts to explore this class of mitigation methods and the discussion below summarizes the foundational analysis and validation work on this concept. Computational modeling involved application of fast vortex methods to identify potentially promising methods for exploiting the instabilities of multipair vortex wakes. Validation of the concept was done by way of tow tank experiments that both provided flow visualization of predicted wake on wake interactions and measurements of vortex transport indicating substantial mitigation of wake effects.

Quackenbush, T. R., Boschitsch, A. H. and Bilanin, A. J.

"ASSESSMENT OF AIRCRAFT AND ROTORCRAFT WAKE FLOW FIELDS FOR WAKE HAZARD APPLICATIONS"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

NASA has identified the objective of tripling airport throughput over the next decade as an air transport goal, and a likely major component of such an effort is the utilization of rotorcraft to provide feeder service to major airports. Among the key challenges in ensuring safe, high-volume terminal area rotorcraft operations are identifying and mitigating potential hazards posed by vortex encounters between rotorcraft and fixed wing aircraft. To address these challenges, a family of fast yet high-fidelity vortex wake modeling methods must be developed for eventual incorporation into both off-line assessment tools and pilot-in-the-loop simulation environments. Though considerable additional technology development is required, several elements of a hierarchy of physics-based models for assessment of a range of possible encounter scenarios are currently in hand. This paper will review the development status of these models and examine key features of the predicted flow fields, particularly with respect to the likely impact of wake-induced forces and moments on the flight dynamics of nearby aircraft. Also described are databases suitable for model validation as well as further technology

developments that are likely necessary to address the full range of complex aeromechanical phenomena in future terminal area operations environments.

Quackenbush, T. R., Teske, M. E. and Bilanin, A. J.

"DYNAMICS OF EXHAUST PLUME ENTRAINMENT IN AIRCRAFT VORTEX WAKES"

AIAA Paper No. 1996-0747, Reno, NV, January 1996

The prediction of wake/exhaust mixing for subsonic and supersonic aircraft is an important aspect of the assessment of the atmospheric effects of aviation. This paper focuses on the development, modification, and testing of analysis methods for the specific application of predicting the mixing of the aircraft vortex wake with the engine exhaust. The case studies described indicate the importance of buoyancy and variable density effects in realistic simulations, and having helped quantify important differences in plume entrainment and detrainment between major classes of commercial aircraft.

Quackenbush, T. R., Teske, M. E. and Bilanin, A. J.

"COMPUTATION OF WAKE/EXHAUST MIXING DOWNSTREAM OF ADVANCED TRANSPORT AIRCRAFT"

AIAA Paper 93-2944, July 1993, Orlando, FL.

The mixing of engine exhaust with the vortical wake of high speed aircraft operating in the stratosphere can play an important role in the formation of chemical products that deplete atmospheric ozone. An accurate analysis of this type of interaction is therefore necessary as a part of the assessment of the impact of proposed High Speed Civil Transport (HSCT) designs on atmospheric chemistry. This paper describes modifications to the parabolic Navier-Stokes flow field analysis in the UNIWAKE unified aircraft wake model to accommodate the computation of wake/exhaust mixing and the simulation of reacting flow. The present implementation uses a passive chemistry model in which the reacting species are convected and diffused by the fluid dynamic solution but in which the evolution of the species does not affect the flow field. The resulting analysis, UNIWAKE/PCHEM (Passive CHEMistry) has been applied to the analysis of wake/exhaust flows downstream of representative HSCT configurations. The major elements of the flow field model are described, as are the results of sample calculations illustrating the behavior of the thermal exhaust plume and the production of species important to the modeling of condensation in the wake. Appropriate steps for further development of the UNIWAKE/PCHEM model are also outlined.

Querin, O. M.

"ROTOR WAKE INVESTIGATION USING THE SMOKE FLOW VISUALIZATION TECHNIQUE"

MS Thesis, March 1993, University of Sidney, Sidney, Australia.

Experiments were carried out on a small four bladed rotor at different climb rates. The smoke-filament technique was used to visualize the rotor tip vortices; video equipment was then used to

record the images produced. The recorded images were digitized and enhanced to assist in the identification of the vortex location. The vortex trajectories were compared with established data and with the paths generated by the general tip vortex path equations. It was found that these equations oversimplified the vortex trajectories, modelling neither the interaction between vortices nor their meandering. The wakes studied showed evidence of vortex interaction. It was found that vortices close to one another combined in pairs and spun about a common center as they moved downstream. A new mean path equation was thus defined which could model this type of behavior. An exponential equation was selected to model the mean path. To assist in the determination of the order which best suited the curve, the least squares method was used. The meandering of the vortex trajectory about its mean path was studied and the types of instability present were determined. Three types of instability were found in tip vortices; short-wave, mutual-inductance, and long-wave. It was discovered that the helical path followed by a hovering rotor's tip vortex was unstable under most flight conditions and that fluid damping suppressed the magnitude of these instabilities.

"THE COMPREHENSIVE STUDY ON ADVANCED WINGTIP DEVICES IN LARGE CIVIL AIRCRAFT"

ICAS Paper 2012-8.8.3, September 2012, Brisbane, Australia.

Adding a wingtip device to wings of aircraft can reduce the induced drag, improve lift-drag ratio, and dissipate the strong wake vortex in aerodynamics, etc. However, the flutter characterization of the aircraft is changed simultaneously, and so is the structural weight. There are many researches on the drag reduction of wingtip devices all over the world, however, the flutter characterization of three kinds of advanced wingtip devices (blended, sharklet, ladder) is not studied fully, especially the overall performance from aerodynamic flutter and weight. So three kinds of advanced wingtip devices (blended, sharklet, ladder) are researched by using the numerical simulation method from aerodynamics, flutter and weight in this paper. Meanwhile, the effects of wingtip device height on aircraft's flutter is also investigated.

"HIERARCHICAL VARIABLE FIDELITY METHODS FOR ROTORCRAFT AERODYNAMIC DESIGN AND ANALYSIS"

American Helicopter Society 67th Annual Forum, May 2011, Virginia Beach, VA.

A coupling framework has been developed for unstructured computational fluid dynamic (CFD) solvers to allow for simple activation of a variety of wake solvers. In addition, the interface has been parallelized and extended to support dynamic, overset meshes in rotating frames. Wake capture and performance calculations demonstrate the validity of the framework. Demonstration cases include an oscillating wing, the hovering Caradonna-Tung rotor and ROBIN rotor-fuselage interaction for multiple coupling variations between CHARM, VorTran-M, and FUN3D. These results illustrate that the hybrid methods can provide more accurate results with reduced grid sizes for various applications. The

modification of only one solver at each incremental level of analysis permits the user to identify the source of changes in solution results.

Raat, J.

"VORTEX DEVELOPMENT AND BREAKDOWN"

AIAA Paper No. 1975-0881, Hartford, CT, June 1975

A trailing vortex is assumed to consist of a thin axisymmetric viscous core embedded in an inviscid flow of uniform circulation and with axial velocity that may depend on the distance along the core. Self-similar solutions for axial velocity and circulation are presented for the special case of an external velocity inversely proportional to the core length. Integral solutions for uniform external flow fall into three different categories: (1) Wake-type vortex development, (2) Breakdown when the prescribed azimuthal energy conversion mechanism can no longer be satisfied, (3) Breakdown through core flow reversal. The effect of external pressure gradients on breakdown is exhibited.

"EFFECT OF A SPLITTER PLATE ON THE DYNAMICS OF A VORTEX PAIR"

AIAA Paper No. 2011-3894, June 2011, Honolulu, Hawaii.

An experimental and numerical study was performed to investigate the behavior of a counter-rotating vortex pair as well as a single vortex in the vicinity of a wall. A wind tunnel with two NACA0012 profiles mounted vertically with an optional splitter plate in the center and a 3D PIV system were used to experimentally study the interactions between two counter-rotating vortices, as well as the interactions between a vortex and a wall. Many fundamental differences were found between the two configurations, which promote the growth of the Crow instability in the two-vortex configuration, but not in the one vortex/wall configuration. The numerical results obtained re-enforced the experimental results, and emphasize the fundamental physical differences between the two configurations. While modeling a vortex wall system with an image vortex may give correct integral results for loads experienced by blades, this model does not accurately describe the downstream dynamics of the vortex system.

"DYNAMIC SEPARATION MINIMA COUPLED WITH WAKE VORTEX PREDICTIONS IN DEPENDENT RUNWAY CONFIGURATIONS"

ICAS Paper 2012-10.4.2, September 2012, Brisbane, Australia.

Wake vortices are an issue affecting both capacity and safety of air traffic and therefore need to be dealt with by appropriate measures and procedures. Today, the only means to prevent wake vortex encounters is procedural separation which however is static and in many cases conservative. The

concept of dynamic separations using wake vortex predictions aims at optimizing the separation between consecutive aircraft based on the knowledge of the actual position and strength of the wake vortices. A concept for approach procedures has been developed that involves dynamical calculation of minimum safe distance, adaption of follower aircraft speed and the corresponding approach types. The concept, its implementation and simulation test results will be presented and it will be discussed how it can be applied to contribute to an optimized use of available capacity while maintaining and improving the safety level.

"USE OF A DEFORMABLE CORE VORTEX MODEL IN PREDICTING VORTEX-SURFACE INTERACTIONS"

AIAA Paper No. 1999-0169, Reno, NV, January 1999

The direct collision of a vortex with a surface is an important problem because significant impulsive loads may be generated leading to premature fatigue. Experimental results for the impingement of a tip-vortex on a cylindrical airframe indicate that a strong suction peak forms on the top of the airframe that subsequently decreases within milliseconds of vortex-surface contact. Previous attempts to simulate the decrease in the suction peak have resulted in numerical error as the vortex vorticity overlaps the physical airframe in an unphysical manner on close approach. In this paper we present a vortex model that allows the vortex core to deform, preventing any vorticity overlap. Unlike our previous results, this model predicts the reversal in the suction peak without significant error.

"3D EULER CALCULATIONS OF MULTIBLADED ROTORS IN HOVER: INVESTIGATION OF THE WAKE CAPTURING PROPERTIES"

Aerodynamics and Aeroacoustics of Rotorcraft, AGARD-CP-552, August 1995, pp. 13-1 to 13-16.

The 3D flowfield of a hovering rotor is calculated solving the Euler equations. Performing a grid refinement study, it is demonstrated that an Euler method can capture the wake and vortices of a hovering rotor without any wake modeling. Accurate prediction of these rotational flow field phenomena needs fine grids with a high resolution in the complete region of the wake system. Additionally, high accuracy for the treatment of all numerical boundaries, which affect the vortex wake, is required. On the other hand, the investigations have shown that surface air loads are less affected by a more detailed resolution of the wake system. A second part of the study is concerned with wake capturing properties on block boundaries, especially on inner boundaries of overlapping grids. Overlapping grids are very attractive for the computation of a rotor in lifting forward flight or a rotor-body flowfield in hover. The effect of overlapping grids using the chimera technique is investigated comparing Euler solutions for a hovering rotor on a chimera grid system and on conventional single block and two block calculations. The chimera solution reproduces all flow features. The present implementation shows disadvantages concerning the detailed resolution of the wake system.

"INVESTIGATION OF FACTORS AFFECTING MINIMUM INTERVAL BETWEEN AIRCRAFT TAKEOFFS (MITO)"

TM 79-9.12/1, September 1979, Calspan Corp., Los Angeles, CA

The factors that affect MITO fall into two basic categories: (1) the aerodynamic factors that contribute to vortex generation and to the control of following aircraft, and (2) the propulsion factors that contribute to the generation of exhaust turbulence and combustion by-products. A literature and data search failed to turn up any information related to the propulsion factors and only limited data related to the aerodynamic factors. The best current source of data are the DOT studies on landing and takeoff intervals of commercial aircraft. Although DOT's objectives in conducting these studies are significantly different from SAC's objectives for alert aircraft, it is possible that the DOT data will provide a good initial understanding of the takeoff interval problem.

"LONG-RANGE INTERACTION AND ELASTIC COLLISIONS OF ISOLATED VORTICES"

J. Fluid Mech., Vol. 610, 2008, pp. 285-310

This study explores the interaction of two nearly axisymmetric two-dimensional vortices using a combination of numerical simulations and analytical arguments. We consider isolated or 'shielded' eddies, characterized by zero net vorticity. The ability of such vortices to propagate and interact is associated with the small dipolar component that is introduced initially. Numerical contour dynamics experiments indicate that the interaction of shielded eddies takes one of two forms, depending on

their initial separation and on the relative orientation of their dipolar components. Eddies can influence each other by remotely modifying the dipolar moments of partner vortices, an effect manifested in a gentle deflection of their trajectories from a straight course. Strong interactions occur when eddies collide and rebound. The remote interaction is explained by weakly nonlinear theory in which the basic state consists of identical circularly symmetric eddies and the perturbation is assumed to be small. It is argued that the elastic rebounds observed during direct collisions are induced by the exchange of fluid between colliding vortices.

"RESEARCH CONCERNING THE INTERACTION BETWEEN THE GROUND AND THE TURBULENT AIRCRAFT WAKE VORTEX"

Proceedings of the World Congress on Engineering , Vol. II, July 2009, London, UK.

The problem developed in this contribution is encountered in airplane aerodynamics and concerns the influence of long-life longitudinal wake vortices generated by wing tips or by external obstacles such as reactors or landing gears. At the edge of such obstacles, longitudinal vortices are created by pressure differences inside the boundary layers and rotate in opposite senses. The numerical simulation used for understanding the mechanisms were generally time evolution computation on a fixed space box with periodic boundary conditions using a transformation of the time evolution into a downstream evolution. The flow will be perturbed by prescribed disturbances or by a turbulent field.

Raffel, M.

"PIV MEASUREMENTS OF WAKE VORTICES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

Over the past decade particle image velocimetry (PIV) has matured from its developmental stage to a reliable whole field flow measurement technique and now finds uses in a continuously broadening range of applications. An especially important field of PIV applications is the measurement of wake vortices in aeronautics. The application of the PIV technique has been demonstrated by various experimental investigations on wake vortices. Two experiments were performed in order to investigate details of the vortex formation from helicopter blade tips in a large wind tunnel. Furthermore, the wake measurements of a propeller, which have been performed in a smaller facility, and in addition to that, simultaneous measurements of the velocity and density fields were conducted in a transonic wind tunnel to characterize the structure of compressible vortices. These results will be presented together with further examples of wake vortex PIV measurements in aerodynamics.

"BACKGROUND-ORIENTED SCHLIEREN IMAGING FOR FULL-SCALE AND IN-FLIGHT TESTING"

Journal of the American Helicopter Society, Vol. 59, 2014, pp. 012002-1 to 012002-9.

Background-oriented schlieren (BOS) methods suited for large-scale and in-flight testing are presented with special emphasis on the detection and tracing of blade tip vortices in situ. Retroreflective recording and photogrammetric epipolar analysis for the computation of the vortices' spatial coordinates in the wind tunnel are described. Feasibility and fidelity of reference-free BOS in conjunction with natural formation backgrounds and related evaluation methods are discussed, additionally, illustrating their simplicity and robustness. Results of successful image acquisition from a chaser aircraft are presented allowing vortex wakes to be identified at a wide range of flight attitudes, including complex maneuvers.

"EXPERIMENTAL ASPECTS OF PIV APPLIED TO A BO 105 HELICOPTER IN HOVER-FLIGHT CONDITION"

Paper No. 1192, 4th International Symposium on Particle Image Velocimetry, Gottingen, Germany, September 2001.

PIV experiments have been performed to derive quantitative flow velocity data of the blade tip vortex of a helicopter at full-scale. Due to relatively rough outdoor conditions e.g. to the helicopter induced wind, the ambient light, the large observation distances and changing winds, the seeding illumination and recording of this type of flow was challenging. This paper describes technical aspects of the measurement and presents first results.

"RECORDING AND EVALUATION METHODS OF PIV INVESTIGATIONS ON A HELICOPTER ROTOR MODEL"

Experiments in Fluids, Vol. 36, 2004, pp. 146-156

Three-component particle image velocimetry measurements at moderate speeds and observation distances can now be accomplished on a routine basis. This article discusses the experiment performed on a 4 m-diameter model rotor in the 6-mx8-m open test section of the Large Low Speed Facility of the German-Dutch Wind Tunnels. More than half a terabyte of raw data was recorded at various positions on the advancing and retreating sides of the rotor to obtain detailed measurements of the trailing vortex in the frame of an international project. This paper addresses measuring techniques and possible sources of errors and presents a limited number of cases for the purpose of illustrating the solutions to numerous technical challenges relating to the acquisition and analysis of vortical flows.

"RECORDING AND EVALUATION METHODS OF PIV INVESTIGATIONS ON A HELICOPTER ROTOR MODEL"

11th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Lisbon, Portugal, July 2002

Particle image velocimetry (PIV) experiments have been performed in order to derive quantitative flow velocity data of blade tip vortices of a large-scale helicopter model and during a three-week wind tunnel test. The helicopter rotor model used was a model of the MBB Bo 105 of the German aerospace establishment DLR in Braunschweig. The rotor consists of four hingeless blades with 0.121 m chord length, rectangular blade planform, and -8 degrees linear twist. The airfoil was a NACA 23012 with tabbed trailing edge. During the test, the model was mainly operated in descent flight conditions where blade vortex interaction dominates the noise emission. The rotor rotational frequency was 17.35 Hz leading to a tip speed of 218 m/s. The PIV system consisted of five digital cameras and three double pulse Nd: YAG lasers with 2x320mJ each, which were mounted onto a common traversing system to keep the distance between the cameras and the light sheet constant while scanning the rotor wake.

Raffel, M., Seelhorst, U. and Willert, C.

"VORTICAL FLOW STRUCTURES AT A HELICOPTER ROTOR MODEL MEASURED BY LDV AND PIV"

The Aeronautical Journal, Vol. 102, No. 1014, April 1998, pp. 221-227.

Flowfield measurements of the blade tip vortices from a rotating helicopter rotor model were performed by three component laser-Doppler velocimetry (3D-LDV) and conventional (two component) particle image velocimetry (PIV). In general, the results are in good correspondence, but also illustrate the different properties of both techniques: LDV offers the capability of three-component measurements, whereas PIV captures the unsteadiness of the flowfield.

Raffel, M., Tung, C., Richard, H., Yu, Y. and Meier, G. E. A.

"BACKGROUND ORIENTED STEREOSCOPIC SCHLIEREN (BOSS) FOR FULL-SCALE HELICOPTER VORTEX CHARACTERIZATION"

Proceedings of 9th International Symposium on Flow Visualization, Edinburgh, Scotland, August 2000, pp. 450-1 - 450-11

Application of a novel schlieren technique, referred as Background Oriented Schlieren (BOS), with two different helicopter tests are presented. Additionally, another extended method, called Reference-free Background Oriented Stereoscopic Schlieren (BOSS), and the differences between these two techniques will be discussed. Experimental studies have been carried out to investigate details of the vortex formation from blade tips of different helicopters, an Eurocopter BK117 and a large US utility helicopter. The background-oriented techniques appear to well complement other optical techniques like shadowgraphy or focusing schlieren methods and yield additional quantitative information. Furthermore, these techniques allow - in contrast to laser-based techniques - to study the effect of Reynolds numbers on vortex development from blade tips in full-scale flight tests more easily.

"RESPONSE AND RECOVERY OF AN MRAC ADVANCED FLIGHT CONTROL SYSTEM TO WAKE VORTEX ENCOUNTERS"

AIAA Paper 2013-5209, August 2013, Boston, MA,

A three-dimensional, twin-core wake vortex model is developed within the MATLAB/Simulink environment, and the effects of this disturbance on a 6 Degree of Freedom general aviation-based MRAC flight control system is studied. An envelope protection scheme is developed to augment the aircraft's response to the disturbance, and three scenarios are tested to evaluate the controller's performance in response to and recovery from the wake vortex. These scenarios include the controller responding with no pilot input, the controller responding with pilot input, and the pilot responding with no controller input. Pilot-in-the-loop testing and simulation runs are performed, and it is found that having the controller active greatly improves response and recovery performance during and after the wake vortex encounter.

Ragab, S.

"DIRECT NUMERICAL SIMULATION OF INSTABILITY WAVES IN A TRAILING VORTEX"

AIAA Paper No. 1995-0591, Reno, NV, January 1995

Temporal direct numerical simulation is performed to study the nonlinear development of helical instability waves in a trailing vortex. The basic state is given by the q-vortex and the disturbance field is initialized by the helical mode. A sixth-order compact finite-difference method is used in the cross plane while Fourier series is used in the periodic axial direction. Contours of a passive scalar are used to study the entrainment process that redistributes angular and axial momentum between the core and its surroundings. Such a process leads to relaminarization of the core.

Ragab, S. A. and Sreedhar, M. K.

"LARGE SCALE STRUCTURES IN TRAILING VORTICES"

AIAA Paper No. 1994-2316, Colorado Springs, CO, June 1994

Large eddy simulation (LES) is performed to study the response of trailing vortices to random and controlled disturbances. The q-vortex (Batchelor 1964) is used as a model of such vortices. When the vortex is linearly unstable, the disturbances grow and result in the generation of large-scale helical structures. During the period of growth of the disturbance, the mean tangential velocity deficit weakens appreciably. This results in a stabilizing mean flow which quenches the large-scale motions, and the vortex returns to a laminar configuration.

Ragab, S. and Sreedhar, M.

"NUMERICAL SIMULATION OF VORTICES WITH AXIAL VELOCITY DEFICITS"

Phys. Fluids, Vol. 7, No. 3, March 1995, pp. 549-558

Axial velocity deficit is a source of instability in vortices that may otherwise be stable. Temporal large-eddy simulation is performed to study the response of vortices with axial velocity deficits to random and controlled disturbances at high Reynolds numbers. The q vortex is used as a model of such vortices. When the vortex is linearly unstable, the disturbances grow and result in the appearance of large-scale helical sheets of vorticity. Later, these large-scale helical structures break up into small-scale filaments. Associated with the formation of the large-scale structures is a redistribution of both angular and axial momentum between the core and the surroundings. The redistribution weakens the axial velocity deficit in the core while strengthens the rigid-body-like rotation of the core. The emerging mean velocity profiles drive the vortex core to a stable configuration. The vortex eventually returns to a laminar state, with an insignificant decay in the tangential velocity, but with a much-weakened axial velocity deficit. A direct numerical simulation obtained at a lower Reynolds number confirms the above conclusions.

Ragsdale, R. G.

"APPLICABILITY OF MIXING LENGTH THEORY TO A TURBULENT VORTEX SYSTEM"

NASA TN D-1051, August 1961, Lewis Research Center, Cleveland, OH

Techniques of mixing length theory established for pipe flow are used to develop analogous expressions for turbulent vortex flow; the ability of these functions to correlate vortex data is then evaluated. Experimentally measured tangential velocity and static-pressure profiles are used to determine turbulent Reynolds numbers from Navier-Stokes solutions for compressible flow in the annular region of a vortex with constant eddy viscosity assumed. Karman and Prandtl type mixing length expressions for vortex flow are given for various assumed boundary conditions. A modified Karman expression for eddy viscosity is derived and best correlates the data for the entire range of experimental conditions.

Rahm, S.

"RECENT AND ONGOING COHERENT DOPPLER LIDAR MEASUREMENTS AT DLR"

17th Coherent Laser Radar Conference, June 2013, Barcelona, Spain.

In the past the coherent Doppler Lidar of DLR was used both onboard the Falcon research aircraft and ground based in a 20 ft container. At the ground-based measurements mainly wake vortex of aircrafts were investigated but there was also one campaign with observations at a wind energy power plant. At airborne campaigns the 3-dimensional wind field was the main interest. However having a lidar available at sudden events like the Eyjafjallajökull eruption on Iceland has opened an opportunity for measurements where normally another Lidar with shorter pulse and depolarization channel would have been chosen if available in this moment. This paper will report about the following campaigns: (A) 2009, Wind energy Bremerhafen: Measurement of the flow before and after a wind power plant. (B) 2010, Eyjafjalla volcanic ash: This was an ad-hoc campaign to make some statement to volcanic ash content over Europe. (C) 2012, Wake vortex reference measurements Belgium: Here the DLR System was used as a 'reference' for a recently developed direct detection lidar. (D) 2013, Saltrac/Volcats: Current campaign at the Cape Verde Islands and Antigua in order to trace Sahara dust outbreaks.

"AIRCRAFT WAKE VORTEX MEASUREMENT WITH AIRBORNE COHERENT DOPPLER LIDAR"

J. Aircraft, Vol. 45, No. 4, July-August 2008, pp. 1148-1155

An experiment for airborne Doppler lidar measurement of wake vortices generated by a large transport aircraft in the free atmosphere has been successfully carried out. In this paper, the description of the experiment, data processing procedure, and measurement results are given. It was shown using smoke generators placed on large transport aircraft wings allows some high-quality wake vortex measurements with 2 micron coherent Doppler lidar installed in a second aircraft.

Rahm, S., Smalikho, I. and Kopp, F.

"CHARACTERIZATION OF AIRCRAFT WAKE VORTICES BY AIRBORNE DOPPLER LIDAR"

Journal of Aircraft, Vol. 44, No. 3, May-June 2007, pp. 799-805

This paper presents a new method of wake-vortex characterization by using the 2-micron coherent Doppler lidar in airborne configuration. After modification of the scanning and data acquisition tools, the lidar system has been integrated in the DLR research aircraft Falcon 20. For wake-vortex generation a second DLR aircraft, the Advanced Technologies Testing Aircraft System equipped with a smoke generator on the portside wing, was used. Different scanning modes and flight strategies have been investigated and tested during three tryout flights. Results of vortex trajectories and circulation strengths, measured in the upper part of and above the atmospheric boundary layer, are presented. Based on the results of the tryout flights, the potential of this method for characterization of wake vortices from large transport aircraft equipped with smoke generators is estimated.

Raj, P. and Iversen, J. D.

"COMPUTATIONAL SIMULATION OF TURBULENT VORTEX MERGER AND DECAY"

AIAA Paper 1979-0278, January 1979, New Orleans, LA.

The interaction and eventual merger of corotational vortices and the decay of a single vortex have been studied by employing zero-, one-, and two-equation turbulent-flow models to gain a better understanding of the role of turbulence. An implicit finite-difference procedure is used to integrate the unsteady, two-dimensional equations in a cross-plane. The zero- and one-equation formulations utilize a mixing-length model, which incorporates the streamline curvature effect by prescribing a spatially-varying mixing-length. In the two-equation model, the turbulence kinetic energy equation and a modified rate of dissipation equation which includes a streamline curvature correction are solved. Computational results of different models applied to various flow-configurations are presented and compared with available experimental data whenever possible.

Raj, P. and Iversen, J. D.

"COMPUTATIONAL SIMULATION OF TURBULENT VORTEX MERGER AND DECAY"

AIAA Journal, Vol. 18, No. 8, August 1980, pp. 865-866

In recent years, many theoretical and experimental studies have been conducted to gain a better understanding of corotational vortex merger in connection with the pairing of organized vortex structures observed in mixing layers and with the attenuation of wake-vortex hazard associated with wide-body aircraft. The latter is accomplished by modifying the wing such that two or more corotating vortices are shed from each half-span. The merger of these vortices can result in a redistribution of vorticity such that the hazard to trailing aircraft is considerably reduced compared to the conventional wing. In the present investigation, the interaction and merger of corotational vortices and the decay of a single vortex have been studied by employing zero-, one-, and two-equation turbulent flow models to bridge the gap between the theoretical models and experimental observations. The zero- and one-equation formulations utilize a mixing-length model which incorporates the streamline curvature effect by prescribing a particular spatial variation. In the two-equation model, a turbulence kinetic energy equation and a rate of dissipation equation modified to include streamline curvature correction are solved. The computed results corresponding to the different flow models are compared with the available experimental data.

Raj, P. and Iversen, J. D.

"COMPUTATIONAL STUDIES OF TURBULENT MERGER OF COROTATIONAL VORTICES"

AIAA Paper No. 1978-0108, Huntsville, AL, January 1978

A computational study has been conducted to gain a better understanding of the criteria governing the merger of corotating vortices. The zero-equation and one-equation turbulent-flow models are used to model the interaction of two rolled-up, corotational vortices. A model appropriate for the swirling

flow under consideration has been proposed to prescribe the algebraic variation of mixing-length in the flow field. The unsteady, two-dimensional equations in a cross-plane are solved for primitive variables using an implicit finite-difference code. The computed downstream merging distances are in good agreement with available wind tunnel data.

Raj, P. and Iversen, J. D.

"INVISCID INTERACTION OF TRAILING VORTEX SHEETS APPROXIMATED BY POINT VORTICES"

J. Aircraft, Vol. 15, No. 12, December 1978, pp. 857-859

A computational study of the mutual interaction of vorticity sheets shed behind wings kept at a small distance apart has been made. The sheets are modeled by arrays of discrete point vortices and their inviscid motion is computed. The gross features exhibited by the results confirm the experimental observation that for a small initial separation distance, the trailing vorticity sheets roll up together.

Raju, S. P. G., Nigam, A. and Verghese, M. P.

"DEVELOPMENT OF A VORTICITY METER"

Journal of Aircraft, Vol. 15, No. 11, November 1978, pp. 799-800.

A vorticity meter which is simple to construct and reliable in operation has been designed and fabricated. It has been shown that correction to the measured rotor speed arising due to bearing friction obeys a simple law and can be easily derived by using two shaft (and bearing) sizes in sequence in the same instrument. Errors arising due to the inclination of the flow to the axis of the instrument have been shown to be insignificant for inclinations of the order of 5 degrees. The instrument is expected to be useful in studying flows with vorticity, such as trailing vortices.

Ramachandran, K., Steinhoff, J. and Yonghu, W.

"FREE-WAKE COMPUTATION OF HELICOPTER ROTOR FLOWFIELD FOR GENERAL FLIGHT REGIME"

Report ARO 25623.4-EG-S, March 1993, Flow Analysis Inc., Brooklyn, NY.

A CFD based computer code, HELIX II, has been developed for computing helicopter rotor flowfield in hover and in forward flight. In order to predict the vibratory airloads in forward flight and the performance in hover the effect of shed wake must be accurately accounted for. This has been accomplished by an unique vorticity embedding procedure. The wake is convected in a Lagrangian sense and does not suffer from numerical dissipation. The effect of this convected wake is included in the Eulerian using Clebach representation. The unsteady full potential equation is solved in the Eulerian grid with the embedded vortical velocity accounting for the influence of wake. The wake evolves as a part of the solution. Dynamic grid modifications are performed at each time step to account for blade motion and deformation. These modifications are confined to regions near the blade using suitable blending functions. In addition, a vorticity confinement method is developed which involves adding a

term to the momentum conservation equation of fluid dynamics. This modification is very useful in the numerical solution of flow problems involving vortical regions. The Euler equations solved with this extra term can convect vortices without numerical dissipation.

Ramaprian, B. R.

"INTERACTIONS OF SPANWISE AND CHORDWISE VORTICITY ASSOCIATED WITH THREE-DIMENSIONAL DYNAMIC STALL OVER AN OSCILLATING WING"

US Army Research Office Report, Oct. 1994, Washington State Univ., Pullman, WA.

The research work involved the measurement of the pressure and velocity fields in the three-dimensional flow field surrounding and in the wake of the tip region of a rectangular wing of NACA 0015 profile. Measurements were made both with the wing stationary and with the wing oscillating sinusoidally in pitch about its quarter-chord axis. Pressure transducers and three-component laser Doppler velocimetry were used in these measurements. The results have been used to understand the vorticity dynamics in three-dimensional steady and unsteady flows. The study is relevant to helicopter rotor aerodynamics.

Ramaprian, B. R. and Zheng, Y.

"NEAR FIELD OF THE TIP VORTEX BEHIND AN OSCILLATING RECTANGULAR WING"

AIAA Journal, Vol. 36, No. 7, July 1998, pp. 1263-1269

Data on the evolution of the unsteady three-dimensional tip vortex in the near wake (0-3 chord lengths behind the wing) of a rectangular NACA 0015 wing oscillating sinusoidally in pitch about its quarter-chord axis are presented. These data were obtained using three-component laser Doppler velocimetry (LDV). The experiments were performed in a low-speed wind tunnel at a Reynolds number of 180,000. The wing had a semi aspect ratio of 2. It was oscillated at a frequency of 1 Hz and an amplitude of 5 deg around a mean incidence of 10 deg. The instantaneous LDV data were used to obtain information on the distribution of phase-locked velocity and vorticity components across the vortex, as well as the phase-locked circulation associated with the evolving vortex. The data indicate that the average trajectory of the oscillating vortex in the near field is very nearly the same as for a stationary wing at the mean incidence. The length and circulation scales, as well as the maximum circulation carried by the vortex flow under the conditions studied, are modulated in a significantly nonquasisteady manner. Nevertheless, beyond about 0.7 chord length, the normalized circulation distribution across most of the inner part of the vortex exhibits, at all times, the same universal behavior as the vortex behind a stationary wing.

Ramaprian, B. R. and Zheng, Y.

"MEASUREMENTS IN ROLLUP REGION OF THE TIP VORTEX FROM A RECTANGULAR WING"

AIAA Journal, Vol. 35, No. 12, December 1997, pp. 1837-1843

The evolving three-dimensional flowfield of the tip vortex in the near wake of a rectangular wing at incidence was studied in detail, using three-component laser Doppler velocimetry. The flow quantities measured were the three components of the instantaneous velocity. These data were used to obtain the distributions of velocity, vorticity, and circulation across the vortex at several axial locations in the flow for several angles of incidence. The data have been used to understand the process of rollup of the shear layer into the vortex in the near wake, as well as its kinematic structure. The data indicate that the rollup takes place quite quickly and the inner part of the three-dimensional vortex becomes nearly axisymmetric within about two chord lengths downstream of the trailing edge. Even though the vortex behavior in the near wake is, in general, strongly dependent on the initial conditions, the vortex trajectory appears to be described reasonably well by the overall wing lift and the freestream velocity. Also, even in the near wake, circumferentially averaged mean flow properties in the inner part of the nearly axisymmetric vortex begin to exhibit a universal structure characteristic of conceptual asymptotic trailing vortices.

Ramasamy, M. and Leishman, J. G.

"REYNOLDS NUMBER BASED BLADE TIP VORTEX MODEL"

61st Annual Forum and Technology Display, American Helicopter Society International, Grapevine, TX, June 2005

A mathematical model has been developed to estimate the temporal growth properties of helicopter blade tip vortices at any vortex Reynolds number. One unique feature of the model is that it takes into account rotational stratification (Richardson's number) effects on the distribution of turbulent viscosity inside the tip vortices. This model is combined with another model for the effects of filament stretching in predicting the temporal evolution of the vortex. A turbulent growth model solves exactly for the tangential (swirl) velocity starting from the Navier-Stokes equations using an assumed variation in eddy viscosity across the vortex core. This variation is a function of the local Richardson's number, and the final solution becomes dependent on vortex Reynolds number. A more parsimonious functional approximation is given to represent the induced velocity distribution in the tip vortices for practical applications. It is shown that the temporal core growth rate predicted by the new model increases with an increase in vortex Reynolds number, which is consistent with experimental observations. The predictions from the model were validated, wherever possible, with tip vortex measurements from both model- and full-scale rotors.

"PHASED-LOCKED PARTICLE IMAGE VELOCIMETRY MEASUREMENTS OF A FLAPPING WING"

Journal of Aircraft, Vol. 43, No. 6, November-December 2006, pp. 1867-1875.

The unsteady aerodynamics of a biomimetic inspired flapping-wing mechanism has been analyzed by performing detailed phase-locked diagnostics of its flow field. Flow visualization and particle image velocimetry results have shown the presence of a shed dynamic stall vortex that spans across most of the wing span. The shedding of this type of leading-edge vortex was accompanied by the formation of another leading-edge vortex before the first vortex reached the midchord, resulting in multiple shedding leading-edge vortices on the top surface of the wing during each wing stroke. A strong starting vortex was also formed at the trailing edge of the wing during the early part of its translational stroke. This vortex continuously gained strength from shed vorticity as the wing accelerated into its stroke. The starting vortex remained close to the trailing edge until the wing reached midstroke. A pair of vortices that continuously trailed from the root and tip of the wing were identified, both of which induced a significant downwash velocity over the wing surface. These trailed vortices were found to exhibit a contracting wake structure as they convected into the wake before the wing, consistent with an increase in slipstream velocity. The evolution of the tip and root vortex pair showed rapid diffusive characteristics with an increase in time (wake age)..

"BENCHMARKING PARTICLE IMAGE VELOCIMETRY WITH LASER DOPPLER VELOCIMETRY FOR ROTOR WAKE MEASUREMENTS"

AIAA Journal, Vol. 45, No. 11, November 2007, pp. 2622-2633

An experiment was conducted to identify and measure the sources of uncertainty that are associated with the application of particle image velocimetry to the measurement of the vortical wakes trailing from helicopter rotor blades. Phase-resolved, three-component particle image velocimetry measurements were performed in the wake of a subscale rotor operating in hover, and were compared with high-resolution three-component laser Doppler velocimetry measurements obtained with the same rotor under identical operating conditions. This helped formulate the essential experimental conditions that need to be satisfied for particle image velocimetry to accurately resolve the high-velocity gradient, high streamline curvature flows that are present inside the rotor wake and in the blade tip vortices. Uncertainties associated with the calibration, acquisition, and processing of the particle image velocimetry images were analyzed in detail. It was shown that the optimization of laser pulse separation time is fundamental to reduce the errors associated with acceleration and curvature effects. Similarly, the interrogation window size was shown to play a critical role in determining the velocity gradient bias errors. The correlation between the laser Doppler velocimetry and particle image velocimetry measurements of the tip vortex characteristics, such as core radius and peak swirl velocity, were found to be excellent.

"INTERDEPENDENCE OF DIFFUSION AND STRAINING OF HELICOPTER BLADE TIP VORTICES"

Journal of Aircraft, Vol. 41, No. 5, September-October 2004, pp. 1014-1024

An experiment was performed to help quantify the interdependence of viscous/turbulent diffusion and straining effects on the development of helicopter rotor tip vortices. The properties of the blade tip vortices were measured in the wake of a small-scale hovering rotor and compared to the results for the case when the wake approached a solid boundary. The presence of the boundary created velocity gradients that forced the tip vortex filaments to strain, allowing the effects of this process on the vortices to be measured relative to the baseline case without the boundary. It is shown that vortex stretching begins to decrease the viscous core size, and when the strain rates become large, this can balance the normal growth in the vortex core resulting from diffusion. The present results were used to help develop a more general tip vortex model suitable for use in a variety of helicopter rotor aero acoustic applications. The proposed engineering model combines the effects of turbulent diffusion and strain on the vortex core growth. The empirical coefficients of this model have been derived based on the best available results from rotating-wing tip vortex measurements.

"FLOWFIELD MEASUREMENTS TO UNDERSTAND EFFECTS OF WAKE BEHAVIOR ON ROTOR PERFORMANCE"

AIAA Paper No. 2010-4237, June-July 2010, Chicago, Illinois.

The effect of large twist on hovering rotor performance was investigated using detailed flowfield measurements. The experiments were conducted using a three-bladed model-scale rotor with two different sets of blades. One employed simple rectangular untwisted blades while the other used scaled-down XV-15 tilt-rotor blades, with a large non-linear twist. The highly-twisted blades were expected to give better hover performance at high thrust coefficients. However, the model scale rotor could not be operated at sufficiently high thrust because of early onset of blade stall at the low Reynolds numbers. At lower thrusts, the untwisted blades showed somewhat better performance than the highly-twisted blades. Nevertheless, the flowfield measurements showed some key wake differences between the two rotors. These observations together with simple blade element momentum theory (also called annular disk momentum theory) helped understand the rotor performance.

"FLOWFIELD OF A ROTATING-WING MICRO AIR VEHICLE"

Journal of Aircraft, Vol. 44, No. 4, July-August 2007, pp. 1236-1244.

Experiments were conducted to measure the performance of a rotor, typical of that used on a rotating-wing micro air vehicle, which was shown to develop relatively low hovering efficiency. This inefficiency can be traced to high profile drag losses on the blades and to the relatively large turbulent and rotational aerodynamic losses that are associated with the structure of the rotor wake. High-resolution flow visualization images have divulged several interesting flow features that appear unique

to rotors operating at low Reynolds numbers. The wake sheets trailing from the rotor blades were found to be much thicker and more turbulent than their higher chord Reynolds number counterparts. Similarly, the viscous core sizes of the tip vortices were relatively large as a fraction of blade chord. However, the flows in the tip vortices themselves were found to be similar, with laminar flow near their core axis and an outer turbulent region. Particle image velocimetry measurements were made to quantify the structure and strength of the wake flow, including the tip vortices. An analysis of the vortex aging process was conducted. A new nondimensional equivalent time scaling parameter is proposed to normalize the rate of growth of the vortex cores that are generated at substantially different vortex Reynolds numbers.

Ramasamy, M., Paetzel, R. and Bhagwat, M. J.

"APERIODICITY CORRECTION FOR ROTOR TIP VORTEX MEASUREMENTS"

67th AHS Annual Forum, May 2011, Virginia Beach, VA.

The initial roll-up of a tip vortex trailing from a model-scale, hovering rotor was measured using particle image velocimetry. The unique feature of the measurements was that a microscope was attached to the camera to allow much higher spatial resolution than hitherto possible. This also posed some unique challenges. In particular, the existing methodologies to correct for aperiodicity in the tip vortex locations could not be easily extended to the present measurements. The difficulty stemmed from the inability to accurately determine the vortex center, which is a prerequisite for the correction procedure. A new method is proposed for determining the vortex center, as well as the vortex core properties, using a least-squares fit approach. This approach has the obvious advantage that the properties are derived from not just a few points near the vortex core, but from a much larger area of flow measurements. Results clearly demonstrate the advantage in the form of reduced variation in the estimated core properties, and the self-consistent results obtained using three different aperiodicity correction methods.

"LONGITUDINAL RESPONSE OF AN AIRCRAFT DUE TO A TRAILING VORTEX PAIR"

J. Aircraft, Vol. 10, No. 10, October 1973, pp. 638-639

An approximate method to predict the response of a small aircraft in longitudinal motion when it is flying through a trailing vortex of a large aircraft was developed. The longitudinal stability equations of motion were linearized. The loads were computed assuming the wing and the horizontal tail as the lifting surfaces and neglecting the wing-body-tail interference effects. The results of the lift and moment coefficients variations with respect to the distance between the test aircraft, and time histories of the flight variables u -bar, α , and θ were shown.

"SIMULATING WAKE VORTEX DETECTION WITH THE SENSIVU DOPPLER WIND LIDAR SIMULATOR"

NASA/CR-2014-218276, January 2014, Aerospace Innovations, Yorktown, VA.

In support of NASA's Atmospheric Environment Safety Technologies NRA research topic on Wake Vortex Hazard Investigation, Aerospace Innovations (AI) investigated a set of techniques for detecting wake vortex hazards from arbitrary viewing angles, including axial perspectives. This technical report describes an approach to this problem and presents results from its implementation in a virtual lidar simulator developed at AI. Three-dimensional data volumes from NASA's Terminal Area Simulation System (TASS) containing strong turbulent vortices were used as the atmospheric domain for these studies, in addition to an analytical vortex model in 3-D space. By incorporating a third-party radiative transfer code (BACKSCAT 4), user-defined aerosol layers can be incorporated into atmospheric models, simulating attenuation and backscatter in different environmental conditions and altitudes. A hazard detection algorithm is described that uses a two-component spectral model to identify vortex signatures observable from arbitrary angles.

Ramsey, D. J. and Chi Nguyen, D. P.

"CHARACTERIZING AIRCRAFT WAKE VORTICES WITH GROUND-BASED PULSED COHERENT LIDAR: EFFECTS OF VORTEX CIRCULATION STRENGTH AND LIDAR SIGNAL-TO-NOISE RATIO ON THE SPECTRAL SIGNATURE"

AIAA Paper 2011-3198, June 2011, Honolulu, Hawaii.

The pulsed coherent lidar is a well-known instrument for detecting and characterizing transverse cross-sections of aircraft wake vortices. One class of algorithms uses spectral 'maximum velocities' to estimate vortex parameters, and these velocities are dependent upon several factors described in this paper. A lidar simulator, developed by Lockheed Martin Coherent Technologies, was used to investigate these factors and explore their qualitative effects on the spectral signature. An algorithm is briefly described which attempts to manage these effects, and examples are shown of vortex tracks resulting from processing simulated and field-measured lidar data.

Ramsey, V. W.

"ACOUSTIC SCATTERING FROM AN AIRCRAFT TRAILING VORTEX"

Ph.D. Thesis, May 1974, Stanford Univ., Palo Alto, CA

A detailed analysis is presented of acoustic scattering from the velocity field of an aircraft trailing vortex. A model of a turbulent vortex is obtained from the aerodynamic literature. Published vortex theories and experimental data are used to evaluate vortex flow compressibility, turbulence level versus that of the environment, the existence of an inertial subrange, and vortex turbulence scales. Much of this information then provides a basis for discussing refraction, multiple scattering, and the validity of the Born approximation in aircraft vortices.

Ramsey, V. W. and Peterson, A. M.

"ACOUSTIC SCATTERING FROM A TURBULENT VORTEX"

NASA-CR-141186, January 1974, Stanford University Electronics Labs., Palo Alto, CA

With the aid of the Born approximation, the time autocorrelation and power spectral density are calculated for the received acoustic signal scattered from velocity fluctuations in a turbulent aircraft trailing vortex. The turbulence is required to be globally stationary, but only locally homogeneous. The treatment includes the effects of spectral broadening due to convection of the scattering eddies by a spatially varying mean flow and by macro eddies. The 3 dB bandwidth of the received signal is related to the scattering angle and the core Mach number of the vortex. A primary feature of the analysis is that it provides a method for inferring the radial intensity distribution of turbulence in a vortex. The analysis technique is also applicable to scattering from other turbulent flows where significant variations of turbulence level occur over distances on the order of the macro eddy size.

"COMPUTATION METHOD FOR FORCES ON AIRCRAFT IN CLOSE PROXIMITY"

Aerotecnica Missili e Spazio, Vol. 76, Nos. 3-4, July-December 1997, pp. 93-100.

Numerical modeling of the unsteady aerodynamics of aircraft in proximity is important for quantifying the wake-vortex hazard on following aircraft. Issues include unsteady motions and the structural loads due to the unsteady force. This paper presents a method for computing unsteady loads and wake trajectories as one aircraft passes through the wake of another. The method is based on recent extensions of unsteady vortex lattice theory which use desingularization techniques to reduce numerical instabilities associated with discretized vortex sheets. Results are presented showing the method to be relatively insensitive to the discretization of the aircraft. Several cases are analyzed, demonstrating the effect of wake roll-up, vertical displacement, and incidence angle on the force and moment time histories of the following aircraft.

Ran, H.

"NUMERICAL STUDY OF THE DYNAMICS AND SOUND GENERATION OF A TURBULENT VORTEX RING"

Ph.D. Thesis, June 2004, California Institute of Technology, Pasadena, CA

In the present study, Direct Numerical Simulations (DNS) of the fully compressible, three-dimensional Navier-Stokes equations are used to generate an axisymmetric vortex ring to which three-dimensional stochastic disturbances are added. The radiated acoustic field is computed directly in the near field, and by solving the wave equation in a spherical coordinate system in the far field. At high Reynolds number, a vortex ring will undergo an instability to azimuthal waves. The instability produces higher azimuthal modes and induces nonlinear interaction between the modes, and will cause the vortex ring to break down and transition to turbulence. The early stages of the simulation agree well with the linear instability theory. Nonlinear stage of instability, transition, formation of axial flow and

streamwise vorticity are analyzed and compared with experimental results. After turbulent transition, the evolution of statistical quantities becomes independent of viscosity and the initial geometry, and the flow become self-similar. The temporal evolution of quantities including total circulation, axial velocity profile, vortex ring displacement and vorticity profile agrees well with the self-similarity law. Turbulent energy spectrum, Reynolds stresses and turbulence production are also presented.

Ran, H. and Colonius, T.

"NUMERICAL SIMULATION OF SOUND RADIATED FROM A TURBULENT VORTEX RING"

AIAA Paper No. 2004-2918, Manchester, UK, May 2004

The acoustic field radiated by a turbulent vortex ring is studied. Direct Numerical Simulations (DNS) of the fully compressible, three-dimensional Navier-Stokes equations are used to generate an axisymmetric vortex ring to which 3D stochastic disturbances are added. The disturbances cause instability and turbulent transition of the vortex ring. Detailed information about temporal evolution of sound pressure level, spectrum and directivity associated with each mode is investigated. The peak frequency agrees well with experiments, and the directivity of each azimuthal mode agrees well with predictions of vortex sound theory. Based on the self-similar decay of the turbulent near field, the self-similar decay of the sound field is investigated. We also explore the connections with jet noise by modeling the jet as a de-correlated train of vortex rings.

Ran, H. and Colonius, T.

"NUMERICAL SIMULATION OF THE SOUND RADIATED BY A TURBULENT VORTEX RING"

Aeroacoustics, Vol. 8, No. 4, 2009, pp. 317-336.

The acoustic field radiated by a turbulent vortex ring is studied. Direct Numerical Simulations (DNS) of the fully compressible, three-dimensional Navier-Stokes equations are used to generate an axisymmetric vortex ring to which 3D stochastic disturbances are added. The disturbances cause instability and turbulent transition of the vortex ring. Detailed information about temporal evolution of sound pressure level, spectrum and directivity associated with modes of oscillation and their turbulent breakdown are investigated. The peak frequency agrees well with experiments, and the modal directivities agree well with predictions of vortex sound theory. Based on the self-similar decay of the turbulent near field, the self-similar decay of the sound field is investigated. We also explore the connections with jet noise by modeling the jet as a de-correlated train of vortex rings.

"THE CRITICAL STATE - A TRAPPED WAVE MODEL OF VORTEX BREAKDOWN"

J. Fluid Mech., Vol. 58, No. 3, May 1973, pp. 495-515

1765

A model of vortex breakdown is presented and its predictions compared with the experiments of Sarpkaya. The model is centered about a theory of long, weakly nonlinear waves propagating on critical flows in tubes of variable cross-section. Although the weakly nonlinear theory must be extended beyond its domain of formal validity, many of the experimentally observed features of vortex breakdown are reproduced by the model. The description of the time evolution of the flow field that is presented requires numerical calculations that are not simple, but some important conclusions may be determined by easy computations. In particular, the axial position of a breakdown may be found from a very simple equation.

Ranjan, P. and Ansell, P. J.

"COMPUTATIONAL ANALYSIS OF VORTEX WAKES WITHOUT NEAR-FIELD ROLLUP CHARACTERISTICS"

Journal of Aircraft, Vol. 55, No. 5, September-October 2018, pp. 2008-2021.

A computational study on the wake characteristics of span-optimized wings is discussed, where the effect of the wing span load on the resulting wake rollup characteristics and structure is emphasized. Two wing configurations, each optimized for minimum induced drag at a fixed $C_{sub L}$ and fixed bending-moment constraint, are studied; and their wake characteristics are compared against an elliptically loaded wing. Results from Navier-Stokes simulations across the near-field wake demonstrate a symmetric large-scale rotation of the entire wake structure, centered roughly at the quarter-span location, for the bending-optimized wings. This wake structure is contrasted with the classical tip vortex formation associated with the elliptic span load, which occurs immediately in the wing near-field wake. The far-wake structure was also studied using a free-wake simulation approach. The results from this analysis indicate a gradual rollup of the entire wake far downstream for the bending-optimized wings. This absence of wake rollup in the near field is envisaged as a potential means to reduce vortex interactions with downstream surfaces of aircraft and prevent other adverse operational challenges associated with wingtip vortices.

Rankenburg, J.

"THE WAKE VORTICES WARNING SYSTEM (WVWS) FOR FRANKFURT AIRPORT PARALLEL RUNWAY SYSTEM 25"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206233, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 537-548

The WVWS objective is to reduce/suspend increased wake vortex separation minima between staggered aircraft on final approach to the two parallel runways 25 at Frankfurt airport to increase arrival capacity whilst maintaining or increasing safety. Aircraft approaching the same runway will continue to be separated according to the increased (ICAO) wake vortex separation minima. Issues and analysis supporting this objective are presented.

"AIRCRAFT JET-BLAST EFFECTS AT INTERSECTION OF RUNWAYS 31L-4R, JOHN F. KENNEDY INTERNATIONAL AIRPORT"

Technical Letter Report NA-77-70-LR, December 1977, FAA National Aviation Facilities Experimental Center, Atlantic City, NJ.

This project was performed in response to a letter request from the Eastern Region, AEA-1, requiring additional studies be conducted at John F. Kennedy International Airport to facilitate the determination of the minimum distance from the jet blast fence that a takeoff may commence on Runway 31L without causing interference to aircraft landing simultaneously on Runway 4R. The study was completed and velocity envelopes were developed for each class aircraft for use in establishing minimum distance from the fence that takeoff rolls could commence to permit simultaneous operations.

Rath, C. B.

"WING TIP VORTEX STAGNATION PRESSURE SURVEY OF VARIOUS TIP SHAPES"

MS Thesis, August 1991, University of Texas, Arlington, TX.

The effects of wing tip shape on the tip vortex were studied experimentally under flow conditions typical of helicopter rotor tip operation ($M = 0.75$ and 0.78 , with $Re = 3,200,000$ and $5,600,000$). Four planforms were tested; rectangular, swept, tapered, and swept-tapered. Vortex stagnation pressure surveys were conducted at 1, 3 and 6 chords downstream of the tip. This yielded qualitative results in the initial roll-up region. Comparisons were made of the effects of Mach number, Reynolds number, downstream distance and tip shape on the vortex size, shape, location and minimum stagnation pressure ratio. The effects of tip shape were quite significant. The swept and swept-tapered tips produced larger, more diffuse vortices than the rectangular or tapered tips.

Rauleder, J. and Leishman, J. G.

"INTERACTIONS OF A VORTICAL FLOW WITH DISPERSED PARTICLES BELOW A ROTOR"

AIAA Journal, Vol. 54, No. 11, November 2016, pp. 3361-3373.

Measurements were made of the vortically dominated flow produced by a rotor hovering in ground effect over a mobile sediment bed. Time-resolved particle image velocimetry and particle tracking velocimetry were used to measure the two-phase flow as the rotor wake interacted with the bed. Mobilized sediment particles were tracked, with the objective to relate the particle motion to individual vortical structures and turbulent motions of the fluid. Although the tip vortices trailed from the rotor blades were the dominant flow features, secondary flow structures and organized turbulent motions were identified to affect the process of particle uplift. A vortex-induced secondary vortical structure convected downstream in between two consecutive blade tip vortices, and in a dynamic interplay with the tip vortices was shown to contribute to the uplift process of particles from the bed. Most tip vortices trailed a region of negative streamwise velocity fluctuations, which decelerated the particles

that could subsequently be picked up by a succeeding tip vortex. A quadrant analysis showed the preferential distribution of turbulence that could be correlated to sediment mobilization and uplift. Positive wall-normal velocity fluctuations (ejection and outward interaction events) were induced primarily by the tip vortices and correlated with the uplift of particles from the bed and their subsequent suspension.

Rautenberg, A., Allgeier, J., Jung, S. and Bange J.

"CALIBRATION PROCEDURE AND ACCURACY OF WIND AND TURBULENCE MEASUREMENTS WITH FIVE-HOLE PROBES ON FIXED-WING UNMANNED AIRCRAFT IN THE ATMOSPHERIC BOUNDARY LAYER AND WIND TURBINE WAKES"

Atmosphere, Vol. 124, No. 10, March 2019.

For research in the atmospheric boundary layer and in the vicinity of wind turbines, the turbulent 3D wind vector can be measured from fixed-wing unmanned aerial systems (UAS) with a five-hole probe and an inertial navigation system. Since non-zero vertical wind and varying horizontal wind causes variations in the airspeed of the UAS, and since it is desirable to sample with a flexible cruising airspeed to match a broad range of operational requirements, the influence of airspeed variations on mean values and turbulence statistics is investigated. Three calibrations of the five-hole probe at three different airspeeds are applied to the data of three flight experiments. Mean values and statistical moments of second order, calculated from horizontal straight level flights are compared between flights in a stably stratified polar boundary layer and flights over complex terrain in high turbulence. Mean values are robust against airspeed variations, but the turbulent kinetic energy, variances and especially covariances, and the integral length scale are strongly influenced. Furthermore, a transect through the wake of a wind turbine and a tip vortex is analyzed, showing the instantaneous influence of the intense variations of the airspeed on the measurement of the turbulent 3D wind vector. For turbulence statistics, flux calculations, and quantitative analysis of turbine wake characteristics, an independent measurement of the true airspeed with a pitot tube and the interpolation of calibration polynomials at different Reynolds numbers of the probe's tip onto the Reynolds number during the measurement, reducing the uncertainty significantly.

Rayleigh, L.

"ON THE DYNAMICS OF REVOLVING FLUIDS"

Proceedings Royal Soc. London, Series A, Vol. 93, 1916, pp. 148-154

So much of meteorology depends ultimately upon the dynamics of revolving fluid that is desirable to formulate as clearly as possible such simple conclusions as are within our reach, in the hope that they may assist our judgment when an exact analysis seems impracticable.

Rayner, J. M.

"DYNAMICS OF THE VORTEX WAKES OF FLYING AND SWIMMING VERTEBRATES"

Symposia of the Society for Experimental Biology, Vol. 49, 1995, pp. 131-155.

The vortex wakes of flying and swimming animals provide evidence of the history of aero- and hydrodynamic force generation during the locomotor cycle. Vortex-induced momentum flux in the wake is the reaction of forces the animal imposes on its environment, which must be in equilibrium with inertial and external forces. In flying birds and bats, the flapping wings generate lift both to provide thrust and to support the weight. Distinct wingbeat and wake movement patterns can be identified as gaits. In flow visualization experiments, only two wake patterns have been identified: a vortex ring gait with inactive upstroke, and a continuous vortex gait with active upstroke. These gaits may be modeled theoretically by free vortex and lifting line theory to predict mechanical energy consumption, aerodynamic forces, and muscle activity. Longer-winged birds undergo a distinct gait change with speed, but shorter-winged species use the vortex ring gait at all speeds. In swimming fish, the situation is more complex: the wake vortices form a reversed von Karman vortex sheet, but little is known about the mechanism of generation of the wake, or about how it varies with speed and acceleration or with body form and swimming mode. An unresolved complicating factor is the interaction between the drag wake of the flapping fish body and the thrusting wake from the tail.

Rayner, J. M. V.

"A VORTEX THEORY OF ANIMAL FLIGHT. PART 2. THE FORWARD FLIGHT OF BIRDS"

Journal of Fluid Mechanics, Vol. 91, part 4, 1979, pp. 731-763.

The vortex wake of a bird in steady forward flight is modelled by a chain of elliptical vortex rings, each generated by a single downstroke. The shape and inclination of each ring are determined by the downstroke geometry, and the size of each ring by the wing circulation; the momentum of the ring must overcome parasitic and profile drags and the bird's weight for the duration of a stroke period. From the equation of motion, it is possible to determine exactly the kinematics of the wing-stroke for any flight velocity. This approach agrees more readily with the nature of the wing stroke than the classical actuator disk and momentum-jet theory; it also dispenses with lift and induced drag coefficients and is not bound by the constraints of steady-state aerodynamics. The induced power is calculated as the mean rate of increase of wake kinetic energy. The remaining components of the flight power (parasite and profile) are calculated by the traditional methods; there is some consideration of different representations of body parasite drag. The lift coefficient required for flight is also calculated; for virtually all birds the lift coefficient in slow flight and hovering is too large to be consistent with steady-state aerodynamics. A bird is concerned largely to reduce its power consumption on all but the shortest flights. The model suggests that there are several ways in which power reduction can be achieved. These various strategies are in good agreement with observation.

Rayner, J. M. V.

"A VORTEX THEORY OF ANIMAL FLIGHT. PART 1. THE VORTEX WAKE OF A HOVERING ANIMAL"

Journal of Fluid Mechanics, Vol. 91, part 4, 1979, pp. 697-730.

The distribution of vorticity in the wake of a hovering bird or insect is considered. The wake is modelled by a chain of coaxial small-cored circular vortex rings stacked one upon another; each member of the chain is generated by a single wing-stroke. Circulation is determined by the animal's weight and the time for which a single ring must provide lift; ring size is calculated from the circulation distribution on the animal's wing. The theory is equally applicable to birds and insects, although the mechanism of ring formation differs. This approach avoids the use of lift and drag coefficients and is not bound by the constraints of steady-state aerodynamics; it gives a wake configuration in agreement with experimental observations. The classical momentum jet approach has steady momentum flux in the wake, and is difficult to relate to the wing motions of a hovering bird or insect; the vortex wake can be related to the momentum jet, but adjacent vortex elements are disjoint and momentum flux is periodic. The evolution of the wake starting from rest is considered by releasing vortex rings at appropriate time intervals and allowing them to interact in their own velocity fields. The resulting configuration depends on the feathering parameter f (which depends on the animal's morphology); f increases with body size. At the lower end of the wake rings coalesce to form a single large vortex, which breaks away from the rest of the wake at intervals. Wake contraction depends on f ; the minimum areal contraction of one-half (as in momentum-jet theory) occurs only in the limit $f \rightarrow 0$, but values calculated for smaller insects of just over one-half suggest that the momentum-jet may be a good approximation to the wake when f is small. Induced power in hovering is calculated as the limit of the mean rate of increase of wake kinetic energy as time progresses. It can be related to the classical momentum-jet induced power by a simple conversion factor. For an insect or hummingbird, the usual momentum-jet estimate may be between 10 and 15% too low, but for a bird it may be as much as 50% too low. This suggests that few, if any, birds can sustain aerobic hovering, and that as small a value of f as possible would be necessary if the bird were to hover. Tip losses (energy cost of the vortex-ring wake compared with the equivalent momentum jet) are negligible for insects, but can be in the range 15-20% for birds.

"EXPERIMENTAL VALIDATION OF QUADROTOR SIMULATION TOOL FOR FLIGHT WITHIN BUILDING WAKES"

Aerospace Science and Technology, Vol. 67, 2017, pp. 169-180.

Experimental test flights are conducted to validate a novel simulation tool capable of predicting the effects of building generated turbulent winds on the flight performance of autonomous quadrotors. Wind conditions are modeled using time accurate Large Eddy Simulations where five representative points within the building wake are used to predict an average position hold deviation. Three control methods for autonomous position control tuned under no wind conditions are evaluated (Proportional Derivative (PD), Integral Backstepping, and Fuzzy Logic). Flight tests using a small (approximately 2 kg)

quadrotor UAV within a building wake show that the simulation tool can predict average position deviation to within a single body length (0.55 m) in the horizontal plane for observed freestream wind speeds between 1 and 2 m/s (with predicted gusts of up to ± 6 m/s). The simulation tool is also shown to be able to predict relative differences between control methods both overall and specifically along each co-ordinate axis. A PD controller is predicted to hold position more accurately with a building wake in the direction perpendicular to the freestream wind by approximately $\pm$ half a body length while a Fuzzy controller achieves the same result in the direction parallel to the freestream wind. These results are validated by flight test data where both the most effective control strategy, and the magnitude of the position control difference, are shown to match the simulation results.

"FLAP SIZING FOR WAKE VORTEX INSTABILITY"

SAE Paper 2000-01-1693, May 2000, Wichita, KS

The authors explore the possibility of designing the flap system on a given wing for enhanced Crow instability. The problem motivation in terms of increased traffic volume and increased safety is described. A brief review of the technical literature is given. An exploratory two-dimensional potential flow formulation is presented. A generic wing and flap combination is used for trade-off studies. The authors show that the frequency with which the flap-tip and the wing-tip vortex filaments swirl around each other can be tuned to match that which corresponds to the largest rate of amplitude growth in the wake. The extent of the analysis being two-dimensional, the authors suggest careful wind- or water-tunnel testing in three dimensions to validate the concept.

Rebours, R., Kliment, L. K. and Rokhsaz, K.

"FORCED RESPONSE OF A VORTEX FILAMENT PAIR MEASURED IN A WATER TUNNEL"

Journal of Aircraft, Vol. 41, No. 5, September-October 2004, pp. 1163-1168

Crow instability is examined and quantitative measurements made in a water tunnel are presented. The results of the application of a novel technique for quantitative data acquisition that allows

measurement of the vortex strength, the oscillation frequency of the vortex filaments, and the rate of growth of their amplitude simultaneously, are presented. A pair of vortex filaments, typical of those of wing-tips, is created by individual vortex generating blades in a water tunnel. The filaments are then subjected to periodic inputs, and their responses are measured downstream. The vortex system is excited over a range of frequencies. The filaments are visualized with dye injection, whereas their cross sections are illuminated with light sheets at different downstream locations. Time history of the vortex position is extracted from video recordings of the illuminated cross sections. The results show that most of the essential features associated with Crow instability, such as the inclination angle of the plane of vortex motion and the growth rate of the amplitude, are in qualitative agreement with the theoretical model. Disagreements between theoretical and experimental results are examined and discussed. These experiments prove the viability of the experimental approach. Furthermore, the results demonstrate clearly that manipulation of the excitation frequency can control the rate of growth of amplitude.

"FORCED RESPONSE OF A VORTEX FILAMENT PAIR MEASURED IN A WATER TUNNEL"

AIAA Paper No. 2001-2448, June 2001, Anaheim, CA.

This paper examines Crow instability and presents quantitative measurements made in a water tunnel. The authors present the results of applying a novel technique for quantitative data acquisition that allows measuring the vortex strength, the oscillation frequency of the vortex filaments, and the rate of growth of their amplitude simultaneously. A pair of vortex filaments, typical of those of wing tips, is created by individual vortex generating blades in a water tunnel. The filaments are then subjected to periodic inputs and their responses are measured downstream. The vortex system is excited over a range of frequencies. The filaments are visualized using dye injection while their cross sections are illuminated with light sheets at different downstream locations. Time history of the vortex position is extracted from video recordings of the illuminated cross sections. The results show that most of the essential features associated with Crow instability, such as the inclination angle of the plane of vortex motion and the growth rate of the amplitude are in qualitative agreement with the theoretical model. Disagreements between theoretical and experimental results are examined and discussed. These experiments prove the viability of the experimental approach. Furthermore, the results demonstrate clearly that manipulating the excitation frequency can control the rate of growth of amplitude.

"ROTOR WAKE MODELLING METHODS SURVEYED DURING AN OVERSEAS VISIT"

AR-004-474, Aerodynamics Technical Memorandum 381, 1986, Aeronautical Research Laboratories, Melbourne, Australia.

Between 8th September and 9th October 1985, the author attended the Eleventh Rotorcraft Forum in London, and visited ten research Establishments in England, West Germany, and the USA. The main purpose of the overseas visit was to investigate rotor wake modelling methods currently used. A report is given on the Forum attendance and discussions held at the establishments, together with a general review of rotor wake modelling.

Reddy, K. R.

"PREDICTION OF HELICOPTER ROTOR DOWNWASH IN HOVER AND VERTICAL FLIGHT"

ARL/AERO-REPT-150, January 1979, Aeronautical Research Labs, Melbourne, Australia

A vortex-wake method to calculate the rotor downwash in hovering and vertical flight is presented. The blade is represented by a lifting line. The rotor wake is simulated by a vortex sheet and a series of rolled up root and tip vortices, similar in form to that of a classical fixed wing. The concept of rectangularization of the rotor wake is used in obtaining a formula for the normal component of induced velocity. Wake contraction based on experimental data is introduced into the calculations. Numerical calculations are performed for two rotor configurations. Computed induced velocities and blade loadings are compared with the available flight data.

Reddy, K. R.

"THE VORTEX FLOW FIELD GENERATED BY A HOVERING HELICOPTER"

7th Australasian Hydraulics and Fluid Mechanics Conf., Institution of Engineers, Brisbane, August 1980

Important vortex elements in the wake of a hovering helicopter are identified based on well-established fixed wing theory. The vortex positions are specified using experimental results. To make the problem mathematically simple, Willmer's rectangularization principle is introduced. Using this wake model, the calculated velocity field and blade loading are compared with available helicopter flight data. The comparison shows that the present simple method yields satisfactory results.

Reddy, K. R.

"A ROTOR WAKE MODEL FOR FORWARD FLIGHT SIMULATION STUDIES"

ARL/AERO-NOTE-402, June 1981, Aeronautical Research Labs., Melbourne, Australia

This Note presents an attempt to develop a rotor wake model for forward flight which requires only modest computing time and, therefore, is suitable for flight simulation studies. Free and rigid wake models are discussed, together with various simplifying assumptions, in order to reduce the computation time to acceptable levels for simulation studies. Using a tip vortex wake model and the Biot-Savart relation, induced velocities are calculated in the rotor plane. It is then assumed that the tip vortex wake takes the form of a skewed helix. Such a simple prescribed model requires little computing

time and the accuracy of its results when compared with more elaborate free wake models shows considerable promise.

Reddy, K. R.

"VORTICITY IN THE WAKE OF A HELICOPTER ROTOR IN FORWARD FLIGHT"

8th Australasian Fluid Dynamics Conf., University of Newcastle, Nov. 1983.

In this paper, important vortex elements in the wake of a helicopter rotor are first identified. Various simplifying assumptions are then introduced to reduce the computational time to acceptable levels. Using a blade tip vortex model, several wake geometries have been investigated. The results show that a simple skewed helical vortex wake model provides acceptable results for helicopter flight simulation and performance studies.

"SIMULATION, A VALUABLE TOOL IN THE ESTIMATION OF HELICOPTER FLIGHT DYNAMIC CHARACTERISTICS"

18th World IMACS/MODSIM Congress, July 2009, Cairns, Australia, pp. 1643-1649.

Estimating helicopter flight dynamic characteristics is a challenge. Manufacturers of the aircraft generally establish these characteristics by flight testing over a range of operational conditions. However, it is not always possible to test the aircraft in certain conditions. Simulation can play an important role in filling the gaps between the flight test data sets and extending the operating limits beyond the boundaries of the test envelope. A helicopter flight dynamic simulation requires a representation of the aerodynamics, dynamics, and control systems. In this paper we model an important component of aerodynamics, that is, the rotor wake flow field. This very complex flow condition is often unsteady and dominated by vorticity. Important elements of the rotor wake vorticity are identified, then simplified (using a vortex sheet to represent the near wake of the rotor blade, and vortex rings to represent the intermediate and far wake) and then applied to mathematically simulate helicopter vertical flight conditions. Using this simple flow model, helicopter velocity and blade loadings have been calculated for hovering flight and compared with published data, including test data, to establish the validity of the model. The model has been extended to capture unusual blade loading associated with vertical flight including vertical gust effects and vortex ring states. It is difficult to safely and repeatably replicate such flight conditions during flight tests. By hypothesizing helicopter flight as the flow represented by the generation and interaction of two jets of varying strength the unsteady flow can be better understood. The rotor can be seen to be producing one jet; the other is produced by the motion of the helicopter through the air. These two jets will interact producing a region of unstable flow. As the descent rate of the helicopter increases the location of the interface moves closer to the rotor disc and influences its lift generating capacity. Using the simple flow model, we can simulate flight conditions, often in unsteady flow states, and extract meaningful data. Numerical

simulations and results are presented in this paper for a range of operating conditions associated with helicopter vertical flight..

"WINGLETS -- MULTIOBJECTIVE OPTIMIZATION OF AERODYNAMIC SHAPES"

11th World Congress on Computational Mechanics (WCCM XI), July 2014, Barcelona, Spain.

Various configurations for airplane wing tip winglets have been investigated by performing 3D aerodynamic analysis. An existing blended winglet has been equipped with a secondary lower element to create a split winglet configuration. At winglet tips, a trailing edge extension was added to create scimitar streamwise spikes. A total of eight variables were used to define the winglet geometry. The presented design methodology utilizes a second order continuous, 3D geometry generation algorithm based on locally analytical surface patches. This algorithm requires a minimal number of design parameters to be varied in order to create vastly different 3D geometries of the winglets attached to a clean wing which is blended with the fuselage. A 3D, compressible, turbulent flow analysis was performed using a Navier-Stokes solver on each configuration to obtain objective function values. Each configuration was analyzed at free stream Mach number of 0.25 and an angle of attack of 11 degrees to mimic takeoff conditions of a passenger aircraft. Multi-objective optimization was carried out using modeFRONTIER utilizing a radial basis function response surface approximation coupled with a generic algorithm. Maximizing coefficient of lift and lift-to-drag ratio, while minimizing coefficients of drag and magnitude of coefficient of moment, were the four simultaneous objectives. Performance benefits of individual components of the optimized geometry were also investigated.

Reed, III, W. H.

"AN ANALYTICAL STUDY OF THE EFFECT OF AIRPLANE WAKE ON THE LATERAL DISPERSION OF AERIAL SPRAYS"

NACA TR-1196, January 1954, NACA Langley Aero. Lab., Langley Field, VA

Calculations are made to determine the trajectories of liquid droplets introduced into the air disturbances generated by an airplane engaged in aerial spraying. The effects of such factors as the positions at which droplets are ejected into the disturbances, airplane lift coefficient, and altitude are investigated. The distribution of deposit on the ground is computed for several droplet-size spectra, variations in the rate at which mass is ejected along the span, and lateral flight-path spacings. Consideration is then given to the problem of adjusting these factors with the aim of improving the uniformity and increasing the effective width of the deposit. The results indicate that the lateral dispersion of droplets is increased when the spanwise position at which particles are ejected is moved toward the wing tip. Greater dispersion also results when the airplane lift coefficient or altitude is increased.

"PROPERTIES OF THE LATERAL RANDOM OSCILLATIONS OF TRAILING VORTICES OBSERVED IN WIND-TUNNEL TESTS"

NEAR TR-47, January 1973, Nielsen Engineering and Research Inc., Mountain View, CA

The characteristics and causes of the lateral oscillations of trailing vortices observed during tests in the 40- by 80-foot and 7- by 10-Foot Wind Tunnels at Ames Research Center are studied. Various statistical properties of the oscillations are computed from movie camera data. A comparison of these data with a derived analytical expression indicates that the vortex oscillation is caused by the tunnel turbulence and the rms amplitude is independent of the properties of the vortex for the range of parameters considered.

"NEW DESIGN AND OPERATING TECHNIQUES FOR IMPROVED TERMINAL AREA COMPATIBILITY"

SAE Paper No. 740454, Dallas, TX, 1974

Current aircraft operating problems that must be alleviated for future high-density terminal areas are safety, dependence on weather, congestion, energy conservation, noise, and atmospheric pollution. The microwave landing system (MLS) under development by FAA provides increased capabilities over the current ILS. It is however, necessary and urgent to develop the airborne system's capability to take maximum advantage of the MLS capabilities to solve the terminal area problems previously mentioned. A major limiting factor in longitudinal spacing for capacity increase is the trailing vortex hazard. Promising methods for causing early dissipation of the vortices are being explored. Also, flight procedures for avoiding the hazard will be explored.

Rees, F. L.

"METHOD OF DETECTING WEATHER CONDITIONS IN THE ATMOSPHERE"

US Patent 6,034,760, March 2000

Method and apparatus for detecting conditions in the atmosphere which are hazardous to flying aircraft and providing early warning to pilots or ground personnel. The method includes using a laser beam and a coherent optical receiver to optically sense sound waves produced by those hazardous conditions and measuring the effect of those sound waves on the transmitted and received optical beams.

"PARTICLE IMAGE VELOCIMETRY MEASUREMENT OF TORNADO-LIKE VORTICES COMPARED WITH DOPPLER RADAR DATA"

17th International Symposium on Application of Laser Techniques to Fluid Mechanics, July 2014, Lisbon, Portugal.

Particle Image Velocimetry (PIV) technique was employed to characterize the flow field of simulated tornado vortices and to establish a relationship between laboratory generated tornadoes and the field ones. Field data collected by mobile Doppler radars were analyzed using a mathematical method namely the Ground-based Velocity Track Display and the velocity fields were extracted. The horizontal velocity field of tornado vortices, simulated in Model WindEEE Dome, was measured using PIV for a wide range of vortex intensity. The substantial mismatch between the averaging time of the full-scale data and the laboratory data which is originated in the very small length scale of the simulation and the low sampling rate of the PIV system, was addressed and corrected using the Durst curve. Once modified, the velocity field of the simulated vortex was compared with that of the full-scale tornado and the swirl ratio of the field tornado as well as the length and velocity scales of the simulation were identified. This practice, for the first time, provided an opportunity to compare the velocity field of tornado vortices obtained through PIV and radar measurements using proper scaling.

Rehback, C.

"NUMERICAL STUDY OF THE INFLUENCE OF THE WING TIP SHAPE ON THE VORTEX ROLL UP"

NASA-TT-F-14538, August 1972, Scientific Translation Service, Santa Barbara, CA

A computer program to analyze the wing tip vortex distribution as a function of wing tip shape is presented. The wing and the sheet are replaced by a vortex surface. The continuous vortex distribution over the surface is replaced by a discrete vortex distribution, which is a horseshoe distribution of finite magnitude and is placed over the wing only. The shear appears in the form of a series of vortex threads which emanate at moderate incidence angles from the leading edge to the wing tip. Starting with the given initial position, the threads evolve during the course of an iteration calculation and assume equilibrium positions parallel to the average velocity over the sheet.

Rehm, F.

"PREDICTION OF AIRCRAFT DELAYS AS A FUNCTION OF WEATHER"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

The impact of the weather on the delay of flights is often underestimated when simulating airport scenarios. However, recent studies have shown that certain weather factors influence the air traffic significantly. In this work we will show in detail, which weather factors in the closer region of a big international airport have an impact on the delay of flights in which extent. Beside the results of a linear regression model, we will also present in this paper the results of some modern data mining approaches, such as neuronal networks and fuzzy clustering techniques. We will show that several weather situations have a similar influence on the delay of flights. Our analyses focus the delay that will be explicitly caused by weather factors in the vicinity of the airport, the so-called traffic

management area (TMA). Thus, delay caused by some weather influences on the departure airport or by other circumstances during the flight, will not bias our results. With our methods it becomes possible to predict the delay of flights if certain weather factors are known. We will specify these factors and quantify their impact on delays.

"INFLUENCE ON LAND AND AIRSPACE DEMANDS OF TECHNIQUES IN CURRENT USE"

Air Traffic, Navigation and the Community, Royal Aeronautical Society and Institute of Navigation, Symposium on Air Traffic in the 1980's, May 1970

Study of the limitations of techniques already commonly applied, and of the more promising points of application for new technology in navigation, surveillance, and traffic control. In seeking the latter, some of the current trends in other fields, particularly aircraft design, are considered. Considerable emphasis is placed on the efficient use of land at airports, in view of the strength of feelings aroused in communities by questions of apportionment and exploitation of land resources. The incidence of much stronger wing tip vortices associated with heavy CTOL aircraft is likely to make increases in land productivity difficult, if not impossible, to achieve.

Reichmuth, J.

"OPERATIONAL AND CAPACITY INVESTIGATIONS FOR THE ALLEVIATION OF WAKE VORTEX SEPARATION PROBLEMS AT THE AIRPORT OF FRANKFORT"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 26-1 - 26-23

Since 1989 a working group named 'Capacity for Frankfurt Airport' exists with the goal to identify means by which an increase of capacity at Frankfurt airport would be possible. One candidate was a wake vortex warning system for the two parallel runways at Frankfurt, separated only 517 m. Up to now work related to a wake vortex warning system was done in three main areas. Field measurements were performed at Frankfurt airport to obtain the necessary knowledge about vortex propagation and structure in the boundary layer. The feasibility of a prognostic system which predicts the behavior of the wake vortices under different meteorological conditions was investigated. The outcome of these measurement is that a prediction about wake vortex free regions can be made up to 20 min. and that a situation where the two parallel runways at Frankfurt could be operated independent of wake vortices would be present 60% of the time. Fast Time Simulations with the programs SIMOD and ADSIM were used to model the airspace structure of Frankfurt and the behavior of aerodrome traffic from arrival to departure. These programs are now able not only to simulate the present situation but also the effects on capacity and delays due to changes induced by a wake vortex warning system operationally. These fast time simulations predict an increase of arrivals of 1 to 5 aircraft per hour. Real Time Simulation allowed a closer look on three different operational concepts under well-defined conditions. Controllers and pilots were involved in the concept development phase early. This helps to find

displays and operations acceptable for a realistic environment. The present paper concentrates on the real time simulations performed in June and July this year. The implementation in the simulator environment will be described together with the three different operational concepts under simulation.

"A PRELIMINARY STUDY OF A WAKE VORTEX ENCOUNTER HAZARD BOUNDARY FOR A B737-100 AIRPLANE"

NASA TM-110223, April 1996, Langley Research Center, Hampton, VA

A preliminary batch simulation study was conducted to define the wake decay required for a Boeing 737-100 airplane to safely encounter a Boeing 727 wake and land. The baseline six-degree-of-freedom B737 simulation was modified to include a wake model and the strip-theory calculation of the vortex-induced forces and moments. The guidance and control inputs for the airplane were provided by an autoland system. The wake was positioned such that the desired flight path traversed the core of the port vortex. Various safe landing criteria were evaluated for defining a safe encounter boundary. A sensitivity study was also conducted to assess the effects of encounter model inaccuracies.

"STEREO-PIV DATA OBTAINED BEHIND AN F-15 MODEL COMPARED TO CFD RESULTS"

AIAA Paper 2008-3712, June 2008, Seattle, WA

A stereoscopic Particle Image Velocimetry (PIV) system has recently been implemented in the Aerodynamic Wind Tunnel 4T at Arnold Engineering Development Center. Sequences of instantaneous three-component velocities were obtained in the wake of a 1/20th scale F-15 model in a 40- by 40-cm planar region situated perpendicular to the tunnel's freestream flow. Data sets were obtained in Mach number 0.4 flow at eight different model attitudes. A preliminary comparison between PIV results and computational fluid dynamics (CFD) solutions shows similar counter-rotating wake structures. This paper compares experimental PIV data with CFD predictions.

"SCATTERING OF SOUND WAVES BY A CYLINDRICAL VORTEX: A SEMI-ANALYTICAL THEORY"

J. Fluid Mech., Vol. 333, 1997, pp. 273-299

A semi-analytical theory for the scattering of plane sound waves by a compressible, non-homentropic, circular-cylindrical, single vortex is presented in this paper. As a special case, the scattering of sound by a cylindrical inhomogeneity (hot spot) is investigated. Contrary to the otherwise analogous quantum-mechanical scattering problem, there are singularities in the modified acoustic wave equation when the scattering by a vortex is considered. It will be shown how these singularities can be treated. This sound-scattering theory is applied to the problem of the interaction of weak plane shock waves with a

strong cylindrical vortex. The calculated scattered sound signal has a rather complicated structure in which a cylindrical wave with an essentially quadrupolar directivity pattern is discernible. In the case of shock-hot-spot interaction a scattered sound signal with dipole-like amplitude is obtained. Both results qualitatively agree with experimental findings.

Reitebuch, O.

"WIND LIDAR FOR ATMOSPHERIC RESEARCH"

In: Atmospheric Physics, Research Topics in Aerospace, U. Schumann (editor), Springer-Verlag Berlin Heidelberg, 2012 pp. 487-507.

Wind lidars use the optical Doppler effect to measure the atmospheric wind with high spatial and temporal resolution. This offers a wide range of applications from aircraft wake vortex detection and characterization to measurement of turbulent quantities like fluxes to resolving small and mesoscale atmospheric flows, and even global wind profiling from space in the future. Principles of wind lidars including two complementary techniques and applications for atmospheric research are discussed.

Remaly, M. A.

"DEVELOPMENT OF A LABORATORY SCALE AIRCRAFT WAKE VORTEX DETECTION SYSTEM"

College of Engineering Research Symposium, Penn. State University, University Park, PA, March 2006

Aircraft wake vortices have a major impact on the efficiency of airports due to minimum separation requirements. Encountering a leading aircraft's wake could be hazardous to a following aircraft. A system known as a Radar Acoustic Sounding System (RASS) has been used to measure the strength of these vortices for aircraft on approach for landing. However, that system was adapted from a RASS that was initially designed for meteorological purposes. It is therefore the purpose of this research to contribute to the development of a RASS designed specifically for wake vortex detection and measurement by designing and testing a sub-scale laboratory system. The primary components of the sub-scale system are the radar transmitter/receiver and an acoustic array. In addition, a swirling jet facility will be used to generate a flow field that will simulate a single aircraft trailing vortex.

Remaly, M. A.

"DEVELOPMENT OF A LABORATORY SCALE AIRCRAFT WAKE VORTEX DETECTION SYSTEM"

M.S. Thesis, December 2006, Pennsylvania State University, University Park, PA

NASA is developing an Advanced Vortex Sensing System (AVOSS) which, if implemented, would be used to monitor and predict wake vortices to support Reduced Spacing Operation (RSO) and increase Terminal Area Productivity (TAP). A Radar Acoustic Sounding System (RASS) has been used by researchers as the vortex sensing component of the AVOSS and results have shown good agreement with known vortex properties; however, that system was originally designed for meteorological

purposes. It was therefore the overall goal of this thesis to develop a laboratory scale vortex system based on a RASS. The sub scale system permits a cost-effective method for carefully evaluating each component of the sensing system to ensure optimum vortex sensing characteristics. Contained in this thesis are the experimental studies and development of a 24 kHz acoustic array used to generate a highly directed beam, and a 10.4 GHz radar system for tracking the acoustic waves. Additionally, a swirling jet facility was developed and characterized to simulate a single aircraft wake vortex; experimental techniques included flow visualization, Particle Image Velocimetry, and a five-hole pitot probe. Laboratory RASS experiments, however, were unable to detect an acoustically induced echo above the background reflections from the sidewalls of the laboratory. Consequently, the swirl jet's flow field was never interrogated by the RASS. However, several important results, conclusions, and system design considerations are presented and provide the ground for future work to successfully develop a laboratory scale system.

"FLIGHT-TEST EVALUATION OF THE TOOL FOR ANALYSIS OF SEPARATION AND THROUGHPUT"

Journal of Aircraft, Vol. 45, No. 1, January-February 2008, pp. 323-332

The tool for analysis of separation and throughput has been developed to predict the range of possible trajectories of aircraft performing any given continuous descent arrival and thereby determine the minimum target spacing at a metering point, such that there is a high probability of no separation violations thereafter. The resulting reduced need for controller intervention is expected to facilitate the implementation of continuous descent arrival. This tool includes a fast-time Monte Carlo trajectory simulator and a theoretically rigorous separation analysis methodology based on the probabilistic characteristics of trajectories. The tool was used to determine the target spacing for a continuous descent arrival flight test conducted in September 2004 at Louisville International Airport. Results of the flight test indicate that the 15-n-mile target spacing yielded a conditional probability of 69.6% for the continuous descent arrival to runway 35L, very close to the predicted value of 68.6%; and an overall total probability of 81.7%, which is between the predicted values of 79.6% and 85.0% for the continuous descent arrival to runway 35L and 17R, respectively. The flight test demonstrated that, by using the tool as developed, continuous descent arrival can be efficiently implemented under moderate to moderately high traffic conditions, thereby achieving much needed environmental and economic benefits.

"DECAY OR COLLAPSE: AIRCRAFT WAKE VORTICES IN GRID TURBULENCE"

Euromech Fluid Mechanics Conf. (EFMC6), June 2006, Stockholm, Sweden.

Trailing vortices are naturally shed by airplanes and they typically evolve into a counter-rotating vortex pair. Downstream of the aircraft, these vortices can persist for a very long time and extend for several kilometers. This poses a potential hazard to following aircraft, particularly during take-off and

landing. Therefore, it is of interest to understand what effects control the decay rate in strength of the trailing vortices. The decay of aircraft wake vortices is strongly dependent on weather conditions. To simulate an environment of atmospheric turbulence, homogeneous isotropic turbulence is introduced next to localized vortical structure. In this contribution, the effect of external turbulence on the vortex decay will be investigated numerically, using a DNS method, and experimentally. Wind tunnel experiments are carried out using a smoke visualization technique.

Ren, T. and Edwards, J. A.

"VORTEX INTERACTION WITH AN AEROFOIL USING CHIMERA AND THE AMR ALGORITHM"

AIAA Paper No. 2002-4806, Monterey, CA, August 2002

Recently, a solution adaptive Chimera grid scheme applying the structured Adaptive Mesh Refinement (AMR) algorithm has been developed by the authors for simulating multiple and moving body supersonic flows. Two CFD methodologies, the Chimera grid method and the AMR algorithm were integrated. A complex multiple and moving body configuration can be easily meshed by the Chimera grid method, and each domain of the initial coarse Chimera grid system is then adapted by the AMR algorithm according to the flow solution. The advantages of the Chimera grid method and the AMR algorithm are combined. In this paper, numerical solutions of a shock interaction with an airfoil, together with the subsequent interaction of a vortex generated at the trailing edge of the airfoil interacting with a further airfoil are presented. The results are obtained from this new solution adaptive Chimera grid scheme (AMRC code) and are analyzed and compared with both experiment and previous computational results. The simulations demonstrate the flexibility of grid generation and the high efficiency and the ability to resolve and track complex flow features.

"CRITICALITY OF COMPRESSIBLE ROTATING FLOWS"

Physics of Fluids, Vol. 19, 2007, pp. 018101 -- 1-018101-4

The effect of compressibility on the criticality of swirling subsonic flows is investigated. This study extends previous works by Rusak and Leo [J. Fluid Mech., 461, 301 (2002); 501, 25 (2004)] on the critical swirl of subsonic vortex flows in a circular straight pipe. We derive an asymptotic solution in the case of an isothermal plug-flow with solid-body rotation. Physically, compressibility is found to slow down phase and group velocities of axisymmetric Kelvin waves, thus decreasing the rotation contribution to flow criticality. It is shown that compressibility damps the stretching mechanism which contributes to the wave propagation in the incompressible limit.

Renaud, T., Le Pape, A. and Benoit, C.

"UNSTEADY EULER AND NAVIER-STOKES COMPUTATIONS OF A COMPLETE HELICOPTER"

31st European Rotorcraft Forum, September 2005, Florence, Italy.

The simulation of the aerodynamic interactions between the different parts of a helicopter becomes more and more important for the understanding of the complex flowfield and the design of the helicopter. Advanced numerical tools have been developed in the elsA solver to represent the various phenomena which occur around the helicopter. Recent progresses have been achieved within the French-German cooperation CHANCE (Complete Helicopter AdvANced Computational Environment) which aims at the numerical simulation of a complete helicopter. This paper presents results of unsteady Euler and Navier-Stokes computations, using Chimera techniques. The first test-case concerns a Dauphin 365N configuration with its main rotor. A numerical analysis (time convergence, mesh refinement, ...) allowed to find the best choices for such a complex unsteady simulation. The CFD solutions are in good agreement with measurements done on a Dauphin helicopter model. In the second part, an automatic Cartesian grid approach is applied on a complete configuration (wind tunnel model like the NH90 helicopter) in pitch-up flow conditions. The Euler simulation allows to describe the complex flowfield and the interactions between the fuselage and the two rotors.

Rennich, S. C.

"ACCELERATED DESTRUCTION OF AIRCRAFT WAKE VORTICES"

Ph.D. Thesis, May 1997, Stanford Univ., Palo Alto, CA

An aircraft's wake often breaks down via the Crow instability. No instability has yet been found which is more rapidly growing or shows a greater ability to mix vorticity of opposite sign than the Crow instability. Thus, the objective of this research is to investigate alleviation schemes by which perturbations, applied to the wake at the wing, survive the roll-up process, excite the Crow instability at large amplitude and lead to accelerated destruction of the wake vortices. To carry out this research, a new, numerical method has been developed which solves the incompressible Navier-Stokes equations in vorticity form in a domain which is periodic in one direction and unbounded in the other two. A code using this method has been used to fully characterize the Crow instability as it exists in a 3D, viscous environment and validate the analytical models of this instability. Finally, a new mechanism to be used in accelerating the destruction of aircraft wake vortices is proposed. Its behavior is investigated using both Navier-Stokes and vortex filament methods. The results indicate that the time required for vortex linking can be reduced by as much as a factor of seven when compared to the time required for equivalent growth via the linear Crow instability.

Rennich, S. C. and Lele, S. K.

"NUMERICAL METHOD FOR INCOMPRESSIBLE VORTICAL FLOWS WITH TWO UNBOUNDED DIRECTIONS"

Journal of Computational Physics, Vol. 137, 1997, pp. 101-129

A new, efficient, and accurate method has been developed for computing unsteady, incompressible, viscous flows in a domain where two dimensions are unbounded, the third dimension is periodic and the vorticity is rapidly decaying in the unbounded directions. We use the term unbounded to mean

doubly infinite (no boundaries of any kind). This is an extension of the methods described by others for flows with two periodic and one unbounded direction, where the irrotational velocities outside the vortical domain are treated analytically. The new method is shown to be both accurate and efficient. The method presented here has finite, but arbitrarily high order, formal accuracy, and incurs substantial additional cost for a given mesh. However, this increased cost is more than offset by the reduction in the number of mesh points required for a given accuracy. The result is that for accurate computations, the present method can be orders of magnitude more efficient than others currently in use. This paper presents the method, discusses implementation issues, validates its accuracy, and presents sample calculations.

Rennich, S. C. and Lele, S. K.

"DIRECT NUMERICAL SIMULATION OF THE BREAKDOWN OF AIRCRAFT WAKE VORTICES"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 30-1 to 30-10

An investigation is initiated that aims to improve the understanding of how disturbances to aircraft vortex wakes, applied at the wing, survive the roll-up process and eventually lead to destruction of the wake. To efficiently perform this investigation, a numerical method is presented which accurately and efficiently computes flows in domains that are unbounded in two directions and periodic in the third, subject to the condition that vorticity is compactly distributed in the unbounded directions. This new code is used to compute the growth of symmetric disturbances on a pair of counter rotating columnar vortices and, for high Reynolds number, the inviscid, linear vortex filament results of Crow which predict the most unstable wavelength and its amplification rate, are reproduced well. From these computations an eigenfunction of the Crow instability as it exists in an evolving viscous vortex pair is extracted. The evolution of a perturbed plane wake due to an elliptically loaded wing is computed. It is observed that a perturbation of the correct wavelength rapidly evolves into the Crow instability and grows at approximately the predicted rate.

Rennich, S. C. and Lele, S. K.

"METHOD FOR ACCELERATING THE DESTRUCTION OF AIRCRAFT WAKE VORTICES"

J. Aircraft, Vol. 36, No. 2, March-April 1999, pp. 398-404

The wake vortices shed by large aircraft and their associated hazard to following aircraft remain an important issue in commercial aviation. Extensive research into methods for alleviating this wake vortex hazard has been continuing for many years. This paper presents results from numerical simulations detailing a potentially useful mechanism for accelerating the destruction of the aircraft vortex wake and reducing the wake hazard. The term 'destruction' is used to refer to the progressive annihilation of the wake caused by mixing of vorticity of opposite sign and the associated elimination of large coherent structures. The emphasis here is on a description of the mechanism and its connection to previous work.

"A TRANSPORT CANADA PERSPECTIVE"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 21-23

This presentation will briefly describe Transport Canada's interest and participation in wake vortex research, and, in general terms, outline suggested requirements in the development of a wake vortex forecasting system.

"EROS: A EUROPEAN EULER CODE FOR HELICOPTER ROTOR FLOW SIMULATIONS"

ICAS 1998, Paper 98-2.6.1, Sept. 1998, Melbourne, Australia.

The helicopter rotor flow field is one of the most complex and challenging problems in applied aerodynamics. Its accurate analysis is essential in the design of rotors with increased performance and in the development of rotors with reduced vibratory loads and with more environmentally-friendly acoustic signatures. There is an industrial need in Europe for a rotor aerodynamic tool able to capture rotational phenomena, such as blade tip and wake vortices, and to predict correctly the unsteady blade pressures over a range of different flight conditions. The EROS project addresses this need by developing a common European system capable of analyzing the inviscid rotor flow environment by solving the 3D Euler equations. The method is based on a proven-technology time-accurate Euler formulation on overlapping structured grids (Chimera method). The grid generator provides an all-in-one capability for grid generation guiding the user from the generation of individual component grids to the Chimera domain decomposition through an interactive process which has embedded visualization and animation capabilities. The cell-centered finite-volume solver adopts a dual-time implicit scheme on deforming grids. Nonconservative interpolation is used to transfer information across grid overlap regions. The current capabilities of the code are presented and future developments are described.

Report, DTFWA-16-D-00005, May 2019.

"This report entitled, 'Final Report on Avionics Prototype and Demonstration Test Flights' describes the Paired Approach Flight Demonstration and discusses significant findings, lessons learned, and future work recommendations. This work was funded by the FAA NextGen organization."

"WIND TURBINE WAKE IN ATMOSPHERIC TURBULENCE"

1785

PhD Thesis, October 2009, Aalborg University, Aalborg, Denmark. Also is report Riso-PhD-53(EN), October 2009, Riso National Laboratory for Sustainable Energy, Roskilde, Denmark.

This thesis describes the different steps needed to design a steady-state computational fluid dynamics (CFD) wind farm wake model. The goal of the project was to design a tool that could analyze and extrapolate systematically wind farm measurements to generate wind maps to calibrate faster and simpler engineering wind farm wake models. The most attractive solution was the actuator disc method with the steady state k-e turbulence model. The first step to design such a tool is the treatment of the forces. This thesis presents a computationally inexpensive method to apply discrete body forces into the finite-volume flow solver with collocated variable treatment (EllipSys), which avoids the pressure-velocity decoupling issue. The second step is to distribute the body forces in the computational domain accordingly to rotor loading. This thesis presents a generic flexible method that associates any kind of shapes with the computational domain discretization. The special case of the actuator disc performs remarkably well in comparison with Conway's heavily loaded actuator disc analytical solution and a CFD full rotor computation, even with a coarse discretization. The third step is to model the atmospheric turbulence. The standard k-e model is found to be unable to model at the same time the atmospheric turbulence and the actuator disc wake and performs badly in comparison with single wind turbine wake measurements. A comparison with a Large Eddy Simulation (LES) shows that the problem mainly comes from the assumptions of the eddy-viscosity concept, which are deeply invalidated in the wind turbine wake region. Different models that intent to correct the k-e model's issues are investigated, of which none of them is found to be adequate. The mixing of the wake in the atmosphere is a deeply non-local phenomenon that is not handled correctly by an eddy-viscosity model such as k-e.

"MODELLING ISSUES WITH WIND TURBINE WAKE AND ATMOSPHERIC TURBULENCE"

Third Conference, Torque 2010, The Science of Making Torque from the Wind, June 2010, Heraklion, Crete, Greece.

The steady-state CFD turbulence models available to simulate the atmospheric boundary layer and wind turbine wake are not performing satisfyingly compared with measurements. This paper demonstrates that, in those specific cases, they operate outside of their constitutive assumptions. Several correction-models proposed in the literature are analyzed and compared with Large Eddy Simulation. None of them are found to restore the physics of the problem.

Rethore, P.-E., Sorensen, N. N., Bechmann, A. and Zhale, F.

"STUDY OF THE ATMOSPHERIC WAKE TURBULENCE OF A CFD ACTUATOR DISC MODEL"

2009 European Wind Energy Conference and Exhibition, March 2009, Marseille, France.

Modelling wind turbine wake using the standard kappa-epsilon atmospheric turbulence model gives a too fast wake dissipation compared to measurements and more advanced turbulence models. The

problem is that the relevant scales of turbulence are different from the point of view of the wind turbines and from the point of view of the terrain. As the atmospheric turbulence model imposes the scale of turbulence, part of the influence of the wind turbine on the airflow is happening at the turbulence level. It becomes therefore necessary to add terms in the turbulence equations to account for the wind turbine activity. In this context two different models are compared together and with wind turbine wake measurements. With the proper parameterization, they are both able to produce similar results, in agreement with the measurements.

"PROOF OF CONCEPT FOR WIND TURBINE WAKE INVESTIGATIONS WITH THE RPAS SUMO"

Energy Procedia, Vol. 94, 2016, pp. 452-461.

The Small Unmanned Meteorological Observer (SUMO) has been operated in the vicinity of five research turbines of the Energy Research Centre of the Netherlands (ECN) at the test site Wieringermeer. The intention of the campaign was to proof the capability of the system for wind turbine wake investigations also for situations above rated wind speed. In rather high wind conditions of 15-20 m/s on May 10, 2014, the system showed a satisfying in-flight behavior and performed five racetrack flights. The racetrack patterns flown parallel to the row of the five turbines (four flights downstream the turbine row, one upstream) enable the characterization and investigation of the strength, i.e. the reduction in the mean wind, and structure, i.e. the horizontal extension and turbulent kinetic energy (TKE) distribution of single turbine wakes.

"ADVANCED RANS MODELING OF WINGTIP VORTEX FLOWS"

Proceedings of the Summer Program 2006, Center for Turbulence Research, pp. 73-85

The numerical calculation of the trailing vortex shed from the wingtip of an aircraft has attracted significant attention in recent years. An accurate prediction of the flow over the wing is required to provide the correct initial conditions for the trailing vortex, while careful modeling is also necessary to account for the turbulence in the vortex core. As such, recent works have concluded that to achieve results of satisfactory accuracy, the use of complex turbulence modeling closures and numerical grids of considerable size is an absolute necessity. The computations here are reported for the flow over a NACA0012 half-wing with rounded wingtip at an incidence angle of 10 degrees, as measured by Chow et al. (1997). The primary aim is to assess the performance of a new turbulence modeling scheme which accounts for the stress-strain misalignment effects in a turbulent flow. This three-equation model bridges the gap between popular two equations eddy-viscosity models (EVM) and the seven equations of a RSM. Relative to a RSM, this new approach inherits the stability advantages of an eddy-viscosity scheme, together with a lower computational expense, and it has already been validated for a range of unsteady mean flows (Revell).

Revuelta, A.

"ON THE AXISYMMETRIC VORTEX BREAKDOWN OF A SWIRLING JET ENTERING A SUDDEN EXPANSION PIPE"

Physics of Fluids, Vol. 16, No. 9, September 2004, pp. 3495-3498

This Brief Communication investigates the onset and bifurcation structure of vortex breakdown in a laminar sudden expansion flow. Bifurcation diagrams for variable inlet swirl levels are determined by integration of the time dependent, incompressible, axisymmetric, Navier-Stokes equations in a sudden expansion with expansion ratio wavelength equals 2.0 and for moderately large values of the Reynolds number. As in the case of swirling flows in pipes, vortex breakdown is seen to occur associated with the emergence of a stagnation point when the Reynolds number is sufficiently small (Re less than or equal to 125 for wavelength = 2), while for larger values it appears as a fold in the solution space. The standing wave analysis for the stream tube emerging from the inlet orifice rim indicates that the local criticality of the flow is a necessary condition for the appearance of the vortex breakdown. The axisymmetric computations also reveal the unsteadiness of the non-slender solutions above Re greater than or equal to 400.

Reyna, L. G. and Menne, S.

"NUMERICAL PREDICTION OF FLOW IN SLENDER VORTICES"

Computers and Fluids, Vol. 16, No. 1, 1988, pp. 239-256.

We study the slender vortex approximation with emphasis on the high Reynolds number behavior. It is shown that the breakdown of the approximation coincides with the criticality condition as introduced by Benjamin. We study free vortices with and without an adverse pressure gradient for viscous and inviscid flows. Finally, we compare with the experimental results from Faler and Leibovich.

"DESIGN, DEVELOPMENT, AND FLIGHT EVALUATION OF PILOT DISPLAYS AND LONG-TRACK CONTROL FOR WAKE SURFING APPLICATIONS"

AIAA Paper 2018-3562, June 2018, Atlanta, GA.

From April to May 2017, the National Aeronautics and Space Administration Armstrong Flight Research Center completed a series of flights with a trail C-20A airplane surfing in the wake of a Gulfstream III airplane using a commercially available datalink as the primary communication between the two aircraft. The purpose of this test was to characterize the aerodynamic benefits received by the trail airplane flying in the upwash portion of the wake generated from the lead airplane. Lateral and vertical relative position in the wake were automatically controlled through an experimental programmable autopilot on the C-20A airplane. Long-track, the separation distance between the two aircraft, was maintained by test pilots managing throttle position using customized cockpit displays. These displays provided the pilots with throttle cues for maintaining long-track position and situational

awareness of the wake vortex relative to the position of the trail airplane. Flight testing demonstrated the ability of the pilots to use these displays to maintain a safe long-track distance, but found there to be trades between tracking performance and the frequency of throttle motion. The wake awareness display provided the pilots with adequate situational awareness of the wake vortex during the flight experiment. This paper presents a summary of the design, development, and flight evaluation of the pilot displays and long-track control.

Ribeiro, R. S.

"ANALYSIS OF WING WAKE ROLL-UP USING A VORTEX-IN-CELL METHOD"

Ph.D. Thesis, 1992, Stanford University, Palo Alto, CA

A wing producing lift generates a thin vorticity sheet behind it, called a vortex wake. This wake is convected downstream, adjusting its shape to remain force-free, and can interact with other surfaces and wakes as it does so. The determination of wake geometries and effects are of great interest in several aircraft design problems, including analysis of canard-wing interference, rotors and propeller-wing interference. This work applies a vortex-in-cell method to a singularity model for wings and wakes in steady, incompressible flow. Wings are represented by a vortex-lattice model, while wakes are formed by line vortices. The vorticity contained in the singularities is spread onto a rectangular grid, using quadratic splines based on the grid-cell dimensions. Velocities are computed from the vorticity field by an infinite boundary Fast Poisson Solver, which employs fast Sine and Cosine transforms and a boundary convolution scheme. Although the grid boundaries are placed close to the singularities, the solution is consistent with the condition of vanishing perturbations at infinity. Provisions are made to consider portions of the wakes downstream of the grid box. Velocities at points inside the grid are obtained by interpolation. The result is the removal of infinite velocities, as if a finite vortex-core model were introduced. The velocities computed with the vortex-in-cell method are used to relax the wake and to correct the singularity strengths on the wing, in a mixed iterative procedure. Several problems are studied to evaluate the performance of the method: velocity induced by single infinite and semi-infinite vortices, lift of rectangular and swept-back wings, roll-up of single wing wakes and interaction between wings and wakes in various arrangements. Solutions for these problems were compared with results from experiments and other methods. Detailed descriptions for wake geometry and accurate load distributions were obtained, even for cases where wakes intercepted wings directly. The method provides velocity values throughout the grid as part of the solution. The computational time required is controlled by the number of grid cells, not the number of singularities.

Ribeiro, R. S. and Kroo, I.

"VORTEX-IN-CELL ANALYSIS OF WING WAKE ROLL-UP"

J. Aircraft, Vol. 32, No. 5, September-October 1995, pp. 962-96.

A vortex-in-cell (VIC) method was coupled with a wing vortex-lattice model to compute steady-state wake roll up. The vorticity concentrated on the wing and wake vortex segments is distributed to a

Cartesian grid through the application of a spreading function. A sub vortex technique is introduced to refine the wake description without altering the number of wing panels. The velocity field induced by the spread vorticity is computed using an infinite domain fast Poisson solver. Interpolation provides velocities at any point inside the grid. The VIC method is used to compute velocities for a wake relaxation procedure and to correct wing panel circulations. The iterative method developed can be applied to configurations with several wings. The method was tested for various one and two-wing problems and compared with results from experiments and from other theories with very good agreement. Detailed descriptions for wake geometry and accurate load distributions were obtained, even for cases where wakes intercepted wings directly.

Ribera, M.

"HELICOPTER FLIGHT DYNAMICS SIMULATION WITH A TIME-ACCURATE FREE-VORTEX WAKE MODEL"

PhD Thesis, 2007, University of Maryland, College Park, MD.

This dissertation describes the implementation and validation of a coupled rotor-fuselage simulation model with a time-accurate free-vortex wake model capable of capturing the response to maneuvers of arbitrary amplitude. The resulting model has been used to analyze different flight conditions, including both steady and transient maneuvers. The flight dynamics model is based on a system of coupled nonlinear rotor-fuselage differential equations in first-order, state-space form. The rotor model includes flexible blades, with coupled flap-lag-torsion dynamics and swept tips; the rigid body dynamics are modeled with the non-linear Euler equations. The free wake models the rotor flow field by tracking the vortices released at the blade tips. Their behavior is described by the equations of vorticity transport, which is approximated using finite differences, and solved using a time-accurate numerical scheme. The flight dynamics model can be solved as a system of non-linear algebraic trim equations to determine the steady state solution, or integrated in time in response to pilot-applied controls. This study also implements new approaches to reduce the prohibitive computational costs associated with such complex models without losing accuracy. The mathematical model was validated for trim conditions in level flight, turns, climbs and descents. The results obtained correlate well with flight test data, both in level flight as well as turning and climbing and descending flight. The swept tip model was also found to improve the trim predictions, particularly at high speed. The behavior of the rigid body and the rotor blade dynamics were also studied and related to the aerodynamic load distributions obtained with the free wake induced velocities.

Ribner, H. S.

"THE SOUND GENERATED BY INTERACTION OF A SINGLE VORTEX WITH A SHOCK WAVE"

Report No. 61, June 1959, University of Toronto Institute of Aerophysics, Toronto, Canada.

The passage of a columnar vortex 'broadside' through a shock is investigated. The vortex is decomposed (by Fourier transform) into plane sinusoidal shear waves disposed with radial symmetry. The plane sound waves produced by each shear wave-shock interaction, known from previous work,

are recombined in the Fourier integral. The waves possess an envelope that is essentially a growing cylindrical sound wave, partly cut off by the shock. The sound wave is centered at the transmitted (and modified) vortex and the peak pressure attenuates inversely as the square root of the growing radius. The strength varies smoothly around the arc, from compression at one shock intersection to rarefaction at the other shock intersection. Comparison is made with results of a shock-tube investigation and heuristic theory by Hollingsworth and Richards in England.

Ricca, R. L.

"THE EFFECT OF TORSION ON THE MOTION OF A HELICAL VORTEX FILAMENT"

Journal of Fluid Mechanics, Vol. 273, 1994, pp. 241-259.

In this paper we analyze in detail, and for the first time, the role of torsion in the dynamics of twisted vortex filaments. We demonstrate that torsion may influence considerably the motion of helical vortex filaments in an incompressible perfect fluid. The binormal component of the induced velocity, asymptotically responsible for the displacement of the vortex filament in the fluid, is closely analyzed. The study is performed by applying the prescription of Moore and Saffman (1972) to helices of any pitch and a new asymptotic integral formula is derived. We give a rigorous proof that the Kelvin regime and its limit behavior are obtained as a limit form of that integral asymptotic formula. The results are compared with new calculations based on the re-elaboration of Hardin's (1982) approach and with results obtained by Levy and Forsdyke (1928) and Widnall (1972) for helices of small pitch, here also re-elaborated for the purpose.

Ricciardi, T. R., Wolf, W. R. and Bimbato, A. M.

"AN ASSESSMENT OF THE FAST MULTIPOLE METHOD APPLIED TO A VORTEX SHEET ROLL-UP PROBLEM"

AIAA Paper 2016-4173, June 2016, Washington, DC.

Aerodynamic wakes of large aircraft and their induced velocity may cause serious hazards to smaller aircraft, affecting the take-off and landing operations in airports. A simplified but representative model of the problem is the evolution of a vortex sheet in the Trefftz plane. In this work, we employ the discrete vortex method (DVM) accelerated by the fast multipole method (FMM) to simulate this problem. Due to the cost associated with vortex clustering, the reduction in time from $O(N^2)$ to $O(N)$ by the FMM is achieved when N is sufficiently large and a hierarchical multi-level multipole expansion is used. In the current paper, we show a study of the accuracy of the FMM compared to the Biot-Savart law when applied to the Trefftz plane simulation, which is shown to be a very sensitive non-linear problem where accuracy is a critical factor to avoid spurious instabilities. The analysis discusses the effects of time marching method, time step, level of refinement of the FMM, number of particles in the discretization and the balance between near and far-field computational costs. The DVM-FMM algorithm is also employed to solve the temporal evolution in a shear-layer with periodic boundary conditions.

Richard, H. and Raffel, M.

"VISUALIZATION OF VORTICAL STRUCTURES BY DENSITY GRADIENT DETECTION"

Proceedings of PSFVIP-3, March 2001, Maui, Hawaii.

Applications of an advanced schlieren technique, in the following referred to as Background Oriented Schlieren or synthetic schlieren, are presented. Three experimental studies have been carried out to investigate compressible vortices. Beside other things, those vortices play a major role in the blade vortex interaction phenomena, which leads to the typical impulsive noise at helicopters. Therefore, two experiments have been performed to investigate details of the vortex formation from blade tips of two different helicopters in flight: an Eurocopter BK117 and a large US utility helicopter. Simultaneous measurements of the velocity and density fields have then been conducted to characterize the structure of compressible vortices. The background oriented schlieren appears to well complement other optical techniques like shadowgraphy or focussing schlieren methods and yield additional quantitative information. Furthermore, in the case of helicopter aerodynamics, this technique allows the effect of Reynolds number on vortex development from blade tips to be studied in full-scale flight tests more easily than using laser-based techniques.

"APPLICATION OF PARTICLE IMAGE VELOCIMETRY UNDER CRYOGENIC CONDITIONS"

20th International Congress on Instrumentation in Aerospace Simulation Facilities (ICIASF), Aug. 2003, pp. 393-398

Cryogenic investigations of the trailing vortices of large future transport aircrafts have been performed on an aircraft half-model with different wing tip devices. The model has been installed in the cryogenic wind tunnel (KKK) of the German-Dutch wind tunnels (DNW) in Cologne. During the tests, PIV flow field measurements have been performed in addition to conventional force, moment, and pressure distribution measurements. The measurements of the velocity field gave an insight into important aerodynamic effects as, for example, the dependents of vortex strength with changing angles of incidence as well as the differences in the spatial vorticity distribution in the wake. The PIV technique offers special advantages for the investigation of those wakes at very low temperatures, but also yields to special experimental difficulties, which are also described in this article.

Richard, H., Bosbach, J., Henning, A., Raffel, M., Willert, C. and van der Wall, B. G.

"2C AND 3C PIV MEASUREMENTS ON A ROTOR IN HOVER CONDITION"

13th International Symposium on Applications of Laser Techniques to Fluid Mechanics, Paper No. 1122, Lisbon, Portugal, June 2006

To investigate the development of blade tip vortices under different rotor conditions like thrust and rotational speed, both two- and three-component PIV measurements were performed on a 40 percent Mach scaled Bo105 model rotor in hover condition. The vortices were traced from their creation at the

trailing edge of the blade up to half a revolution behind the blade with azimuth steps between 1 to 10 degrees at different spatial resolutions. In addition, a sequence of three-component measurements was performed just after the vortex creation at finer azimuth steps of 0.056 degrees to generate a three-dimensional volumetric data set of the blade tip vortex. The influence of the PIV image analysis parameters on the vortex parameters derived, in particular sampling window size and window overlap, has been investigated.

Richard, H., Raffel, M., Rein, M., Kompenhans, J. and Meier, G. E. A.

"DEMONSTRATION OF THE APPLICABILITY OF A BACKGROUND ORIENTED SCHLIEN (BOS) METHOD"

10th International Symposium on Applications of Laser Techniques in Fluid Mechanics, July 2000, Lisbon, Portugal.

A novel measurement technique based on the refractive index variation in a compressible flow field is presented. This concept is referred to as 'Background Oriented Schlieren' (BOS) method in the following. The differences between BOS and other optical techniques which it can best be compared with, will be discussed. Already the first results illustrate an encouraging prospect for the future applicability of this technique. The BOS method offers the capability of qualitative and quantitative investigations of unsteady density fields in high speed flows, combustion, and full-scale flight tests. The underlying principle is briefly described and an extension to a three-dimensional quantitative technique by using multiple cameras is outlined. The experimental studies which have been carried out to investigate a supersonic jet, a turbulent flame, and the blade tip vortices of a BK117 helicopter in hover flight will be presented.

Richard, H., Van der Wall, B. G., Raffel, M. and Thimm, M.

"APPLICATION OF PIV TECHNIQUES FOR ROTOR BLADE TIP VORTEX CHARACTERIZATION"

New Results in Numerical and Experimental Fluid Mechanics VI, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 96, 2008, pp. 446-453.

To investigate the development of blade tip vortices under different rotor conditions like thrust and rotational speed, both 2C and 3C PIV measurements were performed on a 40% Mach scaled Bo105 model rotor in hover condition. The vortices were traced from the trailing edge of the blade up to half a revolution behind the blade with azimuth steps between 1 to 10 degrees and different spatial resolutions. In addition, a sequence of three-component measurements was performed just after the vortex creation at finer azimuth steps of 0.056 degrees to generate a 3D volumetric data set of the blade tip vortex. The influence of the PIV image analysis parameters on the vortex parameters derived - in particular sampling window size and window overlap -- has been investigated. The measurements presented are part of the HOTIS (HOVer Tip vortex Structure) project.

"DEVELOPMENT OF A TRAILING VORTEX FORMED WITH SPANWISE TIP BLOWING"

2005 ASME Fluids Engineering Division Summer Meeting and Exhibition, FEDSM2005-77130, June 2005, Houston, TX

Trailing vortices were formed with strong core jets and high turbulence levels in a wind tunnel using a NACA 0015 rectangular semi-span wing having a full span aspect ratio of 5 and a chord Reynolds number of 100,000. The jet on the vortex core was generated by air blown from the wing tip through small holes arranged along the periphery of the wing cross-section. Experiments covered a wide range of tip jet blowing rates for a wing incidence of 5 degrees. Measurements of mean velocity, mean vorticity and turbulence kinetic energy were made up to 32 chords downwind using a hot wire probe. At zero wing incidence the flow was observed to have the form of a jet in cross-flow with counter-rotating streamwise vortices of zero net circulation and a very high turbulence level. With the wing at incidence, the tip vortex envelopes the jet and as it develops its diameter grows and the jet velocity and circumferential velocity decline sharply. Further downwind the vortex formed with tip jets evolves into an axisymmetric form like a natural vortex but with a diameter up to 5 times larger. The turbulence intensities measured on the core without blowing were approximately 2.5% of the free stream velocity while with blowing they were approximately 15% in the near wake and approximately 9% in the far wake.

"A SMOKE GENERATOR SYSTEM FOR AERODYNAMIC FLIGHT RESEARCH"

NASA-TM-4137, January 1989, NASA Dryden Flight Research Center, Edwards, CA

A smoke generator system was developed for in-flight vortex flow studies on the F-18 high alpha research vehicle (HARV). The development process included conceptual design, a survey of existing systems, component testing, detailed design, fabrication, and functional flight testing. Housed in the forebody of the aircraft, the final system consists of multiple pyrotechnic smoke cartridges which can be fired simultaneously or in sequence. The smoke produced is ducted to desired locations on the aircraft surface. The smoke generator system has been used successfully to identify vortex core and core breakdown locations as functions of flight condition. Although developed for a specific vehicle, this concept may be useful for other aerodynamic flight research which requires the visualization of local flows.

"EXPECTED CAPACITY GAINS AND REDUCTION IN DELAYS FROM A WAKE VORTEX ADVISORY SYSTEM USING A PARAMETRIC MODEL OF THE WAKE VORTEX BEHAVIOR AS A FUNCTION OF ACTUAL WEATHER MEASUREMENTS"

Second Workshop WakeNet2-Europe, 'Capacity Gains as Function of Weather and Weather Prediction Capabilities', Langen, November 2004.

NASA Langley Research Center is developing a Concept of Operations for a Wake Vortex Advisory System (WakeVAS). It is known that current wake-safe aircraft spacing is conservative based on worst case conditions. Wake behavior is influenced by an airport's local meteorological environment and under favorable conditions for wake demise or advection the current aircraft spacing requirements could be reduced. To create a model of wake behavior, the Aircraft Vortex Spacing System (AVOSS) wake prediction code demonstrated at Dallas in 2000 was modified. The AVOSS wake prediction algorithm requires as input vertical profiles of wind, temperature, and turbulence. These weather data profiles were collected by a dedicated instrumentation suite at the AVOSS deployment and during a previous field deployment in Memphis. Automated Surface Observation System (ASOS) data, reported at one-minute intervals, is available at most major airports in the U.S. Wind and temperature vertical profiles can be approximated with meteorological theory from this surface data, but turbulence, measured statistically as Eddy Dissipation Rate (EDR), requires high frequency (approximately 10 Hz) wind measurements and cannot be inferred directly from one-minute surface data. A multi-variate statistical analysis was performed to establish correlation between the ASOS inputs and the AVOSS measured EDR. The output from the wake-prediction model includes time-varying (typical 30-minute resolution) reduced aircraft spacing tables. This reduced spacing data was used, along with data derived from simulation using recorded aircraft trajectories and an analysis of the traffic mix at 12 selected U.S. airports, to quantify the expected airport capacity gains. A queuing network model of the U.S. National Airspace System (NAS) was used to obtain an estimate of the delay reductions at individual airports, the overall potential NAS wide delay reduction and consequent benefit to airline operators and passengers that would be expected due to the increased capacity. This presentation describes the development of the parametric model of wake behavior, use of the model to generate reduced aircraft separations and the use of this data in the analysis of the expected capacity gains and delay reductions.

"AN INITIAL STUDY OF THE SENSITIVITY OF AIRCRAFT VORTEX SPACING SYSTEM (AVOSS) SPACING SENSITIVITY TO WEATHER AND CONFIGURATION INPUT PARAMETERS"

NASA TM-2000-209849, January 2000, NASA Langley Research Center, Hampton, VA

A study has been performed on a computer code modeling an aircraft wake vortex spacing system during final approach. This code represents an initial engineering model of a system to calculate reduced approach separation criteria needed to increase airport productivity. This report evaluates model sensitivity toward various weather conditions (crosswind, crosswind variance, turbulent kinetic energy, and thermal gradient), code configurations (approach corridor option, and wake demise

definition), and post-processing techniques (rounding of provided spacing values, and controller time variance).

"AIRBORNE INSECTS AS POTENTIAL SOURCES OF ACOUSTIC REFLECTIVITY"

Journal of Atmospheric and Oceanic Technology, Vol. 14, June 1997, pp. 538-542.

Laboratory measurements of the acoustic backscattering cross sections of a variety of insects at 3.4 kHz are reported. The authors argue from these data, and from what is known (from radar studies) about insect concentrations in the lower atmosphere, that acoustic returns from insects may seriously contaminate sodar data. They suggest that this possibility should be carefully considered when interpreting backscatter coefficient data acquired in acoustic sounding experiments.

"STUDY OF MODIFICATION OF ROTOR TIP VORTEX BY AERODYNAMIC MEANS"

RASA-70-02, January 1970, Rochester Applied Science Associates, Rochester, NY

The analytical investigation shows that it should be possible to significantly alter the characteristics of the trailing tip vortex for all flight conditions in a beneficial manner by injecting an airstream directly into the forming tip vortex. Analytical expressions were developed for the initial and final states of the vortex to evaluate the effects of mass flow injection on the vortex strength, swirl velocity distribution, vortex core pressure, vortex core size, and the induced drag on the blade.

Rinehart, S. A.

"EFFECTS OF MODIFYING A ROTOR TIP VORTEX BY INJECTION ON DOWNWASH VELOCITIES, NOISE, AND AIRLOADS"

J. American Helicopter Society, Vol. 16, No. 4, October 1971, pp. 48-5.

Numerous research efforts have been conducted by different investigators to alter the characteristics of the tip vortex generated by a helicopter blade to alleviate the blade-vortex interaction problem as well as the noise problem associated with impulsive loading. The present analytical investigation shows that it should be possible to significantly alter the characteristics of the trailing tip vortex for almost all flight conditions in a beneficial manner by injecting an airstream directly into the forming tip vortex. Analytical expressions were developed for the initial and final status of the vortex to evaluate the effects of mass flow injection on the vortex strength, swirl velocity distribution, vortex core pressure, and vortex core size.

Rinehart, S. A., Balcerak, J. C. and White, Jr., R. P.

"AN EXPERIMENTAL STUDY OF TIP VORTEX MODIFICATIONS BY MASS FLOW INJECTION"

RASA-71-01, January 1971, Rochester Applied Science Assoc., Rochester, NY

An experimental program was conducted to investigate the modifications of a tip vortex which could be obtained by injecting the core of a tip vortex with a stream of air. Wind tunnel tests of an airfoil model were conducted. The results obtained from flow-visualization studies, balance data and vortex-meter measurements show how the strength of the tip vortex can be reduced significantly by the injection of a linear mass flow of air into the core of the tip vortex.

"THE DEVELOPMENT OF A BOUNDARY LAYER TURBULENCE DATABASE FOR WAKE VORTEX APPLICATIONS"

AIAA Paper No. 2007-287, Reno, NV, January 2007

This paper describes results from extensive validation of wake-vortex environmental simulations at the Dallas Fort-Worth International Airport (DFW) against observations taken using the Aircraft Vortex Observing and Spacing System (AVOSS) during the 17-20 September 1997 field campaign. The effect of horizontal and vertical grid spacing, initialization time, and formulation of characteristic mixing length scales within the newly developed Terminal-Area PBL Prediction System-2 (TAPPS-2) are detailed. Results from the validation simulations were then used to develop an appropriate TAPPS-2 modeling configuration for a limited terminal-area mesoscale climatology at St. Louis-Lambert International Airport for the July-December 2004 period. Preliminary results, with emphasis on statistical quantities and analysis are discussed for wake-vortex forecasting applications from a mesoscale model.

"STUDIES ON VORTEX FLAPS HAVING DIFFERENT HINGE-LINE POSITIONS"

Journal of Aircraft, Vol. 38, No. 2, March-April 2001, pp. 396-398,

In this note the effect of flap hinge-line positions over the performance of the leading-edge vortex flaps has been discussed. Differences of the vortex flap hinge-line position affect the performance of the vortex flap. The best L/D ratio is attained when the delta wing has vortex flaps with a relatively small spanwise length. The formation of leading-edge separation vortex over the wing is suppressed at relatively low angle of attack, even when the vortex flap with only a small spanwise length is deflected.

Rinoie, K. and Shirotake, M.

"VORTEX BEHAVIORS OF ROLLED SUPERSONIC TRANSPORT CONFIGURATION WITH LEADING-EDGE FLAPS"

Journal of Aircraft, Vol. 43, No. 6, November-December 2006, pp. 1904-1913.

Wind tunnel measurements were done to investigate the effect of leading-edge flaps on the rolling moment characteristics of the cranked arrow wing for the supersonic transport. Static rolling moment measurements, flow visualization studies, and crossflow velocity measurements by a particle image velocimetry were made at $Re = 62,000$. Static rolling moment measurements confirmed linear restoring moment at angles of attack less than 16 deg for the models both with and without flap deflection. When the outboard leading-edge flap is deflected 12 deg, rolling moment hysteresis is observed at the roll angle of about 20 deg and angle of attack about 20 deg. The experimental results indicate that the hysteresis is caused by different vortex breakdown behaviors on the inboard wing when the wing is rotated in the clockwise and counterclockwise directions.

"DIRECT NUMERICAL SIMULATION OF TRAILING VORTICES IN HOMOGENEOUS TURBULENCE"

AIAA Paper No. 1996-0802, Reno, NV, January 1996

Among the various meteorological parameters acting on the lifespan of the wake vortices, the atmospheric turbulence is one of major importance. Direct numerical simulations are one of the best tools to study turbulence even if the Reynolds number used in the computations is far below the Reynolds number of the phenomenon. Respecting as much as possible the scales of the real flow field, namely the integral length scale of atmospheric turbulence and the r.m.s. velocity, phenomena explaining the decay and the lifetime of trailing vortices are studied. It is shown in this paper that the interaction between the vortices and the ambient turbulence creates ring of vorticity through a tridimensional mechanism. The first effect of these rings is to generate axial velocities as great as the velocities induced by the vortices. Furthermore, the vortices are curved and the vortex pair could become unstable.

Risso, F., Corjon, A. and Stoessel, A.

"DIRECT NUMERICAL SIMULATIONS OF WAKE VORTICES IN INTENSE HOMOGENEOUS TURBULENCE"

AIAA Journal, Vol. 35, No. 6, June 1997, pp. 1030-1040

Three-dimensional direct numerical simulations of a vortex pair placed in an homogeneous turbulent field are presented. The phenomenon of interaction between the vortices and the turbulence is analyzed in detail from two simulations calculated on a 1353 nodes mesh grid (one case with axial core velocity, the other without). The results show that the role of large and small turbulent eddies can be separated into two independent mechanisms. The large structures are stretched by velocity gradients induced by the vortex pair. That leads to the formation of both tubes of vorticity spinning azimuthally around each vortex and associated axial velocity sheets. These structures cause a strong decrease of the maximal velocity and the curvature of the vortices. These deformations induced by the turbulence initiate an antisymmetric long-wave instability of the pair, which will probably lead to the collapse of the vortices. Concurrently, the small structures can enhance the diffusion of the vorticity out of the

vortex core. From this analysis and scale considerations, the correct form for a model of decay of the vortices is derived. On the other hand, nine simulations on a 813 nodes mesh grid are used to determine the sensibility of the results to the random turbulent initial conditions.

Rist, U.

"VISUALIZATION AND TRACKING OF VORTICES AND SHEAR LAYERS IN THE LATE STAGES OF BOUNDARY-LAYER LAMINAR-TURBULENT TRANSITION"

AIAA Paper 2012-0084, January 2012, Nashville, TN.

The purpose of this contribution is to present some examples for the use of recent data processing and visualization techniques for the study of unsteady vortical flows. The basic idea is to extract vortices, shear layers and data defining their current state from DNS data and to track their evolution in time. Some apparent signatures which help to get additional insight into the flow dynamics have been identified. They demonstrate the promising features of the technique, albeit further studies are necessary to complete this work.

"PARTICLE SIMULATION OF SWIRLING FLOWS"

Flow, Turbulence and Combustion, Vol. 72, 2004, pp. 69-90

The vortex particle method has been applied to the axisymmetric swirling flow of a viscous fluid. The formulation used yields two transport equations which have been solved within the Lagrangian framework of particle method. The diffusion operator for both equations has been approximated by means of a Particle Strength Exchange scheme. Applications to the cases of one isolated vortex ring and two co-rotating vortex rings illustrate the interest of this new method. Special attention has been devoted to the vorticity production resulting from the interaction between the azimuthal components of vorticity and velocity. The generation of small eddies at the boundary of the vortex ring cross-section has been particularly investigated.

Rizzetta, D. P.

"NUMERICAL SIMULATION OF VORTEX INDUCED OBLIQUE SHOCK-WAVE DISTORTION"

AIAA Paper No. 96-0039, January 1996, Reno, NV.

Steady high Reynolds number supersonic flowfields were generated numerically to simulate the interaction of a streamwise wing-tip vortex with an oblique shock wave which forms above a wing surface. Solutions were obtained by time integration of the three-dimensional compressible mass-averaged turbulent Navier-Stokes and Euler equations, corresponding to both vortices and shock waves of varying strength. Effects of turbulence were accounted for by a two-equation closure model which included low-Reynolds number terms and a compressibility correction. Details of the computations are

summarized, and grid resolution and damping coefficient studies are provided to establish accuracy of the numerical results. Features of the flowfields, including vortex breakdown, are discussed, and comparison is made with experimental data in terms of shadowgraph images, static pressure distributions on the wing surface, and the trajectory of the vortex core.

Rizzetta, D. P.

"NUMERICAL INVESTIGATION OF SUPERSONIC WING-TIP VORTICES"

AIAA Paper No. 1995-2282, San Diego, CA, June 1995

Steady high-Reynolds-number flowfields about a finite-span rectangular wing mounted upright in a supersonic stream were generated numerically to investigate formation of the tip vortex. Solutions were obtained by integration of the time-dependent three-dimensional compressible Euler and mass-averaged thin-layer laminar and turbulent Navier-Stokes equations. In the turbulent case, a two-equation (k-epsilon) closure model was employed, which included low-Reynolds-number terms and a compressibility correction. Details of the computations are summarized, and a grid resolution study is provided to assess the accuracy of the numerical results. Comparison is made between the solutions of the respective governing equations, as well as with experimental data in terms of the pressure and Mach number component distributions through the center of the vortex core.

Rizzetta, D. P.

"NUMERICAL SIMULATION OF OBLIQUE SHOCK-WAVE/VORTEX INTERACTION"

AIAA Journal, Vol. 33, No. 8, August 1995, pp. 1441-1446

High Reynolds number supersonic flowfields were generated numerically by integration of the time-dependent three-dimensional compressible Euler and mass-averaged Navier-Stokes equations to simulate the interaction of a streamwise vortex with an oblique shock wave. The vortex develops at the tip of a vortex-generating fin which is suspended from the ceiling of a wind tunnel. Downstream, an oblique shock wave is produced by a wing surface which spans the width of the wind tunnel and has a two-dimensional sharp leading-edge wedge as its airfoil section. Grid resolution studies are provided to assess accuracy of the solutions. Resultant features of the numerical flowfields are discussed, and comparison is made with experimental data in terms of static pressure distributions on the wing surface.

Rizzetta, D. P.

"NUMERICAL SIMULATION OF VORTEX-INDUCED OBLIQUE SHOCK-WAVE DISTORTION"

AIAA Journal, Vol. 35, No. 1, 1997, pp. 209-211

The interaction between a streamwise wing-tip vortex and an oblique shock wave is examined using computational fluid dynamics. Solutions to the compressible three-dimensional mass-averaged

turbulent Navier-Stokes equations were solved with a two-equation turbulence closure model. For weaker interactions than those presented here, which did not result in vortex breakdown, calculations agreed reasonably well with the data. When shock induced vortex breakdown occurred, the numerically simulated interaction was not as strong as the experimental counterpart. This deficiency is attributed to the inability of the turbulent Navier-Stokes equations to accurately simulate formation of the tip vortex. In particular, it has been shown that the turbulence model could not reproduce the experimentally measured wake like axial Mach number profile, which is considered to be crucial to vortex breakdown in this case. Numerical reproduction of strong tip-vortex/shock-wave interaction thus appears to be limited by lack of adequate turbulence modeling for such flows at high Reynolds numbers.

Rizzetta, D. P.

"NUMERICAL INVESTIGATION OF SUPERSONIC WING-TIP VORTICES"

AIAA Journal, Vol. 34, No. 6, June 1996, pp.1203-1208.

Steady high-Reynolds-number flowfields about a finite-span rectangular wing mounted upright in a supersonic stream were generated numerically in order to investigate formation of the tip vortex. Solutions were obtained by integration of the time-dependent three-dimensional compressible Euler and thin-layer laminar and mass-averaged thin-layer laminar and turbulent Navier-Stokes equations. In the turbulent case, a two-equation (k -epsilon) closure model was employed, which included low-Reynolds-number terms and a compressibility correction. Details of the computations are summarized, and a grid resolution study is provided to assess the accuracy of the numerical results. Comparisons are made between solutions of the various governing equations, as well as with experimental data in terms of the pressure and Mach-number component distributions in the vortex core.

Robasky, F. M. and Clark, D. A.

"WIND FORECAST ALGORITHM FOR WAKE MITIGATION FOR DEPARTURES (WTMD): BASELINE ALGORITHM DESCRIPTION AND PERFORMANCE SUMMARY"

Report 43PM Wx-0105, July 2008, MIT Lincoln Lab., Lexington, MA

Wake Turbulence Mitigation for Departures (WTMD) is a developmental FAA system to safely reduce wake-related departure wait times for airports with closely spaced parallel runways. It will apply to aircraft following departures of Heavy Jets or B757s on the adjacent runway if a crosswind exists sufficient to prevent transport of a wake from the leading wake-generating aircraft into the adjacent runway departure's path. A crucial component of this system is a wind forecast algorithm (WFA) developed at MIT Lincoln Laboratory, to determine when such winds will persist for a sufficient time period to safely implement the procedure. This document serves two purposes: 1) to describe the operation and logic of the WFA in detail, down to the level of its constituent functions, and 2) to characterize WFA performance and accuracy, largely based on special verification data gathered at St. Louis Lambert International Airport and Houston George Bush Intercontinental Airport.

Robasky, F. M. and Clark, D. A.

"A WIND FORECAST ALGORITHM TO SUPPORT WAKE TURBULENCE MITIGATION FOR DEPARTURES (WTMD)"

88th AMS Annual Meeting, New Orleans, LA, January 2008

A conceptually simple, reliable, high-update model of future runway-specific crosswinds has been developed to provide an indication of anticipated wind conditions favorable for WTMD procedures. It is expected that the use of these reduced aircraft separation standards will provide a substantial reduction in wake vortex related delay. The formal requirements of the Wind Forecast Algorithm (WFA) are to be specified in early 2008, for subsequent certification and implementation. This baseline WFA, and the experience gained in its development, evaluation, and implementation will also serve as a platform for an approach to mitigating wake vortex related spacing delays for the arrival portion of the overall problem. This is expected to be more challenging, as it involves a domain of concern that is spatially much larger and temporally much longer, due to the need to safely and efficiently manage aircraft approaches to the runways.

Roberts, C. L.

"FLIGHT TEST ANALYSIS OF THE FORCES AND MOMENTS IMPARTED ON A B737-100 AIRPLANE DURING WAKE VORTEX ENCOUNTERS"

M.S. Thesis, March 1999, Howard University, Washington, DC

Aircraft travel has become a major form of transportation. Several of our major airports are operating near their capacity limit, increasing congestion and delays for travelers. As a result, the National Aeronautics and Space Administration (NASA) has been working in conjunction with the Federal Aviation Administration (FAA), airline operators, and the airline industry to increase airport capacity without sacrificing public safety. One solution to the problem is to increase the number of airports and build new runways; yet, this solution is becoming increasingly difficult due to limited space. A better solution is to increase the production per runway. This solution increases the possibility that one aircraft will encounter the trailing wake of another aircraft. Hazardous wake vortex encounters occur when an aircraft encounters the wake produced by a heavier aircraft. This heavy-load aircraft produces high-intensity wake turbulence that redistributes the aerodynamic loads of trailing smaller aircraft. This situation is particularly hazardous for smaller aircraft during takeoffs and landings. To gain a better understanding of the wake-vortex/aircraft encounter phenomena, NASA Langley Research Center conducted a series of flight tests from 1995 through 1997. These tests were designed to gather data for the development of a wake encounter and wake measurement data set with the accompanying atmospheric state information. This data set is being compiled into a database that can be used by wake vortex researchers to compare with experimental and computational results. The purpose of this research is to derive and implement a procedure for calculating the wake-vortex/aircraft interaction portion of that database by using the data recorded during those flight tests. There were three objectives to this research. Initially, the wake-induced forces and moments from each flight were

analyzed based on varying flap deflection angles. The flap setting alternated between 15 and 30 degrees while the separation distance remained constant. This examination was performed to determine if increases in flap deflection would increase or decrease the effects of the wake-induced forces and moments. Next, the wake-induced forces and moments from each flight were analyzed based on separation distances of 1-3 nautical miles. In this comparison, flap deflection was held constant at 30 degrees.

Roberts, C. L., Vicroy, D. D. and Smith, S. T.

"FLIGHT TEST ANALYSIS OF THE FORCES AND MOMENTS IMPARTED ON A B737-100 AIRCRAFT DURING WAKE VORTEX ENCOUNTERS"

AIAA Paper No. 2000-3980, Denver, CO, August 2000

Several of our major airports are operating at or near their capacity limit, increasing congestion and delays for travelers. As a result, the National Aeronautics and Space Administration (NASA) has been working in conjunction with the Federal Aviation Administration (FAA), airline operators, and the airline industry to increase airport capacity and safety. As more and more airplanes are placed into the terminal area the probability of encountering wake turbulence is increased. The NASA Langley Research Center conducted a series of flight tests from 1995 through 1997 to develop a wake encounter and wake-measurement data set with the accompanying atmospheric state information. The purpose of this research is to use the data from those flights to compute the wake-induced forces and moments exerted on the aircraft. The calculated forces and moments will then be compiled into a database that can be used by wake vortex researchers to compare with experimental and computational results.

Roberts, L.

"ON WAKE VORTEX ALLEVIATION"

The Future of Aeronautics, Kansas Univ., 1974, pp. 139-167

Research within NASA relating to the nature of lift-induced vortex wakes behind large aircraft and the means whereby the hazard they represent to smaller aircraft can be alleviated is reviewed. The research, carried out in ground-based facilities and in flight shows that more rapid dispersion of the wake can be affected by several means and that the modification of span-loading by appropriate flap deflection holds promise of early practical application.

Roberts, T. W. and Murman, E. M.

"A COMPUTATIONAL METHOD FOR HELICOPTER VORTEX WAKES"

AIAA Paper No. 1984-1554, Los Angeles, CA, June 1984

A method for calculating the wake geometry and blade loads for a hovering helicopter rotor is presented. The approach incorporates a simplified free wake model of the rotor in a finite difference calculation of the flow field. Calculations showing the effect of vortex core size and the number of vortex filaments representing the wake are presented.

Robins, R. E. and Delisi, D. D.

"MODELING CROSSWIND SHEAR EFFECTS IN NASA'S AVOSS PREDICTION ALGORITHM"

AIAA Paper No. 2006-1076, Reno, NV, January 2006.

A method for including crosswind shear effects in APA, NASA's trailing vortex prediction algorithm, is described. The method is based on an approximation to the evolution equation for axial vorticity. Results from a new model based on the method are compared with field data for two cases from the Memphis vortex-observation field experiment run in August 1995 by NASA, using a continuous wave lidar built by MIT's Lincoln Laboratory. The model is run in predictive and diagnostic mode to improve trajectory predictions, measurements of the crosswind profile, and estimates of circulation decay.

Robins, R. E. and Delisi, D. P.

"3-D NUMERICAL SIMULATIONS OF TRAILING VORTEX EVOLUTION"

AIAA Paper No. 2006-1079, Reno, NV, January 2006.

A new method for solving the 3-D Navier-Stokes equations is described. The key feature of the method is a form of the eddy viscosity, developed by F. Holzapfel, that goes to zero in regions of intense rotation such as the core of a trailing vortex. The method permits the specification of vertically varying ambient current (or wind) and stratification, and uniform ambient turbulence. Comparisons between model results and observations are shown for laboratory-scale and full-scale trailing vortex flows.

Robins, R. E. and Delisi, D. P.

"MODELING OF ATMOSPHERIC EFFECTS ON WAKE VORTICES"

9th Conf. on Aviation, Range, and Aerospace Meteorology, Paper 7.11, AMS, Orlando, FL, September 2000

When instrument flight rules (IFR) are required due to poor visibility, aircraft are required to remain a minimum distance behind the preceding aircraft, with the result that airport capacity can be adversely affected. In certain atmospheric conditions (e.g., strong cross winds), this minimum distance is greater than it needs to be for safe operations. If it could reliably be determined when minimum following distances can be reduced, then airport capacity during IFR could be increased. We have developed an approach to modeling the evolution of aircraft wake vortices which can be used to predict the length of time that wake vortices will remain a hazard to following aircraft. In this approach, atmospheric

conditions are represented by vertical profiles of potential temperature, cross wind, and turbulence. Either eddy dissipation rate (EDR) or turbulence kinetic energy (TKE) can be used to characterize the turbulence. The wake vortices are characterized by their initial position, lateral separation, and initial descent speed. The model has been used by the NASA Langley Research Center as the predictor component in a prototype system (called AVOSS for Aircraft Vortex Spacing System) that could be used by air traffic control to determine when it is acceptable to reduce aircraft spacing. In this paper, we describe our modeling approach and show examples of how various atmospheric conditions can be expected to affect the evolution of aircraft wake vortices.

"NWRA AVOSS WAKE VORTEX PREDICTION ALGORITHM VERSION 3.1.1"

NASA/CR-2002-211746, June 2002, Northwest Research Associates, Bellevue, WA.

This report provides a detailed description of the wake vortex prediction algorithm used in the Demonstration Version of NASA's Aircraft Vortex Spacing System (AVOSS). The report includes all equations used in the algorithm, an explanation of how to run the algorithm, and a discussion of how the source code for the algorithm is organized. Several appendices contain important supplementary information, including suggestions for enhancing the algorithm and results from test cases.

Robins, R. E. and Delisi, D. P.

"POTENTIAL HAZARD OF AIRCRAFT WAKE VORTICES IN GROUND EFFECT WITH CROSSWIND"

J. Aircraft, Vol. 30, No. 2, Mar.-Apr. 1993, pp. 201-206.

Aircraft wake vortices, evolving close to the ground in a crosswind, are a potential hazard to aircraft landing or taking off on the same or parallel runways. The objective of this work has been to study, by means of numerical simulation, the effect of aerodynamic and environmental conditions on the generation and transport of these vortices. The approach has been to use a computer code which solves the two-dimensional, time-dependent, incompressible Navier-Stokes equations expressed in stream function-vorticity form, to study wake vortices in ground effect with crosswind. The code permits the specification of arbitrary atmospheric stability and wind profiles. A mixed no-slip/free-slip lower boundary condition has been invoked to model the interaction of the vortices with the ground. Comparisons of code output with laboratory and field data have been used to validate the code. Simulation results have shown that, even after evolution times and cross-runway transport distances on the order of 3 min and 500 m, vortices generated by large aircraft close to the ground in a crosswind can carry sufficient average circulation to be a potential hazard to smaller aircraft. Additional full-scale data need to be acquired and additional numerical comparisons need to be performed to assess the significance of these new results.

Robins, R. E. and Delisi, D. P.

"3-D CALCULATIONS SHOWING THE EFFECTS OF STRATIFICATION ON THE EVOLUTION OF TRAILING VORTICES"

In *Computation of Three-Dimensional Complex Flows*, Notes on Numerical Fluid Mechanics, Vol. 53, Eds. Deville et al., Vieweg, Braunschweig, 1996

We have computed numerical solutions to the 3-D Navier-Stokes equations for a stratified, incompressible fluid. Our results show that stratification significantly modifies the phenomena that occur during the vertical migration and linking instability of trailing vortices. In particular, we show that stratification accelerates the development of the linking instability and suppresses the vertical migration of the trailing vortices.

Robins, R. E. and Delisi, D. P.

"NUMERICAL SIMULATIONS OF THREE-DIMENSIONAL TRAILING VORTEX EVOLUTION"

AIAA Journal, Vol. 35, No. 9, September 1997, pp. 1552-1555.

We have computed solutions that depict the evolution of trailing vortices, from initially having their axes slightly perturbed from parallel, through the early stages of perturbation growth, to the occurrence of linking, followed by the formation and migration of rings. Our results agree with the findings of Crow, the most significant of which is that the wavelength of maximum perturbation growth for vortices undergoing linking instability is initially about 8.6 times the initial distance between the parallel vortices. In addition, our results extend Crow's analysis by showing that linking occurs sooner for vortices with tighter cores, the maximum growth wavelength decreases as the instability evolves, and the angle of growth of the maximum perturbation evolves from around 48 degrees predicted by Crow to near 65 degrees at the time of linking. Finally, results for vortices composed of a superposition of components having different wavelengths show good agreement with laboratory results.

Robins, R. E. and Delisi, D. P.

"EFFECTS OF STRATIFICATION ON 3-D TRAILING VORTEX EVOLUTION"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 185-201

Two studies are presented. First, the effects of stratification on Crow instability are examined numerically. Results from calculations for Froude number, F , equal to 2, 4, and 8, are shown at non-dimensional times of 4, 6, 8, and 10. Stratification is seen to accelerate the onset of linking due to Crow instability and to suppress the downward migration of the vortices. It is also seen that for low stratification, such that $F > \text{about } 8$, Crow instability results in the formation of downward propagating vortex rings. For higher stratification, such that $F < \text{about } 4$, the ring formation is suppressed. In a second study, laboratory and numerical results, in good agreement, show the occurrence of a small-scale instability for strong stratification, such that $F < \text{about } 2$. These results may be relevant to airport

operations because of the possibility that stratification effects and small-scale instabilities may result in trailing vortices remaining near the flight path of following aircraft.

Robins, R. E. and Delisi, D. P.

"NUMERICAL SIMULATION OF THREE-DIMENSIONAL TRAILING VORTEX EVOLUTION IN STRATIFIED FLUID"

AIAA Journal, Vol. 36, No. 6, June 1998, pp. 981-985

Numerical solutions to the Navier-Stokes equations that depict the evolution of a trailing vortex pair descending in stratified, incompressible fluid are presented. Both three-dimensional and two-dimensional results are shown for the Froude numbers 1, 2, 4, and 8 and infinity. For three and two dimensions, the results indicate that stratification, through generation of countersign vorticity, causes the separation between the vortices to decrease and, through buoyancy forces, suppresses the vertical migration of the vortices. In three dimensions, Crow instability causes the vortices eventually to link and to form rings when the Froude number is greater than or equal to 4, and the rate at which the linking and ring formation occur is greater for higher stratification (lower Froude number). The formation of rings is suppressed, however, for stratification so high that the Froude number is less than or equal to 2.

Robins, R. E. and Delisi, D. P.

"NUMERICAL STUDY OF VERTICAL SHEAR AND STRATIFICATION EFFECTS ON THE EVOLUTION OF A VORTEX PAIR"

AIAA Journal, Vol. 28, No. 4, April 1990, pp. 661-669

The objective of this study is to investigate with a numerical model how coexisting vertical shear and stratification affect the evolution of a vortex pair. Our results show that the Richardson number (the ratio of stratification forces to shear forces) is an important parameter in the evolution. When the Richardson number is large, the vortex pair evolves symmetrically, the left and right vortex decaying equally, or nearly equally, rapidly. In this case, the effect of the shear is small, and stratification dominates the evolution. When the Richardson number is sufficiently small, however, the evolution is dramatically different. Under these conditions, the vortices evolve asymmetrically, and the vortex with rotational sense opposite to that of the mean shear decays while the vortex with the same rotational sense as the mean shear survives. This 'solitary vortex' then decays slowly with time. The transition from solitary to nonsolitary vortex evolution occurs over Richardson numbers between 0.5 and 4 for the Froude number range 0.5 to 4.0.

Robins, R. E. and Delisi, D. P.

"FURTHER DEVELOPMENT OF A WAKE VORTEX PREDICTOR ALGORITHM AND COMPARISONS TO DATA"

AIAA Paper No. 1999-0757, Reno, NV, January 1999.

Recent enhancements have been made to a fast (less than 0.1 sec per case on a state-of-the-art workstation) algorithm that predicts wake vortex transport and decay. The turbulence decay term has been improved, and turbulent kinetic energy (TKE) profiles are now used instead of constant TKE values to represent the ambient turbulence. A database approach has been adopted to quantify comparisons between algorithm predictions and measurements of wake vortex transport and decay. The use of databases to optimize the constant factor, k , in the term governing the effect of turbulence on vortex decay is reported, with the result that k appears to depend on the intensity of ambient turbulence. Several comparisons of algorithm predictions with collections of data are presented, and agreement between predictions and measurements is shown to be reasonably good. Measured circulation decay is shown to be consistent between data sets collected at Memphis and Dallas-Fort Worth, and linear (with time) bounds on the decay are estimated.

Robins, R. E. and Delisi, D. P.

"NUMERICAL SIMULATIONS OF VORTEX EVOLUTION"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

If it were possible to determine when aircraft separation standards imposed by the hazard due to trailing vortices could safely be reduced, then airport capacity could be increased. An important step in being able to realize this possibility is the development of reliable methods for predicting the effect of realistic atmospheric conditions on the behavior of trailing vortices. In this talk, we describe two prediction methods, one based on solving the equations describing fluid motion and the other based on solving equations derived from a heuristic analysis of vortex evolution. Predictions from both methods are compared with full-scale observations and the comparisons are shown to be favorable. We conclude that useful predictions of trailing vortex evolution are feasible and may be useful in the effort to increase airport capacity.

Robins, R. E., and Delisi, D. P.

"EFFECT OF GROUND INTERACTION ON TRAILING VORTEX EVOLUTION"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000.

Lidar observations of position and circulation of trailing vortices generated within 50m of the ground, from NASA deployments at MEM, DFW and JFK airports, are studied to determine the effect of ground interaction on vortex evolution. The data suggest that circulation decay in ground effect is independent of ambient conditions and is approximately bounded by $G/G_0 = 1 - T/8$, where G is circulation, G_0 is initial circulation and T is time normalized by b/V , where b is initial vortex separation and V is initial vortex descent speed. Predictions by engineering models of vortex evolution in ground effect are compared with observations. The models are evaluated by quantifying comparisons of vertical position and circulation decay for over one hundred cases.

Robins, R. E., and Delisi, D. P.

"WAKE VORTEX ALGORITHM SCORING RESULTS"

NASA/CR-2002-211745, June 2002, Northwest Research Associates, Bellevue, WA.

This report compares the performance of two models of trailing vortex evolution for which interaction with the ground is not a significant factor. One model uses eddy dissipation rate (EDR) and the other uses the kinetic energy of turbulence fluctuations (TKE) to represent the effect of turbulence. In other respects, the models are nearly identical. The models are evaluated by comparing their predictions of circulation decay, vertical descent, and lateral transport to observations for over four hundred cases from Memphis and Dallas/Fort Worth International Airports. These observations were obtained during deployments in support of NASA's Aircraft Vortex Spacing System (AVOSS). The results of the comparisons show that the EDR model usually performs slightly better than the TKE model.

Robins, R. E., Delisi, D. P. and Greene, G. C.

"DEVELOPMENT AND VALIDATION OF A WAKE VORTEX PREDICTOR ALGORITHM"

AIAA Paper No. 1998-0665, Reno, NV, January 1998.

The algorithm described herein predicts the trajectories and circulation decay of aircraft trailing vortices. We first present the methodology used by the algorithm to simulate trailing vortex behavior, including (i) the descent of vortices through a realistic atmosphere defined by stratification, turbulence, and cross wind profiles, and (ii) the interaction of the vortices with the ground. Both the increase in separation between the vortices caused by their approaching the ground and the generation of secondary vorticity due to their interaction with the ground are modeled by the algorithm. We then compare algorithm results with field data and discuss the algorithm's validity and sensitivity. We show that the algorithm performs reasonably well for vortices out of ground effect, and produces promising results for vortices in ground effect. Since it runs in less than one-tenth of a second on a state-of-the-art workstation, the algorithm is suitable for use in a real-time aircraft vortex separation system.

Robins, R.E., Delisi, D. P. and Greene, G. C.

"ALGORITHM FOR PREDICTION OF TRAILING VORTEX EVOLUTION"

Journal of Aircraft, Vol. 38, No. 5, September-October 2001, pp. 911-917.

We describe an algorithm that predicts the trajectories and circulation decay of aircraft trailing vortices. We first present the methodology used by the algorithm to simulate trailing vortex behavior, including 1) the descent of the vortices through a realistic atmosphere defined by crosswind, turbulence, and stratification profiles and 2) the interaction of the vortices with the ground. Examples are presented to demonstrate the algorithm's capability. We then describe a database approach for quantifying comparisons between algorithm predictions and measurements of wake vortex transport

and decay. The use of databases to optimize the constant factor k in the term governing the effect of turbulence on vortex decay is reported, with the result that k appears to depend on the intensity of ambient turbulence. Using selected groupings of cases from the database, we have determined that vortices not interacting with the ground decay about a factor of two faster in high-intensity ambient turbulence than in low-intensity ambient turbulence. We also show that the circulation decay for vortices in the ground effect appears to be independent of the ambient turbulence level.

"BOUND AND TRAILING VORTICES IN THE LINEARISED THEORY OF SUPERSONIC FLOW, AND THE DOWNWASH IN THE WAKE OF A DELTA WING"

R. & M. No. 2409, March 1952, Aeronautical Research Council, Great Britain.

The field of flow round a flat airfoil at incidence can be regarded in linearized theory as the result of both bound and trailing vortices for supersonic as well as for low-speed flight. This leads to a convenient method, given the lift distribution over an airfoil, for calculating the flow round it at supersonic speeds. As an application of the results the downwash is calculated in the wake of a delta wing lying within the Mach cone emanating from its apex. The downwash is found to be least just aft the trailing edge and is everywhere less than the downflow at the airfoil. It increases steadily to a limiting value which is attained virtually within two chord lengths of the trailing edge. The ratio of the downwash at any point in the wake to the downflow at the airfoil decreases with increasing Mach number and apex angle.

Robinson, A. and Hunter-Tod, J. H.

"BOUND AND TRAILING VORTICES IN THE LINEARIZED THEORY OF SUPERSONIC FLOW, AND THE DOWNWASH IN THE WAKE OF A DELTA WING"

Report No. 10, October 1947, Cranfield Institute of Technology, Cranfield, Bedford, UK.

The field of flow round a flat airfoil at incidence can be regarded in linearized theory as the result of both bound and trailing vortices for supersonic as well as for low-speed flight. This leads to a convenient method, given the lift distribution over an airfoil, for calculating the flow round it at supersonic speeds. As an application of the results the downwash is calculated in the wake of a delta wing lying within the Mach cone emanating from its apex. The downwash is found to be least just aft the trailing edge and is everywhere less than the downflow at the airfoil. It increases steadily to a limiting value which is attained virtually within two chord lengths of the trailing edge. The ratio of the downwash at any point in the wake to the downflow at the aerofoil decreases with increasing Mach number and apex angle.

"A SIMPLE NUMERICAL CRITERION FOR VORTEX BREAKDOWN"

AIAA Paper No. 1992-0057, Reno, NV, January 1992

Vortex breakdown is currently identified in numerical flow solutions through post-processing techniques. Although these methods can identify breakdown accurately, they need to be simplified and their cost reduced for practical aircraft design use. Therefore, a simple Rossby number criterion is proposed. The criterion is established using solutions to Euler and Navier-Stokes equations for low-speed flow over a flat plate delta wing at high angles of attack. Comparison with experimental data shows consistent values of Rossby number at breakdown. The proposed Rossby number criterion provides an efficient means of locating breakdown in numerical solutions. It is also straightforward to incorporate in any flow solver.

"A FLIGHT EVALUATION OF METHODS FOR PREDICTING VORTEX WAKE EFFECTS ON TRAILING AIRCRAFT"

NASA TN D-6904, November 1972, NASA Flight Research Center, Edwards, CA

The results of four current analytical methods for predicting wing vortex strength and decay rate are compared with the results of a flight investigation of the wake characteristics of several large jet transport aircraft. An empirical expression defining the strength and decay rate of wake vortices is developed that best represents most of the flight-test data. However, the expression is not applicable to small aircraft that would be immersed in the vortex wake of large aircraft.

"A SIMULATION-BASED STUDY OF THE IMPACT OF AIRCRAFT WAKE TURBULENCE WEIGHT CATEGORIES ON AIRCRAFT CAPACITY"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 22-1 to 22-15

The Federal Aviation Administration (FAA) is considering revising the current aircraft wake turbulence weight categories and the associated separation standards during IMC. Various proposals have been submitted to the FAA regarding this revision. This paper presents the results and conclusions of a capacity study conducted by The Boeing Company. This study examined the impact of these proposed changes on airport capacity during instrument meteorological conditions (IMC). The approach taken for this study was to simulate arrival and departure operations at ten major US airports by employing a database derived from the 1993 Official Airline Guide traffic schedule. Simulations were conducted for the traffic mix at each airport utilizing one standard, representative runway configuration. The aircraft wake vortex separation requirements were changed to model various proposed weight categories; these separations were then applied to the traffic set at each airport. In general, it was found that current capacity levels would be reduced by as much as 4%.

"WAKE VORTEX DETECTION AND REPORTING SYSTEM"

US Patent 8,135,500 B1, March 2012.

A method for estimating the effect of environmental conditions on an aircraft, including measuring the motions of an aircraft, estimating the expected motions of the aircraft, wherein the expected motions of an aircraft are estimated using information regarding the aircraft's control inputs and/or control surface positions; and estimating, based on the measured motions of the aircraft and the expected motions of the aircraft, the forces exerted on the aircraft by the environmental conditions, wherein the forces are estimated based on a difference between the measured motions of the aircraft and expected motions of the aircraft.

"THREE-DIMENSIONAL LASER-DOPPLER VELOCIMETER MEASUREMENTS IN SWIRLING TURBULENT PIPE FLOW"

Flow, Turbulence and Combustion, Vol. 70, 2003, pp. 43-67

The present work is an experimental study of the evolution characteristics of swirl in the flow in a pipe at a moderately high Reynolds number and over a wide range of swirl numbers characterizing the swirl strength. The measurements are done by 3D LDV in a specially designed facility that works on the principle of refractive-index matching. Swirl with the well-defined distribution of a constant angular velocity is introduced into the test section of this facility by a swirl generating device in which a tube bundle in the pipe rotates about the pipe axis. The measurements have been processed to yield the mean-velocity vector and the Reynolds stress tensor in this flow. An analysis of the measured evolution characteristics brings out a dominant effect of swirl with a solid body rotation as the annihilation of Reynolds shear stresses.

Rockwell, D.

"VORTEX-BODY INTERACTIONS"

Ann. Rev. Fluid Mechanics, Vol. 30, 1998, pp. 199-229

Interaction of a vortex, or combinations of them, with a cylinder, blade, or foil may involve both rapid distortion of the incident vorticity field and shedding of vorticity from the surface of the body. This review focuses on the underlying flow physics, with the aim of clarifying the origin of the induced loading. In the case of near or direct encounter of the incident vortex, the relation between three-dimensional features of the flow structure and the local loading poses interesting challenges for further research. With recently developed simulation and laboratory techniques, opportunities now exist to determine the instantaneous quantitative structure of these complex distortions and to interpret them within a theoretical, vorticity-based framework. Effective control of vortex interactions appears to be

attainable. It will be necessary, however, to develop creative strategies, distinct from those traditionally employed for control of unstable shear flows.

Rodenhiser, R. J.

"AN ULTRASONIC METHOD FOR AIRCRAFT WAKE VORTEX DETECTION"

M.S. Thesis, August 2005, Worcester Polytechnic Institute, Worcester, MA.

This thesis documents the experimental proof of concept study for an ultrasonic method of wake vortex detection. A new acoustic technique is utilized to measure the circulation produced in the wake of lift-generating aircraft. Ultrasonic signals are transmitted in a path around the wake vortex, and are used to determine the average in-line velocity component along the acoustic path. It is shown herein that this velocity component is directly proportional to the net circulation value within the acoustic path. This is the first study to take this methodology and implement it in a realistic airport setting. This project included constructing a prototype and conducting field tests to prove the validity of this technology in a realistic environment setting. During field tests an acoustic path enclosed the vorticity shed behind one wing of a Piper PA-28 aircraft. Fourteen initial test flights were conducted in calm atmospheric conditions, and results show circulation values measured are comparable in magnitude and direction to expected circulations generated by the Piper PA-28 aircraft. Additional testing in various atmospheric conditions revealed the scope of practice for such a measurement technology. This study demonstrates the validity of the acoustic method in detecting aircraft wake vortices. Future investigations and applications utilizing this technique are discussed within.

Rodenhiser, R. J., Durgin, W. W. and Johan, H.

"ULTRASONIC METHOD FOR AIRCRAFT WAKE VORTEX DETECTION"

Journal of Aircraft, Vol. 44, No. 3, May-June 2007, pp. 726-732

This paper describes the experimental proof of concept study for an ultrasonic method of wake vortex detection for airport use. This new acoustic method utilizes travel time of acoustic pulses around a closed path to measure the net circulation within the acoustic path. In this application the closed path encloses the vorticity shed from one side of a Piper PA-28 aircraft wing. Magnitude and sign of circulation detected is comparable to the expected circulation generated by the Piper PA-28 test aircraft. This study demonstrates the validity of the acoustic method in detecting aircraft wake vortices. Further investigations and applications utilizing this technique are discussed.

"ACOUSTIC TECHNOLOGY FOR AIRCRAFT WAKE VORTEX DETECTION"

Proceedings of the Twelfth Conference on Aviation Range and Aerospace Meteorology, American Meteorological Society, Atlanta, Georgia, Feb. 2006

National research efforts over the past two decades have focused on developing a wake vortex detection technology that could be deployed in an airport setting for real-time wake vortex hazard assessment. Recent research has proven a new acoustic method of wake vortex detection that has been successful in initial field trials at detecting the presence of wake vortex circulations (Rodenhiser, 2005). This paper discusses how this new technology can be utilized to determine the strength and location of wake vortices in the airport terminal area.

Rodoni, C. A.

"AN INVESTIGATION OF THE FLOW PARAMETERS OF A CONFINED TURBULENT VORTEX"

M.S. Thesis, September 1969, Mass. Institute of Technology, Cambridge, MA

The object of this paper is to find out to what extent laminar vortex models can be adjusted by means of empirically derived 'effective eddy viscosity' terms to describe turbulent vortices; and to look directly for empirical correlations for the characteristic flow parameters. A literature search was conducted to obtain the empirical data, and a computer program was written to determine its dependence on the appropriate dimensionless parameters. Although the observed vortex flow patterns are shown to agree with theory, it is found that the 'eddy viscosity' approach to predicting the angular momentum dissipation is not very satisfactory.

"TOWARDS A UNIFIED SWIRL VORTEX MODEL"

AIAA Paper No. 2012-3354, June 2012, New Orleans, LA.

A review of the literature shows the existence of dozens of single-cell, axisymmetric, Newtonian-fluid vortices that, in one form or another, are solutions to the Navier-Stokes Equation. However, little research has been conducted in the literature to investigate common traits that are shared by these vortices. This research lays out a foundation of common mathematical traits, with a focus on the azimuthal velocity v . Notwithstanding their diverse mathematical and physical origin, it can be shown that these vortices are diverse manifestations of a single vortex family -- they are united by a set of at least seven common mathematical traits. As a first common trait, we show that there are only four possible categories of single-cell, axisymmetric, Newtonian-fluid vortices. Next, by normalizing and overlaying the vortices into a single figure, three additional traits are noted, namely that $v(r=0) = 0$; they have similar azimuthal velocity profiles; and the azimuthal velocity is asymmetric about r . Thereafter, a fifth trait is noted by doing a series expansion for the azimuthal velocity of each vortex (as found in the literature), and expressing it as an alternating series that expands geometrically with odd exponents (truncated Laurent series with real coefficients). Finally, two more traits are noted by taking limit bounds for each series, thus showing that one bound is the Rankine (solid body) vortex, and the other is a Lamb-Oseen sine-like bound. In brief, we note that the vortices have seven traits in common, and hereby propose that these vortices are essentially diverse manifestations of a single vortex family.

"VORTICITY CAPTURING"

AIAA Paper 2001-2523, June 2001, Anaheim, CA.

The paper identified one of the most important algorithm development areas to be three dimensional flows with strong vorticity. The importance of the area of research is illustrated by pointing out the general form of the vorticity transport equation involves vorticity transport, diffusion by viscosity and generation by barotropic mechanism. Therefore, a robust algorithm is one that would be able to properly address these vorticity driven physics. Vortex methods, hybrid, vorticity confinement techniques were highlighted and briefly reviewed, followed by illustrations of the spurious features that can result in the various computational schemes. Some initial ideas on attacking these issues have been proposed.

"A COST BENEFIT ANALYSIS OF WAKE VORTEX MEASURES: DEMONSTRATION OF THE ASTER APPROACH FOR SETTING AND OPTIMISING SAFETY TARGETS"

NLR-CR-2001, National Aerospace Laboratory, Amsterdam, The Netherlands

ASTER stands for 'Aviation Safety Targets for Effective Regulation'. It is a project carried out on behalf of DG-TREN of the European Commission in 2000-2001. The objective of ASTER is to develop a method to set and optimize safety targets to achieve the optimum level of safety for the aviation system by distributing the safety burden more evenly among the different actors. This includes the development of a method for cost benefit analysis to assess safety benefits of any change, including changes in legislation and rulemaking, in relation to the costs of implementing those changes. As a demonstration of the ASTER approach for setting and optimizing safety targets, a case study was conducted on wake vortex measures.

"EXPERIMENTAL RESEARCH ON HELICOPTER FUSELAGE AND ROTOR HUB WAKE TURBULENCE"

Journal of American Helicopter Society, Vol. 30, Issue 1, 1985, pp. 43-51.

Various flow visualization experiments (ranging from hydrodynamic tests of small models to tuft and smoke tests conducted on wind tunnel models and full-scale aircraft in flight) show that large eddy structures are convected periodically in the wake generated by helicopter rotor hubs. Spectral analysis of hot film flow signals reveals that discrete energy components are added to the continuous (turbulent) energy spectrum, not only at the integer multiples of the blade passage frequency, but also at every rotor harmonic frequency. Moreover, it is shown that the ratio of discrete/turbulent energy at rotor harmonic frequencies is uniquely determined by the advance ratio. Similar results are found concerning the unsteady air loads on the stabilizers. Some explanations concerning tail-shake

phenomena are given, based on the spectral analysis of wake signals and fin bending stresses, and solutions are suggested to alleviate the problem.

"MIXING IN TWO-DIMENSIONAL VORTEX INTERACTIONS"

Physics of Fluids, Vol. 12, No. 12, December 2000, pp. 3285-3288

We examine the mixing of a passive tracer initially contained within several widely separated vortex patches in a two-dimensional, nearly inviscid, incompressible flow. The initial vortex positions and sizes are chosen so that they collapse toward a common center, resulting in a strong interaction. The area of tracer ejected from the vortices is found to be well correlated with the departure of each tracer contour from an ideal elliptical shape. This result appears to be more widely applicable, and, in particular, it may be useful for quantifying small-scale mixing in realistic atmospheric and oceanic flows.

"SODAR WIND RESOURCE MEASUREMENT RESULTS AT FALMOUTH, MA"

Letter Report, September 2005, Renewable Energy Research Laboratory, University of Massachusetts, Amherst, MA.

SODAR data have been collected at the Falmouth wastewater treatment plant in the spring of 2005 by the Renewable Energy Research Laboratory at the University of Massachusetts at Amherst. The data were collected to estimate the wind resource for possible wind turbines and to determine the wind shear characteristics at the site. Some of the data was determined to be corrupted but good data was collected at several heights during the month of June, 2005. Based on these data, the wind shear at the site can be modeled by exponential fit with a coefficient of 0.33 and the mean annual wind speed at 70 m is most likely between 5.88 and 6.36 m/s.

Rogers, A. W.

"APPLICATION OF TWO-DIMENSIONAL VORTEX THEORY TO THE PREDICTION OF FLOW FIELDS BEHIND WINGS OF WING-BODY COMBINATIONS AT SUBSONIC AND SUPERSONIC SPEEDS"

NACA TN-3227, September 1954, Langley Aeronautical Lab., Langley Field, VA

A theoretical investigation has been made of a general method for predicting the flow field behind the wings of plane and cruciform wing and body combinations at transonic or supersonic speeds and slender configurations at subsonic speeds. The wing trailing-vortex wake is represented initially by line vortices distributed to approximate the spanwise distribution of circulation along the trailing edge of the exposed wing panels. The afterbody is represented by corresponding image vortices within the body. Two-dimensional line-vortex theory is then used to compute the induced velocities at each vortex and the resulting displacement of each vortex is determined by means of a numerical stepwise

integration procedure. The method was applied to the calculation of the position of the vortex wake and the estimation of downwash at chosen tail locations behind triangular-wing and cylindrical-body combinations at supersonic speeds. The effects of such geometric parameters as aspect ratio, angle of attack and incidence, ratio of body radius to wing semi-span, and angle of bank on the vortex wake behind wings of wing-body combinations were studied. The relative importance of wing vortices, the corresponding image vortices within the body, and body crossflow in determining the total downwash was assessed at a possible tail location. It was found that the line-vortex method of this report permitted the calculation of vortex paths behind wings of wing-body combinations with reasonable facility and accuracy. A calculated sample wake shape agreed qualitatively with one observed experimentally, and sample results of the line-vortex method compared well with an available exact crossflow-plane solution. An empirical formula was derived to estimate the number of vortices required per wing panel for a satisfactory computation of downwash at tail locations. It was found that the shape of the vortex wake and the ultimate number of rolled-up vortices behind a wing depend on the circulation distribution along the wing trailing edge. For the low-aspect-ratio plane wing and body combinations considered, it appeared that downwash at horizontal tail locations is largely determined except near the tail-body juncture by the wing vortices alone for small ratios of body radius to wing semispan, and by the body upwash alone for large values of that ratio.

Rogers, A. W.

"APPLICATION OF TWO-DIMENSIONAL VORTEX THEORY TO THE PREDICTION OF FLOW FIELDS BEHIND WINGS OF WING-BODY COMBINATIONS AT SUBSONIC AND SUPERSONIC SPEEDS"

NACA TN-3227, September 1954, Langley Aeronautical Laboratory, Langley Field, VA

A theoretical investigation has been made of a general method for predicting the flow field behind the wings of plane and cruciform wing and body combinations at transonic or supersonic speeds and slender configurations at subsonic speeds. The wing trailing-vortex wake is represented initially by line vortices distributed to approximate the spanwise distribution of circulation along the trailing edge of the exposed wing panels. The afterbody is represented by corresponding image vortices within the body. Two-dimensional line-vortex theory is then used to compute the induced velocities at each vortex and the resulting displacement of each vortex is determined by means of a numerical stepwise integration procedure. The method was applied to the calculation of the position of the vortex wake and the estimation of downwash at chosen tail locations behind the triangular-wing and cylindrical body combinations at supersonic speeds. The effects of such geometric parameters as aspect ratio, angle of attack and incidence, ratio of body radius to wing semispan, and angle of bank on the vortex wake behind wings of wing-body combinations were studied. The relative importance of wing vortices, the corresponding image vortices within the body, and body crossflow in determining the total downwash was assessed at a possible tail location. It was found that the line-vortex method of this report permitted the calculation of vortex paths behind wings of wing-body combinations with reasonable facility and accuracy. A calculated sample wake shape agreed qualitatively with one observed experimentally, and sample results of the line-vortex method compared well with an available exact crossflow-plane solution. An empirical formula was derived to estimate the number of vortices required per wing panel for a satisfactory computation of downwash at tail locations. It was found that

the shape of the vortex wake and the ultimate number of rolled-up vortices behind a wing depend on the circulation distribution along the wing trailing edge. For the low-aspect-ratio plane wing and body combinations considered, it appeared that downwash at horizontal tail locations is largely determined except near the tail-body juncture by the wing vortices alone for small ratios of body radius to wing semispan, and by the body upwash alone for large values of that ratio.

"PARACHUTE/VORTEX INTERACTION STUDY, INITIAL WIND TUNNEL AND DROP TESTING"

AIAA Paper 1997-1479, June 1997, San Francisco, CA.

The multi-ship airdrop mission produces the probability of paratroopers encountering the vortices of aircraft in preceding positions. The basic physics and an analysis method was developed to assess the comparative risk level for any given formation. The basic physics were investigated using scaled parachute testing. The result of the testing indicated that a vectorial analysis of the computed path of a jumper in proximity to a vortex would be the only available analytical method for assessing risk. Testing was performed using two scale model parachutes of the T-10 type used by U.S. Army paratroopers. The testing consisted of vertical wind tunnel testing and drop testing in proximity to a simple dynamic pressure generator. Results show that the gradient of dynamic pressure exposure is the primary mechanism of parachute collapse. The three-dimensional path of the paratrooper is also key to vortex encounter risk.

Rogers, M.

"A REVIEW OF AFOSR EFFORTS IN WAKE TURBULENCE"

Proceedings of the AFFDL/NASA/FAA Wake Turbulence Work Shop, Air Force Flight Dynamics Laboratory, AFFDL-TM-75-16-FGC, 1974, p. 71

A summary is given of the wake turbulence topics which have interested the Air Force Office of Scientific Research. These topics included vortex formation and decay and the way they affect Air Force operations, the effect of viscosity on vortex aerodynamics, and the relationship between span loading and vortex characteristics. Possible future applications of the basic vortex understanding gained were suggested: improved control and performance using vortex technology (use of canard surfaces to control separation over a swept wing), use of helicopter wakes to disperse fog or pollutants, effect of fatigue failure, and the possible coupling of aircraft wakes in the generation of gravity waves.

"EXPERIMENTAL INVESTIGATION OF THE ROLLUP OF THE UNSTABLE SHEET OF DISCONTINUITY BEHIND A WING OF FINITE SPAN"

Zeitschrift fur Flugwiss, Vol. 5, No. 12, December 1957, pp. 365-370

The length over which the trailing vortex sheet is rolled up into two vortex cores and the distance between the rolled-up vortices have been investigated experimentally for a rectangular and a trapezoidal wing with GP-387 airfoil sections, each with the wing tips sharp and rounded off. [In German.

Rokhsaz, K.

"A BRIEF SURVEY OF WING TIP DEVICES FOR DRAG REDUCTION"

SAE Paper No. 932574, September 1993, Anaheim, CA.

A short survey of wing tip geometries for drag reduction is presented. These devices have been divided into two broad categories of passive and active. The first category is made of fixed geometries, while the second group is made of those employing moving parts. The former group is further divided into planar and nonplanar designs. In every case, a brief explanation of the underlying logic is given. Altogether, more than fifteen completely different designs and over seventy references have been cited. Some of these designs, such as winglets, have been explored for many years and have proven to be very effective at reducing the induced drag at higher values of lift coefficient. Some others, such as wing tip turbines, have just begun to attract attention. Wing tip fuel tanks, not being solely employed for drag reduction, have not been included in this paper.

Rokhsaz, K. and Kliment, L. K.

"FEASIBILITY OF MODELING WAKE VORTICES IN GROUND EFFECT IN A WATER TUNNEL"

SAE 2005-01-3360, Aerotech Congress, October 2005, Grapevine, TX

An experiment is performed to investigate the feasibility of using a water tunnel to study the aircraft wake vortex behavior in ground effect. Two blades are used to generate the vortices, simulating an aircraft wake. The ground plane is modeled with a splitter plate. Vortex mean positions are determined using an optical technique. The results show all the critical properties of an aircraft wake in the vicinity of the ground. The vortices are shown to descend monotonically until they start interacting with the ground plane. The minimum height to which the filaments sink is shown to compare favorably with that predicted by numerical methods and the operational data obtained from lidar. The vortex span is shown to increase at the same rate as that estimated from an empirical model based on lidar data as well. Vortex rebound is observed with maximum heights comparing well with other predictions. Partial comparison is also presented with a numerical scheme developed for AVOSS application. These observations all seem to favor a water tunnel as an appropriate means of investigating this type of flow field.

Rokhsaz, K. and Kliment, L. K.

"A BRIEF SURVEY OF THE EXPERIMENTAL METHODS USED FOR WAKE VORTEX INVESTIGATIONS"

SAE Paper No. 2007-01-3788, September 2007, Los Angeles, CA

Some of the methods used for experimental detection and examination of wake vortices are presented. The aim of the article is to provide the reader a brief overview of the available methods. The material is divided into two major sections, one dealing with methods used primarily in the laboratory, and the second part devoted to those used in field operations. Over one hundred articles are cited and briefly discussed.

Rokhsaz, K. and Kliment, L. K.

"EXPERIMENTAL INVESTIGATION OF CO-ROTATING VORTEX FILAMENTS IN A WATER TUNNEL"

Journal of Aircraft, Vol. 40, No. 6, Nov.-Dec. 2003, pp. 1115-1122

The dynamic behavior of co-rotating vortex filaments is investigated in a water tunnel. Comparisons are made between the motion of a single filament and that resulting from interactions between two filaments. Correlation is observed visually between the merger location and the vortex strength. In most cases, vortex merger is shown to occur within one orbit. Quantitative data is presented on the variations of the vortex span, the amplitude of motion, the spiraling rate, and the center of spiraling, all as functions of downstream distance. It is shown that the vortex span does not vary considerably except in cases where the interactions among the filaments are strong. The amplitude of motion is shown to be much larger than that of a single vortex, while growing with downstream distance. Furthermore, the amplitude of motion is shown to exhibit a preferred direction in some cases. The presented data reveals that in the two-vortex cases, the spiraling rate is nearly constant. It is also shown that despite considerable motion of the filaments, the center of spiraling does not deviate significantly from a straight line.

Rokhsaz, K. and Miller, T. S.

"THEORETICAL AND EXPERIMENTAL INVESTIGATION OF THE SELF-INDUCED OSCILLATIONS OF A SINGLE VORTEX FILAMENT"

AIAA Paper No. 2002-3304, St. Louis, MO, June 2002

A simple analytical model, consistent with that of Crow, is used to explore the self-induced oscillations of a single longitudinal vortex filament. The new model is based on the Biot and Savart law and results in an eigenvalue problem for the wavenumber of the first bending mode. Following the method of Crow, the singularity at the lower limit of the Biot and Savart integrals is removed by introducing a cutoff distance that is related to the core radius. It is proven that the first bending mode of the vortex filament is composed of a sinusoidal shape, which cannot be of an arbitrary wavenumber. A concise expression is derived for the associated wavenumber, which is shown to be very different from those of Kelvin waves. The results from the Kelvin's analysis and the present model are compared with a limited amount of previously obtained experimental data. Close agreement is shown between one of the dominant frequencies in the experimental data and that of the present formulation.

Rokhsaz, K. and Rebours, R.

"QUANTITATIVE MEASUREMENTS OF WAKE VORTEX MOTION IN A WATER TUNNEL"

AIAA Paper No. 2001-0111, Reno, NV, January 2001

The paper presents a novel technique for quantitative data acquisition regarding the motion of a pair of vortex filaments in a water tunnel. This technique allows measuring the vortex strength, the oscillation frequency of the vortex filaments, and the rate of growth of their amplitudes simultaneously. The filaments are visualized using dye injection while their cross sections are illuminated with light sheets at different downstream locations and recorded. Time history of the vortex position is extracted from these recordings. This measurement technique is shown to be a viable method of analyzing wake vortex motion. Pairs of vortex filaments, typical of those wingtips, are used in a water tunnel to demonstrate the application of the method. Vortex strength and the distance between the filaments are varied independently and the motions of the vortex pairs are quantified. The method is shown to be robust and reliable, as long as the dye remains in the vortex core.

Rokhsaz, K., Foster, S. R. and Miller, L. S.

"EXPLORATORY STUDY OF AIRCRAFT WAKE VORTEX FILAMENTS IN A WATER TUNNEL"

J. Aircraft, Vol. 37, No. 6, November-December 2000, pp. 1022-1027

The objective of this work is to examine the meandering nature of a single vortex filament. The flow field is typical of that in the vicinity of an aircraft wing tip vortex. Self-induced motion of the vortex filament is examined within the confines of potential flow theory and is compared with experimentally obtained data. A single-sensor constant temperature anemometer is used to obtain the experimental data for comparison. Data is presented that shows the variation of the core radius with distance downstream of the point of origin as a function of the vortex strength. Also, experimental data is presented to show the variation in the amplitude of wandering downstream of the point of origin.

Rokhsaz, K., Rebours, R. and Foster, S. R.

"QUANTITATIVE MEASUREMENTS OF WAKE VORTEX MOTION IN A WATER TUNNEL"

Journal of Aircraft, Vol. 39, No. 5, September-October 2002, pp. 862-867

A novel technique is presented for quantitative data acquisition regarding the motion of a pair of vortex filaments in a water tunnel. This technique allows measuring the vortex strength, the oscillation frequency of the vortex filaments, and the rate of growth of their amplitudes simultaneously. The filaments are visualized using dye injection while their cross sections are illuminated with light sheets at different downstream locations and recorded. Time history of the vortex position is extracted from these recordings. This measurement technique is shown to be a viable method of analyzing wake vortex motion. Pairs of vortex filaments, typical of those of wingtips, are used in a water tunnel to

demonstrate the application of the method. Vortex strength and the distance between the filaments are varied independently, and the motions of the vortex pairs are quantified. The method is shown to be robust and reliable, as long as the dye remains in the vortex core.

Rom, J.

"VORTEX FLOWS AND THE ROLLED-UP VORTEX WAKE"

In: High Angle of Attack Aerodynamics, Chapter 5, Springer-Verlag, New York, 1992, pp. 131-149.

The trailing vortex wake behind the lifting wing is an excellent example of the natural tendency of free vortical shear layers to roll up into well-defined concentrated vortices with the essentially inviscid outer flow rotating around an inner viscous core. Such is the case when the well-known tip vortices are established in the wake of high AR lifting wings. High speed computers provide the means for calculating the characteristics of the complete flow field over the wing as well as its wake and the rolled-up tip vortices. These calculations will be presented and discussed in the following chapters. However, before diving into the details of the calculations, it is of particular interest and importance to gain some insight into the flow field over wings and their wakes. This can best be done by examining analytical solutions, such as those developed by Spreiter and Sacks, to the problems of simulating the main features of the rolled-up vortex flow.

Rom, J. and Zorea, C.

"THE CALCULATION OF THE LIFT DISTRIBUTION AND THE NEAR VORTEX WAKE BEHIND HIGH AND LOW ASPECT RATIO WINGS IN SUBSONIC FLOW"

TA-168, January 1973, Technion-Israel Inst. of Technology, Haifa, Israel

A method is presented for the combined calculation of the lift and lift distribution on a wing and of the trailing vortex flow behind the wing. It is assumed that the lift of a wing is generated by a system of vortices distributed over the complete wing planform and shed away from each elemental area on the planform. Using the concepts of the vortex lattice method, it is assumed in the linear lift variation case, that the vortices are aligned on the wing planform and are shed away from the trailing edges. Vortex line interaction calculations for the trajectories of the vortex lines are programmed. As a result, the leading-edge lift vortices which are obtained on slender wings can now be handled. This report contains a description of the numerical method.

"CALCULATION OF THE NON LINEAR AERODYNAMIC COEFFICIENTS OF WINGS OF VARIOUS SHAPES AND THEIR WAKES, INCLUDING CANARD CONFIGURATIONS"

ICAS 1978, September 1978, Lisbon, Portugal.

This paper introduces a method for the calculation of the non linear, longitudinal aerodynamic characteristics of various planar shapes, including multiple lifting surface configurations in subsonic flow, at high angles of attack. The method developed can handle complex planforms such as closely coupled canard-wing combinations, wing-tail combinations, cruciform types of wing arrangements, various flaps, elevators, dihedral angles as well as ground effect problems. The present work uses a modified 'Vortex Lattice Method' by including the effects of the shedding and of the development of the rolled-up wake. The solution is carried out by an iterative process, saving a lot of computing time. Comparisons with experimental data show very good agreement even in cases of very strong nonlinear effects of leading-edge vortices, or in cases of side-edge vortices rolling up above the surface of low aspect ratio wings.

Rom, J., Portnoy, H. and Zorea, C.

"INVESTIGATIONS OF THE ROLLING-UP OF THE VORTEX WAKE AND CALCULATION OF NON-LINEAR AERODYNAMIC CHARACTERISTICS OF WINGS"

AFOSR-TR-76-1146, June 1976, Technion-Israel Inst. of Technology, Haifa, Israel

This report investigates the rolling-up of vortices over and behind wings of low and high aspect ratios, and simultaneously the evaluation of the aerodynamic characteristics including the spanwise and chordwise pressure distributions on the wings. The present method is based on the extension of the Vortex Lattice concepts also to low aspect ratio wings and the rolled-up vortex which is established over as well as behind the wings. The computer program, which was developed, can reproduce the results of the Vortex Lattice Method (VLM) for linear aerodynamic coefficients for high aspect ratio wings. The wake effect is included in the modified VLM program. This wake calculation showed that the center of the tip vortex is very near the wings' tip for the high aspect ratios wings. The non-linear aerodynamic characteristics are evaluated when the vortices are shed over the wing and begin the rolling-up process from the leading edges. This effect is particularly important for wings of low aspect ratios.

"INVESTIGATION INTO THE FORMATION OF WING-TIP VORTICES"

TAE-199, February 1974, Technion-Israel Inst. of Technology, Haifa, Israel

A resume of the program of theoretical investigations into wing-tip vortex formation which is now in process in the Department of Aeronautical Engineering at the Technion, Haifa is given. The work is proceeding along two separate paths which it is hoped eventually to amalgamate. The first investigation consists of numerical work on the rolling up of the wing trailing vortex system when it is represented by discrete vortices according to a series of models of increasing complexity starting from the two-dimensional elliptic distribution as originally treated by Westwater and proceeding by stages through various lifting-line and lifting surface models, including some exhibiting non-linear lift characteristics.

Rom, J., Zorea, C. and Gordon, R.

"ON THE CALCULATION OF NON-LINEAR AERODYNAMIC CHARACTERISTICS AND THE NEAR VORTEX WAKE"

International Council of the Aeronautical Sciences Paper 74-27, Haifa, Israel, 1974

Methods for the calculation of the distribution of vortices on the wing planform and on the trailing vortex wake by an iterative procedure based on the application of the vortex lattice method concept are described. In the case when the trailing vortices are taken to leave the wing at the trailing edge only, the calculation results in determining the linear aerodynamic characteristics and the shape of a rolled wake. The present investigation considers the case when the vortices for each cell are allowed to leave the wing planform at a fixed angle, and the case when the vortex shedding can be limited to the planform edge only.

"CO-ROTATING VORTEX INTERACTION"

Aircraft Engineering and Aerospace Technology, Vol. 88, No. 2, 2016, pp. 285-293.

The purpose of this paper is to study the structure and dynamic development of a pair of co-rotating trailing vortices, during their formation, interaction and merging, using detailed experimental measurements of the velocity and vorticity fields. The vortices were generated using two half wings (NACA0030) positioned at equal and opposite angles of attack at the entrance of the test section of an open-circuit, subsonic, wind tunnel. Velocity vector measurements were obtained at $Re = 133,000$, on cross-plane grids at several distances from the trailing edges of the wings, using an in-house developed four-sensor hot wire anemometer probe. The results include cross-plane contour plots of the mean and fluctuating velocity as well as mean vorticity fields. Each of these variables is affected in a different way, providing complementary information on the development of the flow field. After shedding, the two vortices are swept along the stream-wise direction and swirl around each other, thereby developing a braid of two vortices, which then deforms the external flow field. Gradually, the interaction with the external flow field links both vortices together until the final merging and the formation of a new stable linear vortex emerges.

"MULTISENSOR HOT WIRE VORTICITY PROBE MEASUREMENTS OF THE FORMATION FIELD OF TWO COROTATING VORTICES"

Flow Turbulence Combustion, Vol. 83, 2009, pp. 153-183.

Experimental evidence is reported, regarding the formation of a pair of co-rotating tip vortices by a split wing configuration, consisting of two half wings at equal and opposite angles of attack. Simultaneous measurements of the three-dimensional vector fields of velocity and vorticity were conducted on a cross plane at a downstream distance corresponding to 0.3 cord lengths (near wake),

using an in-house constructed 12-sensor hot wire anemometry vorticity probe. The probe consists of three closely separated orthogonal 4-wire velocity sensor arrays, measuring simultaneously the three-dimensional velocity vector at three closely spaced locations on a cross plane of the flow field. This configuration makes possible the estimation of spatial velocity derivatives by means of a forward difference scheme of first order accuracy. Velocity measurements obtained with an X-wire are also presented for comparison. In this near wake location, the flow field is dictated by the pressure distribution established by the flow around the wings, mobilizing large masses of air and leading to the roll up of fluid sheets. Fluid streams penetrating between the wings collide, creating on the cross plane flow a stagnation point and an 'impermeable' line joining the two vortex centers. Along this line fluid is directed towards the two vortices, expanding their cores and increasing their separation distance. This feeding process generates a dipole of opposite sign streamwise mean vorticity within each vortex. The rotational flow within the vortices obligates an adverse streamwise pressure gradient leading to a significant streamwise velocity deficit characterizing the vortices. The turbulent flow field is the result of temporal changes in the intensity of the vortex formation and changes in the position of the cores (wandering).

"INTERPRETING VORTEX INTERACTIONS WITH A FREE SURFACE"

Journal of Fluids Engineering, Vol. 116, March 1994, pp. 91-94.

An understanding of the process by which vorticity interacts with a free surface is sought by analytical examination of the free-surface condition for the vorticity flux. A novel mechanism is suggested that permits closed vortex loops to evolve into open loops terminating at the free surface. It is hypothesized that abrupt vortex 'disconnection' observed in physical experiments, arises from a smooth diffusion of vorticity through the interface, with a necessary coincident tangential acceleration of the interface attributed to viscous forces.

Rood, E. P.

"VORTEX INTERACTIONS WITH A FREE-SURFACE"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.2, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 34-1 - 34-5

Free-surface phenomena are characterized by viscous processes that produce vortices of all scales. Although the processes are like those associated with solid wall boundary layers, the quite different boundary conditions distinguish the two types of flow. Recent advances in capabilities for both physical and numerical experiments as well as analytic investigations of boundary conditions have provided the means to comprehensively investigate the detailed dynamics of vortices interacting with the free-surface. An understanding of the three-dimensional interactions is important for interpreting results of laboratory scale aircraft wake studies in which an air-water free-surface is employed as a ground plane. In this paper the physical problem is the interaction between vortices in water and an air-water

interface. The term 'free surface' denotes the interface between water and air on which the shear stresses caused by the motions of the air are insignificant compared to those caused by the motion of the water. Surface contamination, when present, produces a gradient in the surface tension that results in a stress on the water. The focus of this paper is on the qualitative mechanisms underlying the observed interactions between vorticity and the free-surface, such as the apparent rebound of the vortices from the free-surface.

"WAKE TURBULENCE RE-CATEGORIZATION ON APPROACH AND DEPARTURE FOR SAFE AND MORE EFFICIENT AIR TRAFFIC MANAGEMENT"

ICAS 2016, Paper ICAS-2016-0230, September 2016, Daejeon, Korea.

Current wake turbulence separation minima between successive arrival or departure air traffic are usually based on ICAO 3-category scheme (with specific minima for A380), using maximum gross weight as criterion. Possible significant efficiency optimization can be achieved from increased number of categories or establishment of aircraft pair-wise separation minima, enabling a reduction of over-conservatism for some aircraft pairs, while maintaining an acceptable safety level.

"COHERENT WAKE STRUCTURES FOR TRANSPORT AIRCRAFT AT CARGO AIRDROP CONFIGURATIONS INCLUDING PARACHUTES"

AIAA Paper 2013-2536, June 2013, San Diego, CA.

Results of two stereoscopic Particle Image Velocimetry measurement campaigns have been post-processed with the snapshot Proper Orthogonal Decomposition (POD) to identify coherent structures in the wake of a transport aircraft with its tailgate down and with and without various cargo configurations placed in the wake. These configurations are representative of generic airdrop scenarios. Coherent structures are identified in the wake of the transport aircraft with an open ramp. Periodic events are found in the wake of cargo, while including a support plate underneath the cargo suppresses the coherent structures. The influence of the trailing wake of the open ramp and its influence on the coherent wake structures in the cargo wakes are discussed. The snapshot POD also suggests that vortex shedding is present in the wake of a parachute attached to the cargo.

"MEASUREMENT OF VORTEX VELOCITIES OVER A WIDE RANGE OF VORTEX AGE, DOWNSTREAM DISTANCE AND FREE STREAM VELOCITY"

NASA CR-145213, July 1977, Sikorsky Aircraft, Stratford, C.

A wind tunnel test was conducted to obtain vortex velocity signatures over a wide parameter range encompassing the data conditions of several previous researchers while maintaining a common instrumentation and test facility. The generating wing panel was configured with both a revolved airfoil tip shape and a square tip shape and had a semispan aspect of 4.05/1.0 with a 121.9 cm span. Free stream velocity was varied from 6.1 m/sec to 76.2 m/sec and the vortex core velocities were measured at locations 3, 6, 12, 24 and 48 chord lengths downstream of the wing trailing edge, yielding vortex ages up to 2.0 seconds. Wing pitch angles of 6, 8, 9 and 12 deg were investigated. Detailed surface pressure distributions and wing force measurements were obtained for each wing tip configuration. Correlation with vortex velocity data taken in previous experiments is good. During the rollup process, vortex core parameters appear to be dependent primarily on vortex age. Trending in the plateau and decay regions is more complex and the mechanisms appear to be more unstable.

Rorke, J. B. and Moffitt, R. C.

"WIND TUNNEL SIMULATION OF FULL SCALE VORTICES"

NASA CR-2180, March 1973, Sikorsky Aircraft, Stratford, CT.

An experimental investigation has been conducted to determine the important scaling parameters for the flow in the core region of a vortex generated by a rectangular wing tip. The effect of an unconventional planform, the ogee tip, on the tip vortex is also determined. For rectangular planform wings, the measured vortex core diameter to chord ratios, peak tangential velocity ratios, and axial velocity ratios are shown to be functions only of wing lift coefficient and elapsed time from vortex formation, and appear to be independent of both Mach number and Reynolds number. The peak tangential velocities in the diffuse vortex generated by the ogee tip are only 25 percent of those in the vortex generated by the rectangular wing.

"AIRCRAFT VORTEX WAKES AND THEIR EFFECTS ON AIRCRAFT"

ARC Report CP-795, December 1963, Royal Aircraft Establishment, Farnborough, England. (Also, Tech. No. Aero. 2934 and ARC-5419.)

Tests have been made using a Venom traversing aircraft to determine the strength and decay, away from the ground, of vortex wakes behind Comet and Vulcan aircraft. The present tests show that the effects of an intersection at right angles to the wake reduce to a low level (less than 8 ft/sec equivalent gust) after 2 minutes. This result is unlikely to be any more severe for a transport aircraft.

"THE FORMATION OF VORTICES FROM A SURFACE OF DISCONTINUITY"

Proceedings of the Royal Society of London, Series A, Vol. 135, Issue 823, November 1931, pp. 170-192

The surface of discontinuity, which is a vortex sheet, is replaced by a distribution of finite elemental vortices along its trace, and the paths of these vortices are determined by a numerical step-by-step method. The line joining these vortices at any instant is assumed to approximate the actual shape of the surface at that time. It is shown that the effect of instability upon a surface of discontinuity of sine form is to produce concentrations of vorticity at equal intervals along the surface, and it is also shown that the surface of discontinuity tends to roll up round these points of concentration with an accompanying increase in the amplitude of the displacement.

"ON THE DEVELOPMENT OF TURBULENT WAKES FROM VORTEX STREETS"

PhD Thesis, January 1952, California Institute of Technology, Pasadena, CA.

Wake development behind circular cylinders at Reynolds numbers from 40 to 10,000 was investigated in a low-speed wind tunnel. Standard hot-wire techniques were used to study the velocity fluctuations. The Reynolds number range of periodic vortex shedding is divided into two distinct subranges. At $R = 40$ to 150 , called the stable range, regular vortex sheets are formed and no turbulent motion is developed. The range $R = 150$ to 300 is a transition range to a regime called the irregular range, in which turbulent velocity fluctuations accompany the periodic formation of vortices. The turbulence is initiated by the laminar-turbulent transition in the free layers which spring from the separation points on the cylinder. This transition first occurs in the range $R = 150$ to 300 . Spectrum and statistical measurement were made to study the velocity fluctuations. In the stable range the vortices decay by viscous diffusion. In the irregular range the diffusion is turbulent and the wake becomes fully turbulent in 40 to 50 diameters downstream. It was found that in the stable range the vortex sheet has a periodic spanwise structure. The dependence of shedding frequency on velocity was successfully used to measure flow velocity. Measurements in the wake of a ring showed that an annular vortex sheet is developed.

"A TWIST OF FATE"

Business and Commercial Aviation, September 2002, pp. 77-86

In days past, takeoffs and landings were considered the most dangerous flight regimes with respect to wake turbulence. Low, slow and near other aircraft, pilots would have little room to maneuver or recover in the event of a wake turbulence encounter, and the result could prove calamitous. While these are still the most likely times for encountering the dangerous vortices, recent research and empirical evidence suggest that wake turbulence at altitude could pose risks equal to the low-level hazards. Steps are being taken to better understand wake turbulence, and to develop strategies to avoid encounters both en route and in terminal operations.

Rossow, V.

"CLASSICAL WING THEORY AND THE DOWNWARD VELOCITY OF VORTEX WAKES"

Journal of Aircraft, Vol. 43, No. 2, March-April 2006, pp. 381-385

Classical wing theory is extended downstream from a flat vortex sheet to include vortex-wake configurations that can be considered as fully rolled up into a vortex pair. Classical wing theory was chosen as the method to be used because it is based on the flux of downward momentum imparted to the ambient flow field by the lift on a wing. After the theory is reviewed to establish the theoretical process used to analyze vortex wakes, it is extended to the configuration of lift-generated wakes that occur after roll-up of the vortex sheet, and that are composed of a vortex pair inside of an oval-shaped region that propagates downward as a unit. The distribution of downward momentum inside the oval, and in the surrounding fluid, found for the rolled-up vortex pair is then applied to vortex wakes as they undergo instabilities that lead to their decomposition and dispersion.

Rossow, V. J.

"REDUCTION OF UNCERTAINTIES IN PREDICTION OF WAKE-VORTEX LOCATIONS"

Journal of Aircraft, Vol. 39, No. 4, July-August 2002, pp. 587-596

Lift-generated vortex wakes of subsonic transport aircraft are known to pose a rolling-moment hazard to in-trail following aircraft. Hazardous wake-encounters are now avoided by maintaining in-trail separation distances that are larger than needed for other operational considerations. To increase airport capacity, considerable effort has been devoted to the development of techniques and procedures by which vortex wakes can be accurately located as a function of time so that following aircraft can avoid them with less in-trail spacings. To improve the accuracy with which vortex wakes can be located, this paper reports on a study of the uncertainties associated with the determination of the time-dependent location of vortex wakes, and on ways to reduce the uncertainties. It is found that it is beneficial to reduce the uncertainties as much as possible by application of technology currently available for aircraft guidance, and for measurement of wind velocity along the flight corridor by

aircraft. It appears however, that the growth in the size of the hazardous region surrounding wake vortices is so rapid that it currently prevents the reduction to one minute of in-trail spacings between aircraft during approach to airports. Therefore, if airport capacity is to be increased, it is concluded that it will be necessary to also introduce some other system of sequential flight corridors like the ones illustrated here; e.g., to provide more lateral and vertical distance between the flight paths of aircraft so that wake encounters are avoided.

Rossow, V. J.

"TWO-FENCE CONCEPT FOR EFFICIENT TRAPPING OF VORTICES ON AIRFOILS"

J. Aircraft, Vol. 29, No. 5, September-October 1992, pp. 847-855

Previous work on the use of a vortex trapped above a wing to produce high lift at low angles of attack is extended here. It is first postulated that the optimum way to trap a vortex is to design the airfoil section and wing so that the flow along the vortex core is minimized. It is then shown that a vertical fence both in front of and behind the separation bubble generated by the trapped vortex is an effective way to reduce the mass flow removal and its associated drag to a negligible amount. To show that vertical surfaces upstream and downstream of the vortex separation bubble have an opposite effect on the source requirements for vortex trapping, conformal mapping methods are used to obtain the solutions for a variety of simple two-dimensional, inviscid, incompressible flow configurations. Trapped-vortex flowfield solutions for the flow over flat plate and Clark-Y airfoils are then used to demonstrate that the heights of the fences can be tailored to make the required mass withdrawal (and therefore, the drag due to trapping) to be vanishingly small.

Rossow, V. J.

"EFFECT OF GROUND AND CEILING PLANES ON SHAPE OF ENERGIZED WAKES"

J. Aircraft, Vol. 31, No. 25, September-October 1994, pp. 1227-1231

Results are presented that provide insight into the structure of energized wakes in general and in the presence of ground or ceiling planes when powered-lift devices are tested at zero and low wind-tunnel velocities. It was first found that the vortex sheets (that separate the energized wake from the ambient fluid) are approximately constant in strength and move at constant velocity. This characteristic permits the use of free-streamline theory and mapping methods to obtain a solution for an energized wake in free space. It is shown that such a solution is in good agreement with those obtained with point-vortex and vortex-sheet-segment approximations for the wake edges. All three methods indicate that vortex wakes first move inboard, and sometimes also upward, before they turn and go downward, so that interference between the wake and the energizing surface is more likely. Several solutions were then presented to indicate how the presence of a nearby ground plane causes the energized wake to constrict less than when in free space. In contrast, another set of solutions indicate that the presence of a ceiling plane enhances wake constriction so that the wake width is even smaller than when in free

space. Hence, a ground plane tends to reduce the chance for interaction between the wake and the energizing elements, while a nearby ceiling plane tends to increase the likelihood for interference.

Rossow, V. J.

"VORTEX-FREE FLIGHT CORRIDORS FOR AIRCRAFT EXECUTING COMPRESSED LANDING OPERATIONS"

Journal of Aircraft, Vol. 43, No. 5, September-October 2006, pp. 1424-1428.

A factor that limits airport arrival and departure rates is the need to wait between operations for the wake vortices of preceding aircraft to decay to a safe level. As airport traffic demand increases, creative methods will be needed to overcome the limitations caused by the hazard posed by vortex wakes so that airport capacities can be safely increased. The problem addressed here is the design of vortex-free trajectories for aircraft as they fly from their cruise altitudes down to their final approach paths and to a landing. The guidelines presented recommend that the flight path of each aircraft in a group executing nearly simultaneous landings be spaced far enough apart laterally along organized flight paths so that the vortex wakes of preceding aircraft will not intrude into the airspace to be used by following aircraft. An example is presented as to how a combination of straight lines and circular arcs is able to provide each aircraft in a group with a vortex-free trajectory for nearly simultaneous landing on a set of closely spaced parallel runways. Although the guidelines are described for aircraft on approach, the concepts presented are also applicable to departure, and to enroute operations.

Rossow, V. J.

"ORIGIN OF EXPONENTIAL SOLUTION FOR LAMINAR DECAY OF ISOLATED VORTEX"

Journal of Aircraft, Vol. 43, No. 3, May-June 2006, pp. 709-712

The origin of the exact, closed-form, self-similar exponential solution for the laminar decay of an isolated two-dimensional vortex in a viscous incompressible fluid is studied to find a proper name for the function. Two major contributions to the solution are the similarity parameter derived by Boltzmann and the derivation of the form of the solution by Carslaw for the diffusion of heat from a line source, that is, a spark or lightning stroke. Lamb adapted the heat transfer solution derived by Carslaw to the time-dependent diffusion of vorticity from a potential line vortex, and, after publication of his book, has provided a short, complete, and readily available derivation. Oseen's derivation followed about four years later and is not as complete. Various titles for the solution are believed to be appropriate, including a generic name such as exponential vortex solution, or the name of Lamb. The name of Lamb is probably the most appropriate because he was the first in existing literature to put the entire derivation together and because the presentation is compact, complete, and readily available.

Rossow, V. J.

"MEASURED CHANGES IN VORTEX WAKES WITH DOWNSTREAM DISTANCE"

AIAA Paper No. 1998-2425, Albuquerque, NM, June 1998

Data taken in the NASA 80- by 120-foot Wind Tunnel with 0.03 scale models of two subsonic transports is studied to determine what changes occur with downstream distance in the structure of lift-generated vortex wakes. Since the wind tunnel airstream has a turbulence level of about 0.5 percent, it is found that the downstream changes do not follow a uniform or steady decay process as predicted for vortices in non-turbulent flow fields. Instead of a monotonic decay, the vortices sometimes appear to intensify and sometimes decay much as might be expected in flight as the vortex centerlines become sinuous. Tests conducted on the measured vortex structures indicate that some of the profiles exhibit an exponential character like Lamb's and Squire's model for turbulent vortices. It was also found that most also indicate a logarithmic character suggested by Hoffman and Joubert. The measured rolling moments on following wings do not appear to decrease or increase consistently over the one-mile downstream distance in the wind tunnel.

Rossow, V. J.

"LIFT ENHANCEMENT BY AN EXTERNALLY TRAPPED VORTEX"

J. Aircraft, Vol. 15, No. 9, 1978, pp. 618-625

A theoretical study is made of the performance capabilities of a lift concept that utilizes a spanwise vortex over the upper surface of the wing. The vortex is generated by a vertical flap near the leading edge of the wing and maintained by suction through orifices in endplates at the wingtip. The analysis approximates the three-dimensional flowfield with a two-dimensional configuration that is mapped by conformal transformation into the flow about a circle. Theoretical solutions for a range of flap and orifice configurations predict that section lift coefficients up to around 10 can be achieved. It is concluded that such a lift concept is applicable to STOL aircraft if the vortex can be adequately stabilized and if the endplate suction can be generated efficiently.

Rossow, V. J.

"REDUCTION OF UNCERTAINTIES IN PREDICTION OF WAKE-VORTEX LOCATIONS"

AIAA Paper No. 2000-4130, August 2000, Denver, CO.

Lift-generated vortex wakes of subsonic transport aircraft are known to pose a rolling-moment hazard to in-trail following aircraft. Hazardous wake-encounters are now avoided by maintaining in-trail separation distances that are larger than needed for other operational considerations. To increase airport capacity, considerable effort has been devoted to the development of techniques and procedures by which vortex wakes can be accurately located as a function of time so that following aircraft can avoid them with less in-trail spacings. In order to improve the accuracy with which vortex wakes can be located, this paper reports on a study of the uncertainties associated with the determination of the time-dependent location of vortex wakes, and on ways to reduce the uncertainties. It is found that it is beneficial to reduce the uncertainties as much as possible by application of technology currently available for aircraft guidance, and for measurement of wind

velocity along the flight corridor by aircraft. It appears however, that the growth in the size of the hazardous region surrounding wake vortices is so rapid that it currently prevents the reduction to one minute of in-trail spacings between aircraft during approach to airports. Therefore, if airport capacity is to be increased, it is concluded that it will be necessary to also introduce some other system of sequential flight corridors like the ones illustrated here; e.g., to provide more lateral and vertical distance between the flight paths of aircraft so that wake encounters are avoided.

Rossow, V. J.

"AIRCRAFT SPACINGS THAT PRODUCE VORTEX-FREE REGION BELOW FLIGHT FORMATIONS"

AIAA Paper No. 2002-3263, St. Louis, MO, June 2002

A preliminary theoretical study is presented of a concept whereby the vortex wakes shed by a formation of aircraft can be redirected to produce a large region below the formation that is free of vortices. The redirection of the vortices is accomplished by first spacing the aircraft so that vortex pairs are formed between the wingtips of adjacent aircraft. If the aircraft spacings are within certain limits that are presented in the analysis described here, the self-induced velocity field of the vortex pairs causes all the inboard vortices to move upward rather than downward. One application for such a process is the deployment of paratroopers from aircraft so that, while descending to the ground, no parachute will come near the lift-generated vortices shed by the deploying, or other nearby aircraft. The purpose of the study is to find out whether spacings between aircraft in a formation can be established so that the lift-generated vortices being trailed move upward rather than downward. Since the vortices shed by a single aircraft must always descend, attention was focused on multiple aircraft formations. It was found that the method is aerodynamically feasible. That is, close formations of aircraft can be arranged so that all the inboard trailing vortices move upward rather than downward. The two outboard vortices then travel downward at a greatly reduced velocity that depends on the number of aircraft in the formation. All the inboard region below the formation is then free of vortices.

Rossow, V. J.

"USE OF INDIVIDUAL FLIGHT CORRIDORS TO AVOID VORTEX WAKES"

AIAA Paper No. 2002-4874, Monterey, CA, August 2002

Vortex wakes of aircraft pose a hazard to following aircraft until the energetic parts of their flow fields have decomposed to a harmless level. It is suggested here that in-trail spacings between aircraft can be significantly and safely reduced by designing an individual, vortex-free flight corridor for each aircraft. Since each aircraft will then have its own flight corridor, which is free of vortex wakes while in use by the assigned aircraft, the time intervals between aircraft operations can be safely reduced to the order of seconds. The productivity of airports can then be substantially increased. This paper explores how large the offset distances between operational corridors need to be to have them vortex free, and how airports need to be changed to accommodate an individual-flight-corridor process for landing and takeoff operations. Estimates are then made of the productivity of an individual-flight-corridor process

as a function of the in-trail time interval between operations for various values of wake decay time, runway width, and the velocity of a sidewind. The results confirm the need for short time intervals between aircraft operations if smaller offset distances and increased productivity are to be achieved.

"HISTORICAL OVERVIEW OF RESEARCH ON LIFT-GENERATED VORTEX WAKES"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002.

A historical overview is presented of early research conducted on the structure and modification of the vortices generated by the lifting surfaces of subsonic transport aircraft. After some general remarks on wake-vortex research, a summary is presented of the earliest published work on lift-generated wakes. A description is then given of the flight test program carried out by the National Aeronautics and Space Administration (NASA) and the Federal Aviation Administration (FAA) of the United States during the late 1960's and early 1970's. The objective of the flight tests was to quantify the hazard posed by vortex wakes of aircraft, and to more clearly define the in-trail separation distances required between aircraft during landing and takeoff at airports. The flight test program led to a set of separation distances that insure safe approach and departure procedures at airports. Since across-wake procedures at cruise altitudes were not treated in detail, a study was undertaken to determine the structure of vortex wakes at altitude as a function of time. Photographs taken of condensation trails of aircraft, indicate that some instabilities cause the wake to grow rapidly in cross-section even before the long-wave instability begins to occur. It appears that a short-wave type of instability causes the vortex oval to grow by about a factor of 5, but does not lead to an incoherent wake structure.

"AIRCRAFT SPACINGS THAT PRODUCE VORTEX-FREE REGION BELOW FLIGHT FORMATIONS"

Journal of Aircraft, Vol. 38, No. 6, November-December 2001, pp. 977-987

A preliminary theoretical study is presented of a concept whereby the vortex wakes shed by a formation of aircraft can be redirected to produce a large region below the formation that is free of vortices. The redirection of the vortices is accomplished by first spacing the aircraft so that vortex pairs are formed between the wingtips of adjacent aircraft. If the aircraft spacings are within certain limits that are presented in the analysis, the self-induced velocity field of the vortex pairs causes all of the inboard vortices to move upward rather than downward. One application for such a process is the deployment of paratroopers from aircraft so that, while descending to the ground, no parachute will come near the lift-generated vortices shed by the deploying, or other nearby aircraft. The purpose of the study is to find out whether spacings between aircraft in a formation can be established so that the lift-generated vortices being trailed move upward rather than downward. Because the vortices shed by a single aircraft must always descend, attention was focused on multiple aircraft formations. It was found that the method is feasible and makes it possible to arrange close formations of aircraft so that all the inboard trailing vortices move upward rather than downward. The two outboard vortices then

travel downward at a greatly reduced velocity that depends on the number of aircraft in the formation. All the inboard region below the formation is then free of vortices. The stability of spacings between aircraft in successful formulations and the instrumentation required for implementation of the concept introduced are not treated.

"EXTENDED-BETZ METHODS FOR ROLL-UP OF VORTEX SHEETS"

J. Aircraft, Vol. 34, No. 5, September-October 1997, pp. 592-599.

The method derived for the roll-up of vortex sheets shed by lifting wings has been extended so that it can be applied to complex wakes that roll up into more than one vortex pair. Although these so-called extended-Betz methods often predict realistic vortex structures that approximate measured ones, the guidelines need to be improved if the predictions are to be reliable enough for such purposes as the assessment of the hazard posed by a wake or for the validation of other theoretical methods. This paper first describes the problem and then considers whether the five vortex invariants for the time-dependent motion of two-dimensional vortices can provide improved guidelines. In particular, the vortex invariants are studied to find out if they can be used to determine the initial division of the vortex sheet for separation into multiple vortices, and then possible merger into larger vortices. It is concluded that any refinements of the present forms of the extended-Betz methods to better define the structure of multiple vortex wakes will be very difficult and probably cannot be derived from the vortex invariants.

Rossow, V. J.

"ON USE OF GLOBAL POSITIONING TECHNOLOGY FOR SOLUTION OF WAKE-VORTEX PROBLEM"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 43-48

Improved precision of the flight paths used by aircraft to approach and depart airports becomes available when the Global Positioning System (GPS) is implemented at airports. An overview will be given of published information on how GPS precision guidance at airports can be used to avoid encounters with the lift-generated vortices shed by preceding aircraft during landing. It is pointed out that GPS provides two needed services to bring about improved avoidance capability. Firstly, GPS pseudolites are being built and installed at airports so that, when coupled with autopilot systems currently available on subsonic transport aircraft, the aircraft can make precision approaches for zero visibility landings. The same equipment can also be used for precision approaches for wake-vortex avoidance. Secondly, regular monitoring of atmospheric motions along the approach corridor can be obtained by use of GPS equipment on board aircraft that are in the flight corridors. That is, wind velocity is determined by use of GPS equipment to measure the ground speed of the aircraft and then combined with onboard instrumentation to measure the airspeed of the aircraft. The difference between the two measurements yields the wind velocity. When the measured wind velocities are

transmitted to an airport ground station, they are used to monitor whether air motions adverse for safety in the flight corridor are present. If any part of the corridor is unsafe, the spacing of the aircraft, or location of the flight corridor being used, is modified. It is estimated that the spacings between any combination of aircraft can then be safely reduced to a uniform 3 n. mi.

"WAKE VORTEX STRUCTURE FROM LIFT AND TORQUE INDUCED ON A FOLLOWING WING"

AIAA Paper No. 1993-3013, Orlando, FL, 1993

The large wind tunnels at NASA Ames Research Center are frequently used to obtain data on the potential rolling-moment hazard posed by the vortex wake of one aircraft on an aircraft that is following. The results have been found to be a reliable indication of the rolling moment to be expected during a full-scale flight encounter. A disadvantage of the technique is that the data taken in the wind tunnel applies only to the aircraft pair tested. An evaluation of the rolling moments for all possible encounter pairs then requires that all aircraft pairs or wings of interest be tested. Such a requirement is time consuming and expensive. For this reason, a procedure is being developed that uses vortex-lattice theory to interpret the lift and torque measured on a following model in a wind tunnel to retrieve the velocity distribution in the vortex wake that caused the induced forces. It will then be possible to use the wind tunnel data from one encounter pair to predict theoretically the rolling moments expected when any other aircraft or wing encounters the same vortex wake. A procedure used to retrieve the wake velocity distribution, and test cases used to check out and evaluate the procedure are first described. Since a procedure was found that provides very good results for theoretical cases, it is applied to wind tunnel measurements obtained with a model of a large wide-body transport aircraft as the wake-generating aircraft and with various following wings. The retrieved wake-vortex velocities are compared with each other and with measured upwash distributions. The comparisons made test not only the retrieval procedure presented here, but also test the ability of wake-vortex models to represent lift-generated wakes.

"VALIDATION OF VORTEX-LATTICE METHOD FOR LOADS ON WINGS IN LIFT-GENERATED WAKES"

J. Aircraft, Vol. 32, No. 6, November-December 1995, pp. 1254-1262

A study is described that evaluates the accuracy of vortex-lattice methods when they are used to compute the loads induced on aircraft as they encounter lift-generated wakes. The evaluation is accomplished using measurements made in the 80 by 120 ft Wind Tunnel of the lift, rolling moment, and downwash in the wake of three configurations of a model of a subsonic transport aircraft. The downwash measurements are used as input for a vortex-lattice code to compute the lift and rolling moment induced on wings that have a span of 0.186, 0.510, or 1.022 times the span of the wake-generating model. Comparison of the computed results with the measured lift and rolling-moment distributions using the vortex-lattice method is very reliable as long as the span of the encountering or

following wing is less than about 0.2 of the generator span. As the span of the following wing increases above 0.2, the vortex-lattice method continues to correctly predict the trends and nature of the induced loads, but it overpredicts the magnitude of the loads by increasing amounts.

Rossow, V. J.

"MEASUREMENTS IN VORTEX WAKES SHED BY CONVENTIONAL AND MODIFIED SUBSONIC AIRCRAFT"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 26-1 to 26-9

A theoretical and experimental program is underway at NASA Ames Research Center to first obtain a better understanding of the hazard posed by the vortex wakes of subsonic transports, and then to develop methods on how to modify the wake-generating aircraft to make the vortices less hazardous. This paper summarizes results obtained in the 80-by 120-Foot Wind Tunnel at NASA Ames Research Center on the characteristics of the vortex wakes that trail from 0.03 scale models of a B-747 and of a DC-10. Measurements are first described that were taken in the wakes with a hot-film anemometer probe, and with wings that range in size from 0.2 to 1.0 times the span of the wake-generating models, at downstream distances of 81 ft and 162 ft behind the wake-generating model; i.e., at scale distances of 0.5 and 1.0 mile. The data are then used to evaluate the accuracy of a vortex-lattice method for prediction of the loads induced on following wings by vortex wakes.

Rossow, V. J.

"WAKE-VORTEX SEPARATION DISTANCES WHEN FLIGHT-PATH CORRIDORS ARE CONSTRAINED"

J. Aircraft, Vol. 33, No. 3, May-June 1996, pp. 539-546

Improved precision of the flight paths used by aircraft to approach and depart airports will become available when the global positioning system (GPS) is implemented for air traffic control. It is suggested here that the improved precision be used to constrain the approach and departure corridors so that their cross-sectional sizes are small and constant in size. Such a constraint controls the flight paths of the aircraft, and consequently where their vortex wakes are placed, so that the likelihood of a wake-vortex encounter is reduced. If such a program is coupled with a wake-vortex advisory system, and with the operating system being planned for airports when GPS is implemented, preliminary indications are that the wake-vortex spacings currently being used for instrument flight conditions can be reduced to a uniform distance of 3 n mile. Furthermore, if the smaller GPS flight corridors are utilized by vortex advisory or forecast systems that are currently under development, the requirements to be placed on their capabilities can be substantially reduced.

Rossow, V. J.

"VORTEX STRUCTURES AND SPAN LOADINGS FROM ALLEVIATED WAKE MEASUREMENTS"

AIAA Paper No. 1997-2262, Atlanta, GA, June 1997

To find efficient wing designs that shed non-hazardous vortex wakes, an analysis is made of data taken in the wakes of three configurations of a subsonic transport. The study begins with the observation that alleviated-wake configurations often shed vortex wakes that induce about the same rolling-moment coefficient on following aircraft of all sizes. In order to determine the span loadings that correspond to these downstream vortex wakes, the analysis first finds the vortex structures that make up the measured downwash distributions. An inverse Betz method is then used to derive the corresponding span loadings. Analysis of these span loadings, and consideration of the induced drag and the energy in various wakes, yields information on some of the characteristics and penalties associated with the design of wings for less hazardous wakes. It is recommended that tools be developed for an optimization process that includes drag, wing-root bending moment, weight, complexity, etc. and the design of vertical and horizontal lifting surface for vortex wakes that have an acceptable hazard.

Rossow, V. J.

"ESTIMATE OF LOADS DURING WING-VORTEX INTERACTIONS BY MUNK'S TRANSVERSE-FLOW METHOD"

J. Aircraft, Vol. 27, No. 1, January 1990, pp. 66-74.

The inviscid, incompressible interaction of a wing with a vortex is studied by use of Munk's transverse-flow method. The method assumes that the loading on the wing is such that the local circulatory flow of the vortex is turned so that the wing and its vortex wake act as a barrier to the flow. This permits the analysis to be carried out by mapping the transverse flowfield into the flow about a circle to find the vorticity distribution in the wake. Closed-form expressions are then derived for the bound circulation in the wing and for the lift and rolling moment induced by the vortex on the encountering wing. Comparisons of the loads predicted by these relationships with those of vortex-lattice theory for a flat wing of a rectangular planform indicate that they accurately represent the various parameters when the aspect ratio of the encountering wing is less than about two. When flat rectangular wings of higher aspect ratios are considered, some sort of correction is needed. Examples are then presented to illustrate some applications of the results.

Rossow, V. J.

"PROSPECTS FOR ALLEVIATION OF HAZARD POSED BY LIFE-GENERATED WAKES"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 22-1 - 22-40

A review is first made of the successes and failures of previous attempts to bring about a substantial reduction in the rolling-moment hazard posed by the vortices that trail from the wings of subsonic transport aircraft. It is concluded that one of the more promising wake-alleviation schemes uses the span loading on the wing to produce vorticity distributions in the wake that will bring about large self-

induced cross-stream velocities. When this characteristic has been established, the vorticity in the wake is convected about so that the coherent rotary velocities are turned into large-scale random motions that decompose quickly into a non-hazardous wake. It appears that a wide range of span-loadings/wake-vortex distributions will produce these large-scale, self-induced motions. It remains however, to find those that bring about the desired wake dynamics with the least addition of drag and complexity to the wake-generating aircraft. A combined theoretical and experimental research program at NASA Ames Research Center is directed at finding design guidelines for implementation of wake-vortex alleviation on subsonic transport aircraft. The experimental part of the program will include tests in the 80- by 120-foot wind tunnel at scale distances up to one and one-half nautical miles.

Rossow, V. J.

"CONVECTIVE MERGING OF VORTEX CORES IN LIFT-GENERATED WAKES"

J. Aircraft, Vol. 14, No. 3, March 1977, pp. 283-290

The several wake vortices that originate from aircraft wingtips, flap edges, engine pylons, etc. usually merge, in the far field to form a single pair whose structure determines the hazard posed to encountering aircraft. To gain an understanding of the process whereby vortices merge and disperse, a numerical study was made of the interaction of two-dimensional, time-dependent, inviscid vortical regions. It was found that discrete boundaries, which depend on the structure and spacing of the vortices, distinguish merging from nonmerging situations. Furthermore, certain arrays of finite vortex cores that alternate in sign were found to undergo division and merging that may be useful in alleviating the hazard posed by aircraft wakes.

Rossow, V. J.

"ALLEVIATION OF LIFT-GENERATED WAKES BY VORTEX INTERACTIONS"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 150-160.

The requirements for wake alleviation by inviscid convective interaction of vortices are reviewed. It is concluded that these wake structures will disperse and merge to alleviate the wake hazard, but unacceptably large aerodynamic penalties occur when the required loadings are generated by use of trailing-edge flap deflections. It is suggested, therefore, that the vortex pairs of opposite sign be generated above or below the wing with devices such as fins, fences, engine thrust, etc. Guidelines for the effective disposition and strength of these extra or auxiliary vortices are derived and numerical examples are presented for various configurations. Results of some preliminary wind-tunnel experiments confirmed that vortex injection into a wake by fins provides alleviation and warrants further study to optimize the various design parameters.

Rossow, V. J.

"EFFECT OF WING FINS ON LIFT-GENERATED WAKES"

J. Aircraft, Vol. 15, No. 3, March 1978, pp. 160-167

A theoretical and experimental study has been made of the effect of wing-mounted fins on the vortex wakes of subsonic aircraft. The lateral lift on the fins injects vortices into the wake and redistributes the lift on the wing. The revised wake vorticity then interacts convectively to form a new configuration with low rotational velocities. Wind-tunnel tests were used to evaluate the alleviation achievable and to find the optimum values for the various fin parameters. It was found that vertical fins mounted on the upper surface of a wing could lower the wake-induced rolling moments on an encountering wing by a factor of 3 or more.

Rossow, V. J.

"EXPERIMENTAL INVESTIGATION OF WING FIN CONFIGURATIONS FOR ALLEVIATION OF VORTEX WAKES OF AIRCRAFT"

NASA TM-78520, November 1978, NASA Ames Research Center, Moffett Field, CA

A variety of fin configurations were tested on a model of the Boeing B747 in the 40- by 80-Foot Wind Tunnel at Ames Research Center and in the Ship Model Basin at Hydronautics, Inc., near Laurel, Maryland. The test results confirmed that a reduction in wake rolling moment is brought about by the vortex shed by the fins so that a wide range of designs can be used to achieve wake alleviation. It was also found that the reduction in wake-induced rolling moments is especially sensitive to the location of the smaller fins on the wing and that the penalties in lift and drag can probably be made negligible by proper fin design.

Rossow, V. J.

"WAKE HAZARD ALLEVIATION ASSOCIATED WITH ROLL OSCILLATIONS OF WAKE-GENERATING AIRCRAFT"

J. Aircraft, Vol. 23, No. 6, June 1986, pp. 484-491.

An explanation is provided for the difference in wake vortex alleviation achieved by roll oscillations during flight tests with B-747 and L-1011 transport aircraft. Both aircraft had their landing flaps extended and several spoilers deployed. Numerical analysis shows that the growth in amplitude of the initial waves in the vortex filaments is brought about by inviscid vortex interactions. In the case of the B-747, growth is enhanced by a vortex whose strength is about the same as the tip vortex that is shed near the fuselage by the inboard end of the flaps. Conversely, the L-1011 is estimated to shed a negligible fuselage vortex and to have a relatively strong wing tip vortex. These characteristics bring about a rotation and a large amplification of the initial waves in the vortex filaments in the wake of the B-747, but not in the L-1011 vortex wake. An aircraft following the B-747 would then experience only

intermittent encounters with the intense parts of the wake vortices, such that the time-averaged wake-induced rolling moment is substantially reduced.

Rossow, V. J.

"PROSPECTS FOR DESTRUCTIVE SELF-INDUCED INTERACTIONS IN A VORTEX PAIR"

J. Aircraft, Vol. 24, No. 7, July 1987, pp. 433-440

The vortex wakes of large transport aircraft can pose a hazard to smaller following aircraft in the vicinity of airports during landing and takeoff operations if certain separation guidelines are not observed. To reduce the hazard potential, and thereby the separation distances, efforts are being made to find more rapid wake-dissipation mechanisms. In this paper, numerical simulations are made of the three-dimensional time-dependent instabilities that might be initiated in a vortex pair by sinusoidal displacements of the filaments. The objective of the study is to find those displacements and phase angles that produce the most rapid destruction of the vortices. It is concluded that, of the wave patterns tried on the one pair of wake filaments, the only instability made that leads to destructive interactions of the vortices is the Scorer-Crow process.

Rossow, V. J.

"SPUR-TYPE INSTABILITY OBSERVED ON NUMERICALLY SIMULATED VORTEX FILAMENTS"

J. Aircraft, Vol. 25, No. 9, September 1988, pp. 835-841

An instability observed on vortex filaments during numerical simulations of the three-dimensional, time-dependent dynamics of vortex wakes is studied to determine when and why it occurs. It is concluded that the observed instability is a consequence of the use of straight-line vortex segments of finite length to model continuously curving vortex filaments. The instability appears to occur only when the link length is a sizeable fraction of the vortex span and, therefore, is not expected in an experiment. Guidelines are then given that help avoid numerical instabilities when vortex filaments are used in flow simulations.

Rossow, V. J.

"THEORETICAL STUDY OF LIFT-GENERATED VORTEX SHEETS DESIGNED TO AVOID ROLL-UP"

NASA TMX-62,304, September 1973, NASA Ames Research Center, Moffett Field, CA

The random motions of the vortex elements behind a wing that sheds a disturbed translating array of vortices are analyzed. The analysis indicates that the wake would diffuse and decay rapidly when viscosity is present and would produce small rolling moments on encountering aircraft. It was found that comparable results could also be achieved with an array consisting of vortices that are equal in magnitude but which alternate in sign. This observation indicates that random motion can probably be achieved with a variety of stepped loadings.

Rossow, V. J.

"ON THE INVISCID ROLLED-UP STRUCTURE OF LIFT-GENERATED VORTICES"

J. Aircraft, Vol. 10, No. 11, November 1973, pp. 647-650

A simple form is presented of the relationships derived by Betz for inviscid, fully developed structure of lift-generated vortices behind aircraft. An extension is then made to arbitrary span-load distributions by inferring guidelines for the selection of rollup centers for the vortex sheet. These techniques are easier to use and yield more realistic estimates of the rolled-up structure of vortices than the original form of Betz' theory when the span loading differs appreciably from elliptic loading.

Rossow, V. J.

"SURVEY OF COMPUTATIONAL METHODS FOR LIFT-GENERATED WAKES"

Aerodynamic Analyses Requiring Advanced Computers, Part I, NASA SP-347, 1975, pp. 897-923

The persistence and strength of vortices that trail behind heavy aircraft have recently caused attention to be focused on the potential hazard they present to smaller aircraft that might encounter them. A survey is made here of some computational methods that are used to predict the structure and duration of these lift-generated vortices and to explore mechanisms that might significantly reduce their lifetime and hazard potential.

Rossow, V. J.

"THEORETICAL STUDY OF LIFT-GENERATED VORTEX WAKES DESIGNED TO AVOID ROLLUP"

AIAA Journal, Vol. 13, No. 4, April 1975, pp. 476-484

Two hypothetical vortex wakes are introduced and studied theoretically to explore whether the rollup of lift-generated vortex sheets can be suppressed. The circulation distribution across each wake is specified such that one rotates and the other translates as a unit due to their self-induced velocities. Several span loadings are constructed from these solutions and the resulting inviscid wake structure is computed for several span lengths behind the generating wing by use of the discrete vortex method wherein the vortex wake is represented by an array of vortices. The final distribution of vortices is then used to estimate the rolling moment on an encountering wing. It is found that, even though the initial specified motions are not sustained, substantial reductions in rolling moment are predicted for certain ranges of the ratio of the span of the generating wing to the following wing.

Rossow, V. J.

"PREDICTION OF SPAN LOADING FROM MEASURED WAKE-VORTEX STRUCTURE -AN INVERSE BETZ METHOD"

J. Aircraft, Vol. 12, No. 7, July 1975, pp. 626-628

The Betz theory is based on the conservation equations for inviscid, two-dimensional vortices and predicts the circulation in the fully-developed vortex from the span loading on the generating wing. The relationship between span loading and vortex structure is extended here by introducing a so-called inverse rollup method that predicts the span loading on the generating wing when the radial distribution of circumferential velocity in the vortex is given. Several examples are presented wherein measured circumferential velocities in several vortices are used with the inverse method to infer the span loading that produced the vortices. These span loadings are compared with those predicted by vortex-lattice theory for the generating wing. The technique yields a fairly accurate representation of the span loading on the generating wing when turbulence effects are not large.

Rossow, V. J.

"INVISCID MODELING OF AIRCRAFT TRAILING VORTICES"

Proceedings Wake Vortex Minimization Symposium, NASA, SP-409, 1977, pp. 9-60

A survey is presented of inviscid theoretical methods that have proven useful in the study of lift-generated vortices. Concepts derived using these inviscid theories are then presented which have helped to guide research directed at alleviating the velocities and rolling moments imposed on aircraft entering these wakes.

Rossow, V. J.

"LIFT-GENERATED VORTEX WAKES OF SUBSONIC TRANSPORT AIRCRAFT"

Progress in Aerospace Sciences, Vol. 35, No. 6, 1999, pp. 507-660

The flow fields of vortices, whether buoyancy-driven or lift-generated, are fascinating fluid-dynamic phenomena which often possess intense swirl velocities and complex time-dependent behavior. As part of the on-going study of vortex behavior, this paper presents a historical overview of research conducted on the structure and modification of the vortices generated by the lifting surfaces of subsonic transport aircraft. Although primarily presented from an experimental point of view, the derivation and use of relatively compact theoretical formulations and concepts are included. Experience with lift-generated wakes has shown that they are so complex that progress requires application of a combined theoretical and experimental research program, because either alone often leads to incorrect conclusions. The primary purpose of the research to be described is to find a way to reduce the hazard potential of lift-generated vortices shed by subsonic transport aircraft in the vicinity of airports during landing and takeoff operations. The information presented points out that the characteristics of lift-generated vortices are related to the aerodynamic shapes that produce them and that various arrangements of surfaces can be used to produce quite different vortex structures. It is

concluded that a satisfactory aerodynamic solution to the wake-vortex problem at airports has not yet been found, but a reduction in the impact of the wake-vortex hazard on airport capacity may soon become available through wake-vortex avoidance concepts currently under study.

Rossow, V. J.

"APPLICATION OF VORTEX INVARIANTS TO ROLL UP OF VORTEX PAIRS"

Journal of Aircraft, Vol. 41, No. 5, September-October 2004, pp. 1098-1105.

A method developed by Betz for the rolled-up structure of vortices shed by isolated wing tips is extended to vortex pairs (two vortical regions of opposite sign), which are shed by wings of finite span. The present analysis again uses the invariants for the two-dimensional time-dependent motion of vortex systems, but the extension made here to vortex pairs depends primarily on the invariant for kinetic energy. It is found that the total energy in the flowfield can be separated into a part that governs the structure of each vortical region and a part that governs the spanwise distance between the centroids of the vortical regions. Consequently, the rules for the rolled-up structure of vortical regions are the same as the one derived by Betz. Because the analysis does not apply a constraint that forces the circular contours of constant circulation to coincide with streamline paths, the solution is labeled first order. A method that can be used to obtain second- and higher-order approximations is described. Application of the first-order method to the vortex wake of an elliptically loaded wing indicates that a first-order solution for vortex pairs is adequate for many engineering purposes. The method derived here for single vortex pairs also justifies the superposition of axially symmetric vortical cores to simulate complex vortex wakes.

Rossow, V. J.

"INITIATION OF LONG-WAVE INSTABILITY OF VORTEX PAIRS AT CRUISE ALTITUDES"

NASA/TM-2011-216420, Feb. 2011, NASA Ames Research Center, Moffett Field, CA.

Previous studies have usually attributed the initiation of the long-wave instability of a vortex pair to turbulence in the atmosphere or in the wake of the aircraft. The purpose here is to show by use of observations and photographs of condensation trails shed by aircraft at cruise altitudes that another initiating mechanism is not only possible but is usually the mechanism that initiates the long-wave instability at cruise altitudes. The alternate initiating mechanism comes about when engine thrust is robust enough to form an array of circumferential vortices around each jet-engine-exhaust stream. In those cases, initiation begins when the vortex sheet shed by the wing has rolled up into a vortex pair and descended to the vicinity of the inside bottom of the combined shear-layer vortex arrays. It is the in-and-out (up and down) velocity field between sequential circumferential vortices near the bottom of the array that then impresses disturbance waves on the lift-generated vortex pair that initiate the long-wave instability. A time adjustment to the Crow and Bate estimate for vortex linking is then derived for cases when thrust-based linking occurs.

Rossow, V. J. and Brown, A. P.

"EFFECT OF JET-EXHAUST STREAMS ON STRUCTURE OF VORTEX WAKES"

Journal of Aircraft, Vol. 47, No. 3, May-June 2010, pp. 1076-1083.

The study reported here was initiated by observations of condensation trails that occur behind transport aircraft at cruise altitudes under certain atmospheric conditions. The objective of the study reported is to explain why the structure of condensation trails behind aircraft at cruise altitudes differ in some respects from those predicted by classical theory for the roll-up of lift-generated vortex sheets. Because classical roll-up theory does not include the effect of jet-engine exhaust on wake structure, numerical simulations were carried out for the time-dependent interaction of jet-exhaust streams with lift-generated vortex distributions. The simulations indicate that inclusion of jet-exhaust effects produces results that more closely represent observed wakes than those calculated by means of classical roll-up theory. In particular, jet-exhaust streams appear to cause wakes to separate into several nearby parts so that the vertical depth of the wake is increased by over a factor of two. It is therefore recommended that wake-prediction methods include the effect of jet-exhaust streams during takeoff, climb and cruise. Current prediction methods for wake-hazardous regions during approach and landing at airports probably do not need to be changed because engine thrust is small during those operations.

"OVERVIEW OF WAKE-VORTEX HAZARDS DURING CRUISE"

AIAA Paper 1999-3197, July 1999, Norfolk, VA.

A large amount of research effort has been devoted to the hazard posed by lift-generated wakes of subsonic transport aircraft during approach and departure at airports. In contrast, only a small amount of effort has gone into the corresponding potential hazard at cruise altitude. Since more frequent encounters with wakes may occur as the density of aircraft increases with time, improved knowledge is needed of the persistence and magnitude of the hazard posed by lift-generated wakes at cruise altitudes. This paper reviews and extends previous work by describing the various fluid dynamic stages that vortex wakes usually go through as they age. Estimates made of the potential hazard that each stage poses indicate that the rolling-moment hazard during an axial encounter of a vortex wake can be as severe at cruise as for approach at airports, but, as in the airport-approach case, the hazard only persists for several minutes (about 20 nmi) behind the generating aircraft. However, the hazard posed by the downwash in the wake persists for tens of minutes (about 200 nmi) behind the generating aircraft. The downwash hazard is realized as severe vertical loads. A technique for avoiding vortex wakes at cruise altitude is described.

Rossow, V. J. and James, K. D.

"OVERVIEW OF WAKE-VORTEX HAZARDS DURING CRUISE"

J. Aircraft, Vol. 37, No. 6, November-December 2000, pp. 960-975

A large amount of research effort has been devoted to the hazard posed by lift-generated wakes of subsonic transport aircraft during approach and departure at airports. In contrast, only a small amount of effort has gone into the corresponding potential hazard at cruise altitude. Since more frequent encounters with wakes may occur as the density of aircraft increases with time, improved knowledge is needed of the persistence and magnitude of the hazard posed by lift-generated wakes at cruise altitudes. This paper reviews and extends previous work by describing the various fluid dynamic stages that vortex wakes usually go through as they age. Estimates made of the potential hazard that each stage poses indicate that the rolling-moment hazard during an axial encounter of a vortex wake can be as severe at cruise as for approach at airports, but, as in the airport-approach case, the hazard only persists for several minutes (about 20 nmi) behind the generating aircraft. However, the hazard posed by the downwash in the wake persists for tens of minutes (about 200 nmi) behind the generating aircraft. The downwash hazard is realized as severe vertical loads. A technique for avoiding vortex wakes at cruise altitude is described.

"RELATIONSHIP BETWEEN VORTEX MEANDER AND AMBIENT TURBULENCE"

AIAA Paper No. 2006-7811, Wichita, KS, September 2006

Efforts are underway to increase the capacity of airports by use of closely-spaced parallel runways. If achieved safely and efficiently during both visual and instrument flight conditions, it will be necessary to develop more precise methods for the prediction of the motion and spread of the hazard posed by lift-generated vortex-wakes of aircraft. The purpose of the present study is to relate the magnitude of the meandering motion of vortex filaments to the turbulence level in the ambient flow field. The analysis begins with a study of the observations made in the airstreams of the two largest NASA wind tunnels where a small amount of data are available on the magnitude of turbulence-induced vertical and lateral meander of vortices shed by aircraft models. It is found that the turbulence level based on the maximum amplitude of meander is much less than the root-mean-squared value measured in the free-stream of the wind tunnel by use of hot-film anemometers. An analysis of the time-dependent motion of segments of vortex filaments as they interact with an eddy, indicates that the inertia of the filaments and of vortex ovals retards their motion enough in the early part of their travel to account for a large part of the difference in the two determinations of turbulence level. It is concluded that vortices do not move precisely with the fluid elements where they are embedded, but lag behind so that actual meander distances are a fraction of those estimated by the non-slip assumption. Application is then made of the foregoing relationships to meander distances used for the initiation of the long-wave instability, which contributes substantially to wake intrusion distances during landing and takeoff operations at airports. It was found that the best simulation predicts that ovals meander about 58% of the distance predicted without slippage. Because turbulent flow fields are a mixture of eddies rather than a single eddy, a further reduction to the 40% value found in the wind tunnels appears reasonable.

"GUIDELINES FOR AVOIDING VORTEX WAKES DURING USE OF CLOSELY SPACED PARALLEL RUNWAYS"

NASA/TM-2012-215985, January 2012, Ames Research Center, Moffett Field, CA.

A method is proposed for the estimation of the movement and spread of lift-generated vortex wakes as a function of time to better enable aircraft arriving at airports to avoid the hazards associated with the wakes of preceding aircraft. Operations on closely spaced parallel runways are used to illustrate how the method may be applied. The paper begins with an overview of the aerodynamic mechanisms that cause the hazardous parts of lift-generated wakes to spread and to move as a function of time. A computational method is then presented for the determination of the spread and movement of the hazardous parts of vortex wakes as a function of time during operations of aircraft as they approach closely spaced parallel runways for a landing. The results suggest guidelines for efficiently and effectively avoiding the vortex wakes of preceding aircraft. Because uncertainties occur in the theoretical tools developed and, in the measurements, made of the components of the time-averaged wind and its gust magnitudes, flight tests are recommended to confirm and refine the guidelines presented, and to verify the techniques used to measure the atmospheric parameters that control intrusion of the hazardous elements of lift-generated wakes into nearby parallel runways.

"GUIDELINES FOR AVOIDING VORTEX WAKES DURING USE OF CLOSELY-SPACED PARALLEL RUNWAYS"

AIAA Paper 2008-6907, Honolulu, HI, August 2008

This paper proposes a reliable method for estimation of the movement and spread of lift-generated vortex wakes as a function of time to better enable aircraft arriving at airports to avoid the hazards associated with the wakes of preceding aircraft. Operations on closely-spaced parallel runways illustrate how the method may be applied. An overview presents the aerodynamic mechanisms that cause the hazardous parts of lift-generated wakes to spread as a function of time. A computational method developed for determination of the spread of vortex wakes as a function of time is then applied to operations of aircraft as they approach closely-spaced parallel runways. The results suggest guidelines for efficiently and effectively avoiding the vortex wakes of preceding aircraft. Because the theoretical tools developed and the measurements of the components of the time-averaged wind and its gust magnitudes contain uncertainties, flight tests are recommended to confirm and to refine the guidelines presented, and to verify the techniques used to measure the atmospheric parameters that control wake intrusion.

"ON DATA SCATTER IN MEASURED LINKING TIMES FOR LIFT-GENERATED VORTEX PAIRS"

AIAA Paper No. 2008-338, Reno, NV, January 2008

The long-wave instability of a vortex pair spreads vortex wakes vertically and laterally faster than any other known aerodynamic mechanism. Initiated by turbulence in the atmosphere, the long-wave

instability occurs frequently. However, measurements in flight of the timing of the process for a range of atmospheric turbulence levels contain a large amount of scatter around predicted values. Possible causes for data scatter are studied by use of a formulation for initiation and growth of the instability that differs slightly from Crow's and Sarpakaya's. It is concluded that some of the scatter may be because the strength of vortex filaments in vortex pairs may sometimes be lower than the total centerline circulation on the wing, which causes the growth rate of the instability to be less than predicted. Another source for uncertainty may be caused by the way that the strength of the turbulence in the atmosphere was measured. Suggestions are made on how to use existing information to estimate the growth rate of the instability, and on how the turbulence in the atmosphere should be measured to achieve reliability.

"RESEARCH ON AIRCRAFT/VORTEX-WAKE INTERACTIONS TO DETERMINE ACCEPTABLE LEVEL OF WAKE INTENSITY"

J. Aircraft, Vol. 25, No. 6, June 1988, pp. 481-492.

An evaluation of the literature on large aircraft wake-vortex encounters in flight and in flight simulators has furnished an estimate of the level to which the vortex-induced rolling moments must be reduced to be perceived as nonhazardous at a 2-n.mi. separation distance. The criteria are based on the ratio of the vortex-induced acceleration in roll to the aileron-induced roll acceleration. A wake is acceptably alleviated if the ratio of vortex-to-aileron rolling moments is less than about 0.5. When a satisfactory alleviation scheme is identified, the alleviated vortex structure should be inserted into a simulator to ascertain whether the maximum bank angles induced are within tolerable limits.

"MEASUREMENTS OF THE VORTEX WAKES OF A SUBSONIC- AND A SUPERSONIC-TRANSPORT MODEL IN THE 40- BY 80-FOOT WIND TUNNEL"

NASA TM X-62,391, September 1974, NASA Ames Research Center, Moffett Field, CA.

The rolling moment induced on aircraft models in the wake of a model of a subsonic transport and of a supersonic transport was measured as a function of angle of attack for several configurations. A description of the tests and a presentation and analysis of the data is given.

Rossow, V. J., Corsiglia, V. R., Schwind, R. G., Frick, J. K. D. and Lemmer, O. J.

"VELOCITY AND ROLLING-MOMENT MEASUREMENTS IN THE WAKE OF A SWEPT-WING MODEL IN THE 40- BY 80-FOOT WIND TUNNEL"

NASA TM X-62414, April 1975, NASA AMES Research Center, Moffett Field, CA.

Measurements were made in the wake of a swept-wing model to study the structure of lift-generated vortex wakes shed by conventional span loadings and by several span loadings designed to reduce wake velocities. Variations in the span loading on the swept-wing generator were obtained by deflecting seven flap segments on each side by amounts determined by vortex-lattice theory to approximate the desired span loadings. The resulting wakes were probed with a three-component, hot-wire probe to measure velocity, and with a wing to measure the rolling moment that would be induced on a following aircraft. The experimental techniques are described, and the measured velocity and rolling moments are presented, along with some comparisons with the applicable theories.

Rossow, V. J., Fong, R. K., Wright, M. S. and Bisbee, L.

"VORTEX WAKES OF TWO TRANSPORTS MEASURED IN 80 BY 120 FOOT WIND TUNNEL"

J. Aircraft, Vol. 33, No. 2, March-April 1996, pp. 399-406

Measurements are reported on the characteristics of the vortex wakes that trail from 0.03-scale models of a B-747 and a DC-10. Included are the downwash distributions obtained with a hot-film anemometer probe for the standard landing configurations, and the rolling moments induced on various following wings by the vortex wakes of several configurations of both wake-generating models. Both sets of data are presented for downstream distances of 81 and 162 ft, i.e., scale distances of 0.5 and 1.0 mile.

Rossow, V. J., Hardy, G. H. and Meyn, L. A.

"MODELS OF WAKE-VORTEX SPREADING MECHANISMS AND THEIR ESTIMATED UNCERTAINTIES"

AIAA Paper No. 2005-7353, Arlington, VA, September 2005

One of the primary constraints on the capacity of the nation's air transportation system is the landing and takeoff capacities at its busiest airports. Efforts currently underway to increase the capacity of airports by use of closely-spaced runways are extended here by development of more precise methods for monitoring the motion and spread of the hazard posed by the lift-generated vortex wakes of aircraft, and their uncertainties. The study reported here reviews four aerodynamic mechanisms previously studied to estimate the uncertainties they carry with them for wake spreading and transport. In addition, two new models are introduced for the spreading mechanisms brought about by turbulence in the air where the vortices are embedded to enable more accurate estimates of the short-term spreading rate of vortex wakes that are of concern for nearly-simultaneous operations at airports. Suggestions are then made as to the theoretical and experimental research needed to increase the accuracy of and confidence level in the models presented. Best estimates and their uncertainties made with the improved wake models indicate that, if following aircraft are upwind of leading aircraft, the vortex wakes of the leading aircraft will not intrude into the airspace of the following aircraft for about 5s to 10s (based on pessimistic assumptions) for most atmospheric conditions. It was also found that longer time intervals before wake intrusion may be available when atmospheric turbulence levels are mild or moderate. However, if the estimates for increased along-trail

time intervals at these lower turbulence levels are to be reliable, further study is necessary to develop the necessary theory and instrumentation. When available it should be possible to accurately and reliably determine the time at which a given turbulence level will initiate and promote the long-wave instability of a vortex pair, and thereby when wake intrusion may occur.

"MEASUREMENTS IN 80- BY 120-FOOT WIND TUNNEL OF HAZARD POSED BY LIFT-GENERATED WAKE"

AIAA Paper No. 1993-3518-CP, Monterey, CA, August 1993.

The setup used and the results obtained during a wake vortex test conducted in the 80- by 120-Foot Wind Tunnel are described. The test is part of a research effort being carried out in support of a combined FAA and NASA program to study the characteristics of lift-generated vortices to safely increase airport capacity for subsonic transports. In support of that goal, the research is directed at supporting the effort to analyze current separation criteria at airports to find ways by which airport capacity can be increased. The material presented here is divided into three parts. In the first part, test results are obtained to confirm that data measured in the 80- by 120-Foot Wind Tunnel agree with those measured during the test program of the 1970's in the 40- by 80-Foot Wind Tunnel. In the second part, the potential hazard caused by the vortex wake of several configurations of a subsonic transport is evaluated by measuring the maximum rolling moment induced on following models. The wing spans of the followers vary from about 0.1 to 1.0 times the span of the wake-generating model. The configurations of the wake-generating model that are tested include the conventional landing and several modifications of it. In the third part, measured upwash distributions in the wake of three configurations of the wake generator are used with a vortex-lattice method to predict the lift and rolling moment on several following models. These results test the ability of the theory to predict induced loads on encountering aircraft.

Rossow, V. J., Sacco, J. N., Askins, P. A., Bisbee, L. S. and Smith, S. M.

"WIND TUNNEL MEASUREMENTS OF HAZARD POSED BY LIFT-GENERATED WAKES"

J. Aircraft, Vol. 32, No. 2, Mar.-Apr. 1995, pp. 278-284.

The results obtained during a wake-vortex test conducted in the NASA Ames Research Center 80- by 120-ft Wind Tunnel are described. The wind-tunnel test is part of an FAA and NASA program to study the characteristics of lift-generated vortices to safely increase airport capacity for subsonic transports. Data was first obtained to confirm that measurements in the 80- by 120-ft Wind Tunnel agree with those taken in the 40- by 80-ft Wind Tunnel during the test program of the 1970s. Measurements are then presented on the maximum rolling moment induced on following models of various sizes when they encounter the vortex wakes shed by several configurations of a subsonic transport. Finally, measurements are presented of the lift and rolling moment induced on various following models, and of the downwash, as a function of spanwise distance in the wake. The wing spans of the followers vary from 0.085 to 1.022 times the span of the wake-generating model.

Rotger, T.

"WAKE VORTICES"

International Wake Vortices Meeting, Transport Canada, Ottawa, Canada, December 1997.

Wake vortices constitute a severe hazard to following smaller aircraft. Therefore, separation rules must be observed. Airbus Industrie's concern as an aircraft manufacturer is both to reduce the impact of the leading aircraft's vortex and to improve flight safety for the following aircraft. These tasks need an enhanced understanding of wake vortex mechanisms (contribution from different parts of the aircraft to vortex formation, influence of flowfield and meteorological factors on vortex evolution and decay). A better control of wake vortex will allow air traffic management to apply less penalizing separations.

Roth, M.

"REVIEW OF ATMOSPHERIC TURBULENCE OVER CITIES"

Quarterly Journal of the Royal Meteorology Society, Vol. 126, 2000, pp. 941-990.

This paper provides a comprehensive, critical review of turbulence observations over cities. More than fifty studies are analyzed with their experimental conditions summarized in an appendix. The main results are based on 14 high-quality experiments which met criteria based on stringent experimental requirements. The observations are presented as non-dimensional statistics to facilitate comparison between urban studies and work conducted over other rough, inhomogeneous surfaces. Wake production associated with bluff bodies, and the inhomogeneous distribution of sources and sinks of scalars, result in a roughness sub-layer which for the studies reviewed extends to about 2.5 to 3 times the height of the buildings. It is shown that within this region the basis of several traditional micrometeorological approaches to describe the turbulent exchange is in doubt. There are strong similarities to flow over plant canopies, and many of the turbulence characteristics can be interpreted in the framework of a plane mixing layer. Future field observations should concentrate on the turbulent exchange near the top and within the urban canopy as well as within the urban boundary layer.

"VORTEX DRIFT: A HISTORICAL SURVEY"

In: Symposium on Aerodynamics & Aeroacoustics, K. Y. Fung (editor), World Scientific Pub Co Inc, 1994, pp. 173-186.

A historical survey on the topic of the drift motion of a single isolated vortex is presented. Amongst works highlighted and summarized included those of Helmholtz, Kelvin, Kirchhoff, Grobli, Lamb, Hicks, Saffman, Fraenkel, Cantwell, Coles, Dimotakis, Rott, Tung, Ting, Stanaway, Spalart, and Maxworthy.

Rotta, N. R.

"THE STABILITY OF A VORTEX PAIR IN THE PRESENCE OF A GROUND PLANE"

Report 71-81A, June 1971, Oceanics Inc., Plainview, NY

The configuration stability of a vortex pair in the presence of a ground plane is examined. First the motion of a vortex in three dimensions is examined by the solution of matched asymptotic expansions in which the solution of the Navier-Stokes equations are constructed asymptotically. The explicit dependence of the stability on the perturbation wavelength is discussed and illustrated. Comparison of the present analysis in the limit of zero ground effect with photographs of vortices undergoing a configuration instability is made. The viscosity necessary for agreement is found to be on the order of the eddy viscosity for the turbulent line vortex, indicating the existence of turbulence in the vortex core.

"THE VORTEX WAKE HAZARD OF LARGE TRANSPORTS IN TAKEOFF AND LANDING"

Proceedings of the National Aerospace Electronics Conf., IEEE, 1971, pp. 4I-46

The configuration stability of a vortex pair in ground effect is examined for the trailing vortex wake of a large high weight aircraft. In ground effect, the large-scale motion of the vortices is adequately represented by the equations of potential theory which shows the vortex pair to descend to lower altitudes with increased separation. The stability theory indicates the vortex pair to be unstable, with the instability and time estimated for break-up shown to depend on the altitude at which the vortex pair was generated. The results of the study of the landing of a 747 shows good agreement with FAA full-scale flight tests for the behavior of the vortex wake at low altitudes.

Rotunno, R.

"THE FLUID DYNAMICS OF TORNADOES"

Annual Review of Fluid Mechanics, Vol. 45, 2013, pp. 59-84.

Because of the difficulty in making measurements under controlled conditions, most of what is known about the fluid dynamics of tornadoes comes from laboratory experiments that produce vortices with features like those observed in a tornado. Numerical simulation of laboratory experiments has become a valuable analytical tool owing to the greater ease of extracting data. The success of the numerical simulations has inspired better-defined numerical experiments capable of quantitatively describing the basic features of observed tornado vortices and has motivated simple fluid dynamical explanations. The present article reviews the state of knowledge concerning the fluid dynamics of tornadoes as found in laboratory and numerical analogs.

"PILOTED SIMULATION RESULTS OF AN ONBOARD WAKE VORTEX DETECTION, WARNING AND AVOIDANCE SYSTEM AND COCKPIT DISPLAY ASPECTS"

ICAS 2008, Anchorage, AK, Sept. 200.

As part of the European project I-WAKE (Instrumentation systems for on-board WAKE vortex and other hazards detection, warning and avoidance), piloted flight simulations have been performed using an onboard wake vortex Detection, Warning and Avoidance (DWA) system concept including a novel cockpit Human Machine Interface (HMI). This HMI consisted of new information on a Primary Flight Display (PFD), the Navigation Display (ND) and a Vertical Navigation Display (VND). These concepts developed, associated wake alerting flight procedures, experimental set up and main results of the piloted study on a fixed base flight simulator will be addressed.

Roy, C. and Leweke, T.

"EXPERIMENTS ON VORTEX MEANDERING"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

The goal of this work is to provide detailed experimental data about vortex meandering. For this purpose, a single trailing vortex was generated in a water channel, using a NACA0012 half-wing. Nine configurations were tested, involving different free-stream velocities and angles of attack. The circulation-based Reynolds number varied in the range 8700-31500, and the axial velocity defect at the vortex center was between 27 and 55 percent of the maximum swirl velocity. Detailed measurements of the three-dimensional vortex velocity profiles were carried out at 11.2 chord lengths behind the wing, involving stereo-PIV and recentering of individual PIV fields before averaging. The first part of the meandering analysis deals with the statistics of the vortex center positions in the measurement plane. It is found that the amplitude of vortex displacement decreases with Reynolds number, in agreement with earlier findings by Devenport et al. (1996). The meandering amplitude is found to be of the order of the core radius, and the principal directions of motion are identified. In the second part, singular value decomposition (or Proper Orthogonal Decomposition - POD) analysis is carried out, using high-frequency vorticity data from PIV, as well as dye visualization images. After confirming that both inputs give similar results, long time series of dye visualizations are analyzed by POD. The most energetic perturbations are found to be displacement modes of the vortex. Spectral analysis of the projection of the time series on these displacement modes showed that they are characterized by low-frequency oscillations (at the fixed measurement position), corresponding to wavelengths in the frame of reference moving with the vortex that are two orders of magnitude larger than the vortex radius.

Roy, C., Leweke, T., Thompson, M. C. and Hourigan, K.

"EXPERIMENTS ON THE ELLIPTIC INSTABILITY IN VORTEX PAIRS WITH AXIAL CORE FLOW"

XXII International Congress of Theoretical and Applied Mechanics, Aug. 2008, Adelaide, Australia.

We show experimental results concerning the interaction of two parallel counter-rotating vortices presenting a jet-like axial velocity profile in their cores. The vortex pair is generated by two wings in a water channel; it is visualized by dye injection, and characterized quantitatively by stereoscopic Particle Image Velocimetry. Two types of three-dimensional instability are observed: the long-wavelength Crow instability and a short-wavelength core instability caused by the mutually induced elliptic deformation of the vortex streamlines. We here focus on the short-wave (elliptic) instability, for which we deduce the perturbation mode structure, which is different from the one observed without axial flow, the axial wavelength, and the growth rate from the experimental data. Comparisons are made with the results from a numerical linear stability analysis of the measured flow, and good overall agreement is found.

Roy, C., Leweke, T., Thompson, M. C. and Hourigan, K.

"EXPERIMENTS ON THE ELLIPTIC INSTABILITY IN VORTEX PAIRS WITH AXIAL CORE FLOW"

Journal of Fluid Mechanics, Vol. 677, 2011, pp. 383-416.

Results are presented from an experimental study on the dynamics of pairs of vortices, in which the axial velocity within each core differs from that of the surrounding fluid. Co- and counter-rotating vortex pairs at moderate Reynolds numbers were generated in a water channel from the tips of two rectangular wings. Measurement of the 3-dimensional velocity field was accomplished using stereoscopic particle image velocimetry, revealing significant axial velocity deficits in the cores. For counter-rotating pairs, the long-wavelength Crow instability involving symmetric wavy displacements of the vortices, could be clearly observed using dye visualization. Measurements of both the axial wavelength and the growth rate of the unstable perturbation field were found to be in good agreement with theoretical predictions based on the full experimentally measured velocity profile of the vortices, including the axial flow. The dye visualization further revealed the existence of a short-wavelength core instability. Proper orthogonal decomposition of the time series of images from high-speed video recordings allowed a precise characterization of the instability mode, which involves an interaction of waves with azimuthal wavenumbers $m=2$ and $m=0$. This combination of waves fulfills the resonance condition for the elliptic instability mechanism acting in strained vortical flows. A numerical 3-dimensional stability analysis of the experimental vortex pair revealed the same unstable mode, and a comparison of the wavelength and growth rate with the values obtained experimentally from dye visualizations shows good agreement. Pairs of co-rotating vortices evolve in the form of a double helix in the water channel. For flow configurations that do not lead to merging of the two vortices over the length of the test section, the same type of short-wave perturbations was observed. As for the counter-rotating case, quantitative measurements of the wavelength and growth rate, and comparison with previous theoretical predictions, again identify the instability as due to the elliptic mechanism, importantly, the spatial character of the short-wave instability for vortex pairs with axial flow is different from that previously found in pairs without axial flow, which exhibit an azimuthal variation with wavenumber $m=1$.

Roy, C., Schaeffer, N., Le Dizes, S. and Thompson, M.

"STABILITY OF A PAIR OF CO-ROTATING VORTICES WITH AXIAL FLOW"

Physics of Fluids, Vol. 20, No. 9, 2008, pp. 094101-094108

The three-dimensional linear temporal stability properties of a flow composed of two corotating q-vortices (also called Batchelor vortices) are predicted by numerical stability analysis. As for the corresponding counter-rotating case, when the axial flow parameter is increased, different instability modes are observed and identified as a combination of resonant Kelvin modes of azimuthal wavenumbers m and $m + 2$ within each vortex. In particular, we show that the sinuous mode, which is the dominant instability mode without axial flow, is stabilized in the presence of a moderate axial flow. Different types of mode with a large amplitude in the critical layer are also identified. For small separation distances (above the merging threshold), unstable eigenmodes, corresponding to axial wavenumbers that cannot be easily identified with simple resonant interactions of Kelvin modes, are also observed. Their growth rate is a substantial fraction of the growth rates of low-order resonant modes. The effects of the Reynolds number and vortex separation distance on the growth rate parameter map are considered. Finally, we analyze the similarities and differences between the stability characteristics of co- and counter-rotating vortex pairs.

Roy, C., Schaeffer, N., Le Dizes, S., Leweke, T., Thompson, M. C. and Hourigan, K.

"ELLIPTIC INSTABILITY IN VORTEX PAIRS WITH AXIAL CORE FLOW"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

The three-dimensional short-wavelength instability of a flow consisting of two parallel co- or counter-rotating vortices with a jet-like axial core flow is studied by both numerical stability analysis and experiments in a water channel. The numerical study focuses on the linear temporal stability properties of two co-rotating q-vortices (Batchelor vortices). As for the corresponding counter-rotating case, when the axial flow parameter is increased, different instability modes are observed and identified as a combination of resonant Kelvin modes of azimuthal wave numbers m and $m+2$ within each vortex, which characterizes the elliptic instability. We show that the sinuous mode, which is the dominant instability mode without axial flow, is stabilized in the presence of a moderate axial flow. Different types of modes with a large amplitude in the critical layer are also identified. In addition to the numerical analysis, experiments were carried out in a water channel, where vortex pairs with axial core flow were generated using two rectangular NACA 0012 half-wings. Detailed measurements of the three-dimensional velocity profiles characterizing the vortex base flow were made using stereoscopic Particle Image Velocimetry.

Ruan, H.

"INTERACTION OF A VORTEX PAIR AND A FREE-SURFACE: NUMERICAL SIMULATIONS"

PhD Thesis, May 2000, New Jersey Institute of Technology, Newark, NJ.

The interaction between a submerged vortex pair with a deformable free-surface in a viscous, incompressible fluid is directly simulated and the flow is thoroughly analyzed. This is a time-dependent nonlinear free-surface problem which we solve numerically by integrating the two-dimensional Navier-Stokes equations and using boundary-fitted coordinates capable of handling large free-surface deformations. In particular, the numerical simulation of the flow at relatively high Reynolds numbers (500, 1000, 2000) and relatively high Froude numbers (1.125, 2.0) is investigated and analyzed for the first time. Details are given regarding the space-time deformation of the free-surface, the path of the primary vortices, the formation of strong free-surface vorticity and kinetic energy, and the generation of turbulence in the flow. In particular, the turbulence characteristics have been explored at Reynolds number 1000. In this flow, we identified a thin free-surface layer characterized by very fast variations of the turbulent intensity, the kinetic energy dissipation and velocity fluctuations. The turbulence intensity reaches a maximum at the level of the center of the primary vortex, and then decreases significantly as the free-surface is approached. This decay is due to a very large increase of the turbulent kinetic energy dissipation at the free-surface and the formation of large vorticity peaks at the free-surface. Contrarily to previous findings, there is no redistribution of the turbulence intensity at the free-surface, that is a large increase of the horizontal velocity fluctuations at the expense of the vertical velocity fluctuation.

Ruan, X., Song, X. and Yamamoto, F.

"DIRECT MEASUREMENT OF THE VORTICITY FIELD IN DIGITAL PARTICLE IMAGES"

Experiments in Fluids, Vol. 30, 2001, pp. 696-704

A new method called direct measurement of vorticity (DMV) for digital particle images is described in this paper. Unlike previous methods for calculating the vorticity in particle image velocimetry (PIV), the vorticity is determined directly from the average angular displacement of rotation between two matched patterns. In order to improve the stability and precision of the angular displacement, polar coordinates are used instead of Cartesian coordinates to depict gray level patterns. The results of a Monte Carlo simulation of an Oseen-vortex flow indicate that the accuracy of the DMV method is independent of the spatial resolution of the velocity sampling, and the errors in the velocity field will not be propagated into the vorticity field as occurs with some finite difference methods. Therefore, the DMV method is a good method to be used to extract the vorticity field from velocity data that has higher levels of uncertainty.

Rubbert, P. E.

"AIRCRAFT WINGTIP VORTICITY REDISTRIBUTION APPARATUS"

US Patent 5,100,085, May 1992.

A rotor is mounted to an aircraft wing to recover induced drag associated with a wingtip vortex. When the rotor is placed in the vortex stream, the transverse component of relative wind encountered at selected increasing spanwise locations along the blade changes sign due to an increasing transverse

component of blade velocity and decreasing transverse component of vortex velocity with increasing distance from the axis of rotation. To maximize induced drag recovery, the blade is twisted in a spanwise direction so that the inner portion of the blade drives the blade, while the radially outward portion acts as a propeller to resist rotation. The induced drag recovery is in the form of thrust generated by the rotor blade.

Rubin, W. L.

"THE GENERATION AND DETECTION OF SOUND EMITTED BY AIRCRAFT WAKE VORTICES IN GROUND EFFECT"

J. of Atmospheric and Oceanic Technology, Vol. 22, May 2005, pp. 543-554

Sound recorded by the author in March 2002 at JFK International Airport shows that wake vortices in ground effect emit infrasound that is 1) more than 40 dB stronger than audible wake vortex sound; 2) substantially stronger than the infrasound component of wind noise and airport noise; and 3) comparable to, and often stronger than, the infrasound component of aircraft noise. Spectra and time plots of the magnitude of wake-vortex-generated sound are presented for aircraft landing on JFK runway 31R.

Rubin, W. L.

"RADAR-ACOUSTIC DETECTION OF AIRCRAFT WAKE VORTICES"

Journal of Atmospheric and Oceanic Technology, Vol. 17, August 2000, pp. 1058-1065

All aircraft produce trailing wake vortices as a direct consequence of generating lift. Vortices may be dangerous to following aircraft during takeoff and landing. An all-weather airport wake vortex sensor has been sought for more than 25 years as part of a ground-based wake vortex avoidance system that would enable current U.S. Federal Aviation Administration separation standards to be safely reduced under instrument and visual flight rule conditions. A sensitive all-weather radar-acoustic wake vortex sensor is described that satisfies wake vortex avoidance system requirements. Samples of recent vortex data gathered at New York's Kennedy International Airport are presented.

Rubin, W. L.

"GLIDE SLOPE SURVEILLANCE SENSOR"

US Patent 5,208,600, May 1993.

A surveillance sensor for detecting and monitoring aerodynamic conditions in a vicinity of an aircraft landing glide slope utilizes a radar transmitter to illuminate the glide slope. Radar reflections from aircraft induced vortices, clear air turbulence, and glide slope cross winds are received by a monopulse radar system wherein a sum beam doppler spectrum and a difference beam doppler spectrum for the radar returns is determined. The sum and difference beams doppler spectra are processed to

determine the aerodynamic conditions in the glide slope vicinity. These aerodynamic conditions are assessed to determine whether aerodynamic hazardous conditions exist in the glide slope region.

Rubin, W. L., Burnham, D. C., Spitzer, E. A. and Rudis, R. P.

"ROBUST LOW COST AIRPORT WAKE VORTEX SENSOR"

J. Aircraft, Vol. 37, No. 3, May-June 2000, pp. 377-382

A conventional Radar Acoustic Sounding System (RASS) atmospheric profiler has been converted into a wake vortex sensor that can detect/track/measure aircraft wake vortices under all weather conditions. The resulting wake vortex sensor has been operated automatically with real-time processing at New York's Kennedy International Airport, where wakes were detected from aircraft in all weight classes. Comparisons with other wake vortex sensors are presented and show consistent vortex tracking with a very low false alarm rate. Possible applications of the sensor to wake vortex avoidance systems are discussed.

Rudis, R. P. and Burnham, D. C.

"ANEMOMETER ARRAY AND METEOROLOGICAL DATA: May 1998 SOCRATES TEST"

DOT-VNTSC-FAA-98-13, June 1999, DOT Volpe National Transportation Systems Center, Cambridge, MA.

In support of the Federal Aviation Administration, the Volpe National Transportation Systems Center (Volpe Center) is conducting an evaluation of a laser-based system concept called SOCRATES to determine its possible application in detecting potentially hazardous meteorological and wake turbulence phenomena. SOCRATES technology uses a laser beam to detect sound in the atmosphere. The objectives of the test were to define the nature of wake vortex acoustic signals and evaluate the capability of the SOCRATES technology to detect those acoustic signals. The SOCRATES test was conducted at the Wake Vortex Test Site at Kennedy Airport from May 13, 1998 through May 22, 1998. This report presents the data obtained by the Volpe Center using the ground-wind line to provide wake vortex lateral position ground truth and the data obtained using supplementary instrumentation.

"ANEMOMETER ARRAY AND METEOROLOGICAL DATA: MAY 1998 SOCRATES TEST"

DOT/FAA/RD-98, January 1999, DOT Volpe National Transportation Systems Center, Cambridge, MA

SOCRATES sensor technology uses laser beams to simulate an array of microphones. One possible application of this technology is to detect and track aircraft wake vortices by means of the sound emitted. In May 1998, a feasibility test was conducted at the approach to Runway 31R at JFK International Airport. Vortex lateral position was measured using a 700-foot array of horizontal and vertical single-axis anemometers mounted on 28-foot poles. Meteorological sensors provided information about the state of the atmosphere. This report (with an accompanying CD-ROM) presents

the aircraft arrival, wake vortex, and meteorological data from this test, including descriptions of processing algorithms and database formats.

"CROSSWIND MEASUREMENT AND FORECASTING REQUIREMENTS FOR AIRCRAFT WAKE VORTEX AVOIDANCE SYSTEM"

Poster Paper 3.1, AMS 7th Conf. on Aviation, Range and Aerospace Meteorology, Feb. 1997, Long Beach, CA.

Systems have been designed to permit reduced wake-vortex separations, and hence increased airport capacity, under appropriate crosswind conditions. Different systems were designed for landing operations on a single runway and on close-spaced parallel runways (less than 2500 feet apart).

"AVOSS WINDLINE AT DALLAS/FT. WORTH AIRPORT, VOLUME 1: INSTALLATION AND OPERATION"

DOT-VNTSC-RSPA-01-01, May 2001, DOT Volpe National Transportation Systems Center, Cambridge, M.

A 259-meter windline, with horizontal and vertical single-axis anemometers mounted on 9-meter poles, was installed at the Dallas/Ft. Worth Airport under the approach to Runway 17C, as part of NASA's Aircraft VOrtex Spacing System (AVOSS) development program. Real-time processing algorithms provided wake vortex tracking information. Additional weather sensors, including additional anemometers, temperature and dewpoint, weather sensor and a sodar wind profiler were deployed at various times of windline operation. Wake and meteorological data were provided in real time to AVOSS. This report, Volume 1 of a two-volume report, describes the installation, the data processing algorithms, and the data files supplied to AVOSS.

Rudis, R. P., Burnham, D. C. and Jacobs, L.

"AVOSS WINDLINE AT DALLAS/FT. WORTH AIRPORT, VOLUME 2: DATA BASE OF GROUND-BASED ANEMOMETER MEASUREMENTS OF WAKE VORTICES"

DOT-VNTSC-RSPA-01-02, May 2001, DOT Volpe National Transportation Systems Center, Cambridge, M.

A 259-meter array of horizontal and vertical single-axis anemometers mounted on 9-meter poles was installed at the Dallas/Ft. Worth Airport (DFW) under the approach to Runway 17C, as part of NASA's Aircraft VOrtex Spacing System (AVOSS) development program. Real-time processing algorithms were developed that based the vortex detection threshold on the turbulence level. Data from more than 70,000 landings have been recorded and processed. This report documents the current state of algorithm development and provides processed data for other researchers to analyze.

"WAKE VORTEX DECAY NEAR THE GROUND UNDER CONDITIONS OF STRONG STRATIFICATION AND WIND SHEAR"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 11-1 to 11-10

Using the tower fly-by method, decay measurements were made on wake vortices generated by B-727, B-757 and B-767 aircraft. In addition to a 60-meter instrumented tower, two remote sensing systems were deployed: (1) Laser Doppler Velocimeter (LDV) (high resolution vortex profiles at ranges of 40-200 meters) and (2) Monostatic Acoustic Vortex Sensing System (MAVSS) (lower resolution profiles up to 500 meters beyond the tower location). Typical early morning meteorology during the test period consisted of stratified drainage flows. Because of the persistent crosswind, the MAVSS gave the most complete vortex decay information. Meteorological conditions were measured by instruments on the tower and on a tether sonde. The analysis looked for statistical relationships between vortex lifetime and several meteorological parameters, treated independently. Due to the meteorological conditions of stratification, low turbulence and wind shear, the upwind vortex lasted longer than the downwind vortex; the circulation remained above 140 m²/s for up to 125, 150 and 170 seconds for the B-727, B-757 and B-767, respectively. However, in every case, the crosswind was strong enough to sweep both wake vortices away from the generating location; in some cases, the vortices traveled more than 500 meters laterally. Although these durations are much longer than the normally observed vortex lifetimes, they are related, according to the analysis, to strong crosswind shear coupled with low turbulence levels. While this long vortex migration at the observed strength levels might represent a potential vortex encounter hazard for operations on a downwind parallel runway, the drainage flow conditions which led to this unusual vortex behavior would be unlikely to occur at most airports.

"STATUS REPORT SOCRATES CONCEPT EXPLORATION EFFORT"

DOT-VNTSC-RSPA-01-04, October 2001, Volpe National Transportation Systems Center, Cambridge, MA

Project SOCRATES, development of a technology to detect hypothesized acoustic emanations from wake vortices, has been underway for more than four years. This report discusses several aspects of this project including the current level of knowledge concerning wake vortex acoustic properties, SOCRATES detection technology, and wake turbulence sensor deployment issues. Three recommendations are offered to restructure the programmatic approach of Project SOCRATES to reduce the high risk and high cost should the government decide to continue to pursue this program.

Rudland, R. S.

"USE OF SIMULATION IN EVALUATING AN EARLY WARNING SYSTEM FOR AVOIDANCE OF JUMBO JET TRAILING VORTEX TURBULENCE IN AIRPORTS"

Proceedings of Eighth Annual Pittsburgh Conf., Volume 8 - Modeling and Simulation, Inst. Soc. of America, Pittsburgh, PA, April 1977, pp. 393-396

Wake turbulence from large aircraft has created a safety hazard for smaller aircraft that land soon after a Jumbo-Jet. A laser detection system was developed to monitor wake turbulence in the airport and to provide early warning to the air traffic controller. Since each part of the system has been developed separately, proper integration of this system depends on simulation of realistic landing patterns with wake turbulence to see if the detection system and the warning system can provide the controller with the right information at the right time. A description of the simulation model is developed to be able to provide random landing patterns to create realistic aircraft sequencing. With this simulation model controller performance can be evaluated.

Rudland, R. S.

"AVOIDANCE OF TRAILING VORTEX HAZARD BY AIRPORT WARNING SYSTEM."

The 1972 NASA-ASEE Summer Faculty Fellowship Program Research Reports, NASA and American Society of Engineering Education, September 1972, pp. 507-532. (Also, NASA CR-61396..

To improve airport traffic operation near jumbo jets, an airport trailing vortex warning system (ATVWS) was developed to predict trailing vortex turbulence. The ATVWS consists of a computer simulator which is compatible with a vortex sensor such as a laser Doppler velocimeter or an acoustic radar. A study of the traffic in one of the ten busiest airports, Atlanta Municipal Airport, provided information on traffic patterns of a statistical nature. With this information, airport traffic patterns can be studied and hazard statistics developed. Based on a careful study of this simulation model, requirements for the development and testing of an ATVWS can be accurately specified.

"AIRCRAFT WAKE TURBULENCE"

Economics of Air Safety and Long-Range Safety Research and Development, Proceedings of the 26-th Annual International Air Safety Seminar, Flight Safety Foundation, November 1973, pp. 31-47

Discussion of an FAA R&D program aimed at coping with current wake vortex problems which are significant in large transport aircraft. The program is planned to increase aircraft safety in terms of vortex hazard and allow a large increase in airport capacities by reducing the takeoff and landing spacing. The major points of the program include aircraft design modifications for wake vortex elimination, vortex dissipation methods, and automatic wake vortex avoidance systems.

Ruggi, E. and Hanna, M.

"AIR VELOCITY DISTRIBUTION BEHIND WING-MOUNTED AIRCRAFT ENGINES"

Transport Canada TR 13480E, October 1999, APS Aviation Inc, Montreal, Quebec, Canada.

This study had focused on two main objectives: Acquisition of experimental data on the air velocity distribution experienced in the blast from wing-mounted aircraft engines at idle during deicing operations, and Development and evaluation of a method that could be used as a safety check for deicing truck stability, and incorporated into an SAE standard. Two supplemental objectives were also addressed: Measurement of air velocities in the vicinity of the Boeing 777 auxiliary power unit (APU) exhaust, and Measurement of the air velocity profiles 100 m behind a Boeing 777 engine at three-quarter throttle. Nineteen tests were conducted on nine different aircraft at three airports. Air velocity measurements were recorded on all occasions and were considered as a function of aircraft geometry and engine rating. Peak air velocity measurements were recorded for the various aircraft. The Airbus A320 recorded the highest air velocity, 180 km/h. The overturning moment on a deicing truck subject to the jet blast of a wing-mounted aircraft engine at idle was found to be 7.4 percent of that required to overturn the truck. A viable and repeatable preliminary test method was developed. Boeing 777 APU tests observed excessively high heat and recorded an air velocity more than 200 km/h. Boeing 777 three-quarter throttle tests recorded an air velocity more than 190 km/h, but were discontinued because of equipment damage. The stability of the deicing truck during this test was affected by the overwhelming wave of air created by the aircraft engine and the truck was considered unsafe.

Ruith, M. R., Chen, P. and Meiburg, E.

"DEVELOPMENT OF BOUNDARY CONDITIONS FOR DIRECT NUMERICAL SIMULATIONS OF THREE-DIMENSIONAL VORTEX BREAKDOWN PHENOMENA IN SEMI-INFINITE DOMAINS"

Computers & Fluids, Vol. 33, 2004, pp.1225-1250

The suitability of various open boundary conditions is evaluated for direct numerical simulations of three-dimensional, incompressible, spatially and temporally evolving, swirling laminar jets in domains that extend to infinity in the downstream and radial direction. From the point of view of specifying conditions at the open boundaries, this class of flows is particularly challenging due to its ability to support traveling waves. Towards this end, several radial boundary conditions are implemented and tested with respect to their ability to conserve local and global mass, to handle low and high entrainment flow, and to avoid the introduction of artificial waves propagating from the boundaries into the interior: a free-slip condition, two types of homogeneous Neumann conditions, and a radiation condition in spirit of the outflow boundary condition. Global mass is conserved automatically within machine accuracy in the free-slip and simple radiation case, while the Neumann conditions require some iterative modification to conserve mass. This yields a computationally less efficient scheme which additionally exhibits poorer conservation properties due to the limited number of iterations. The free-slip condition typically requires the largest radial extent of the computational domain due to its impermeable character which is particularly problematic for the high entrainment flow. Hence, the radiation condition has been found as the most suitable lateral boundary condition for both high and low entrainment jets.

"THREE-DIMENSIONAL VORTEX BREAKDOWN IN SWIRLING JETS AND WAKES: DIRECT NUMERICAL SIMULATION"

J. Fluid Mech., Vol. 486, 2003, pp. 331-378

Vortex breakdown of nominally axisymmetric, swirling incompressible flows with jet- and wake-like axial velocity distributions issuing into a semi-infinite domain is studied by means of direct numerical simulations. By selecting a two-parametric velocity profile for which the steady axisymmetric breakdown is well-studied (Grabowski & Berger 1976), issues are addressed regarding the role of three-dimensionality and unsteadiness with respect to the existence, mode selection, and internal structure of vortex breakdown, in terms of the two governing parameters and the Reynolds number. Low Reynolds numbers are found to yield flow fields lacking breakdown bubbles or helical breakdown modes even for high swirl. In contrast, highly swirling flows at large Reynolds numbers exhibit bubble, helical or double-helical breakdown modes, where the axisymmetric mode is promoted by a jet-like axial velocity profile, while a wake-like profile renders the flow helically unstable and ultimately yields non-axisymmetric breakdown modes. It is shown that a transition from super- to subcritical flow, as defined by Benjamin (1962), accurately predicts the parameter combination yielding breakdown, if applied locally to flows with supercritical inflow profiles. Thus, the basic form of breakdown is axisymmetric, and a transition to helical breakdown modes is shown to be caused by a sufficiently large pocket of absolute instability in the wake of the bubble, giving rise to a self-excited global mode. Two distinct eigenfunctions corresponding to azimuthal wavenumbers $m = -1$ and $m = -2$ have been found to yield a helical or double-helical breakdown mode, respectively. Here the minus sign represents the fact that the winding sense of the spiral is opposite to that of the flow.

"PREDICTION OF TURBULENT TRAILING VORTEX STRUCTURE FROM BASIC LOADING PARAMETERS"

AIAA Paper No. 1996-2495, June 1996, New Orleans, LA.

A novel analytical method has been developed to accurately predict the core structure of a fully developed trailing vortex. Properties in the trailing vortex are calculated from the load distribution on the generating wing, and satisfy a set of fundamental conservation laws. The present rollup model is based on the Betz method, with significant improvements which address both viscous effects in the vortex core region, and also the effects of viscous drag on the generating wing. Turbulent mixing in the core is handled implicitly through the appropriate choice of solution velocity profiles, which contain free constants. These constants are determined uniquely by conserving properties between an inviscid Betz-type vortex and a vortex with experimentally consistent velocity distribution. The method is developed for arbitrary wing loading and results are presented for several important cases. Comparison with experiment demonstrates the accuracy of the model.

Rule, J. A. and Bliss, D. B.

"PREDICTION OF VISCOUS TRAILING VORTEX STRUCTURE FROM BASIC LOADING PARAMETERS"

AIAA Journal, Vol. 36, No. 2, February 1998, pp. 208-218

An analytical method has been developed to predict the structure of a fully developed trailing vortex with a viscous core. Vortex structure is calculated from the load distribution on the generating wing and fundamental conservation laws are satisfied. The present rollup model implicitly addresses viscous effects in the vortex core region by assuming a turbulent mixing process in the core during formation. Mixing theory suggests the appropriate functional form of the solution velocity profiles within this region, with constants that are determined uniquely by the method for arbitrary wing loading distributions. Important structural properties such as vortex strength, core size, and peak swirl velocity are calculated directly from these solution constants. The viscous core model was validated against two recent experimental studies, which provided new insight into vortex growth.

"NASA TRAPEZOIDAL WING COMPUTATIONS INCLUDING TRANSITION AND ADVANCED TURBULENCE MODELING"

Journal of Aircraft, Vol. 52, No. 2, March-April 2015, pp. 496-509.

Flow about the NASA trapezoidal wing is computed with several turbulence models by using grids from the first high-lift prediction workshop to advance understanding of computational fluid dynamics modeling for this type of flowfield. Transition is accounted for in many of the computations. In particular, a recently developed four-equation transition model is used and works well overall. Accounting for transition tends to increase lift and decrease moment, which improves agreement with the experiment. Upper surface flap separation is reduced, and agreement with experimental surface pressure and velocity profiles is improved. The predicted shape of wakes from upstream elements is strongly influenced by grid resolution in regions above the main and flap elements. Turbulence model enhancements to account for rotation and curvature have the general effect of increasing lift and improving the resolution of the wing-tip vortex as it convects downstream. However, none of the models improve the prediction of flap surface pressures near the wing tip.

Rumsey, Jr., C. B.

"A WATER TUNNEL INVESTIGATION OF A SMALL SCALE ROTOR OPERATING IN THE VORTEX RING STATE"

MS Thesis, June 2003, Naval Postgraduate School, Monterey, CA.

Motivation to expand the understanding of a helicopter rotor descending into the vortex ring state (VRS) stems from the aircraft mishaps that have plagued the helicopter community. The V-22 has become the most recent victim of encounters with VRS. The onset of VRS is associated with the collapse of the helical vortex wake in the plane of the rotor. The resulting wake disturbances develop an irregular and aperiodic flow. Rotor blade interaction with the disturbed vortices causes large variations in the blade spanwise aerodynamic load distribution. Harmonic analysis of the loading indicates that higher harmonic content becomes prevalent in this state. The dynamic flow similarities achieved in a water tunnel are used to explore flow visualization and conduct vibration analysis of a rotor system

operating in the VRS. A scaled rotor system was operated in the NPS Aeronautical Engineering Department's water tunnel. Sensors were used to gather thrust and vibration power spectrum data when operating in VRS. Experimental results correlate with full scale flight data and show a significant increase in the vibration levels of the even multiples of the blade passage frequency. The relative strength of these higher harmonics can be used as an indicator of impending VRS encounters.

Rusak, Z.

"AXISYMMETRIC SWIRLING FLOW AROUND A VORTEX BREAKDOWN POINT"

Journal of Fluid Mechanics, Vol. 323, 1996, pp. 79-105.

The structure of an axisymmetric and inviscid swirling flow around a vortex breakdown point is analyzed. The model assumes that a free axisymmetric bubble surface is developed in the flow with a stagnation point at its nose. The classical Squire-Long equation for the stream function $\psi(x,y)$ (where $y = (r^2)/2$) is transformed into a free boundary problem for the solution of $y(x,\psi)$. The development of the flow is studied in three regions: the approaching flow ahead of the bubble, around the bubble nose and around the separated bubble surface. Asymptotic expansions are constructed to describe the flow ahead of and behind the stagnation point in terms of the radial distance from the vortex axis and from the bubble surface, respectively. In the intermediate region around the stagnation point, the flow is approximated by an asymptotic series of similarity terms that match the expansions in the other regions. The analysis results in two possible matching processes. Analytical expressions are given for the leading term of the intermediate expansion for each of these processes. The first solution describes a swirling flow around a constant-pressure bubble surface, over which the flow is stagnant. The second solution represents a swirling flow around a pressure-varying bubble surface, where the flow expands along the bubble nose. In both solutions, the bubble nose has a parabolic shape, and both exist only when $H' > 0$ (where H' is the derivative at the vortex center of the total head H with the stream function ψ , and can be determined from the inlet conditions). This result is shown to be equivalent to Brown & Lopez's (1990) criterion for vortex breakdown. Good agreement is found in the region around the stagnation point between the pressure-varying bubble solution and available experimental data for axisymmetric vortex breakdown.

Rusak, Z. and Lee, J. H.

"THE CRITICAL SWIRL OF COMPRESSIBLE VORTEX FLOWS"

AIAA Paper No. 2002-0159, Reno, NV, January 2002.

The effect of compressibility on the critical swirl level for breakdown of subsonic vortex flows in a straight circular pipe of finite length is studied. This work extends the critical-state concept of Benjamin to include the influence of Mach number on the flow behavior. The analysis is based on a linearized version of the equations for the motion of a steady, axisymmetric, inviscid, and compressible swirling flow of a perfect gas. The relationship between the velocity, density, temperature, and pressure perturbations to a base columnar flow state are derived. An eigenvalue problem is formulated to

determine the first critical level of swirl at which a special mode of a non-columnar small disturbance may appear on the base flow. It is found that when the characteristic Mach number of the base flow tends to zero the eigenvalue problem and the critical swirl are the same as defined by Wang and Rusak in their study of incompressible swirling flows in pipes. As the characteristic Mach number is increased, the critical swirl level increases and the flow perturbation expands in the radial direction. As the Mach number is increased toward a certain limit value related to the core size of the vortex, the critical swirl reaches very large values and becomes singular. The present results indicate that the axisymmetric breakdown of high Reynolds number compressible vortex flows may be delayed with the increase of the flow Mach number.

Rusak, Z. and Lee, J. H.

"ON THE STABILITY OF A COMPRESSIBLE AXISYMMETRIC ROTATING FLOW IN A PIPE"

J. Fluid Mech., Vol. 501, 2004, pp. 25-42

The linear stability of a compressible inviscid axisymmetric and rotating columnar flow of a perfect gas in a finite-length straight circular pipe is investigated. This work extends a previous analysis to include the influence of Mach number on the flow dynamics. A well-posed model of the unsteady motion of a swirling flow, with inlet and outlet conditions that may reflect the physical situation, is formulated. The linearized equations of motion for the evolution of infinitesimal axially symmetric disturbances are derived. A general mode of disturbance, that is not limited to the axial-Fourier mode, is introduced and an eigenvalue problem is developed. It is found that a neutral mode of disturbance exists at 'the critical swirl ratio for a compressible vortex flow'. The flow changes its stability characteristics as the swirl ratio increases across this critical level. When the swirl ratio is below the critical level (supercritical flow), an asymptotically stable mode is found and, when it is above the critical level (subcritical flow), an unstable mode of disturbance develops. This result cannot be predicted by any of the previous stability criteria. When the characteristic Mach number of the base flow tends to zero, the results are the same as found for incompressible swirling flows in pipes. The growth rate ratio is positive for all Mach numbers, but decreases as Mach number is increased. This ratio vanishes at the limit Mach numbers, but decreases as Mach number is increased. This ratio vanishes at the limit Mach number at which the critical swirl tends to infinity. The present results also demonstrate that the axisymmetric breakdown of high-Reynolds-number compressible vortex flows may be delayed to higher swirl ratios with the increase of the incoming flow Mach number.

Rusak, Z. and Lee, J. H.

"THE EFFECT OF COMPRESSIBILITY ON THE CRITICAL SWIRL OF VORTEX FLOWS IN A PIPE"

J. Fluid Mech., Vol. 461, 2002, pp. 301-319

The effect of compressibility on the critical swirl level for breakdown of subsonic vortex flows in a straight circular pipe of finite length is studied. This work extends the critical-state concept of Benjamin (1962) to include the influence of Mach number on the flow behavior. The analysis is based on a

linearized version of the equations for the motion of a steady, axisymmetric, inviscid, and compressible swirling flow of a perfect gas. The relationship between the velocity, density, temperature, and pressure perturbations to a base columnar flow state are derived. An eigenvalue problem is formulated to determine the first critical level of swirl at which a special mode of a non-columnar small disturbance may appear on the base flow. It is found that when the characteristic Mach number of the base flow tends to zero the eigenvalue problem and the critical swirl are the same as defined by Wang & Rusak (1996a, 1997a) in their study of incompressible swirling flows in pipes. As the characteristic Mach number is increased, the critical swirl level increases and the flow perturbation expands in the radial direction. As the Mach number is increased toward a certain limit value related to the core size of the vortex, the critical swirl reaches very large values and becomes singular. The present results indicate that the axisymmetric breakdown of high-Reynolds-number compressible vortex flows may be delayed with the increase of the flow Mach number.

"THREE DIMENSIONAL DYNAMIC AND STATIC STABILITY OF VORTEX SYSTEMS AND THEIR OBSERVABILITY AND CONTROLLABILITY"

ICAS 1990, Paper No. 3.2.1, September 1990, Stockholm, Sweden.

A general theory for the three-dimensional long-wave linear stability of a general system of straight potential vortices immersed in an incompressible inviscid potential external flow field and in the vicinity of solid surfaces, is presented. The flow field equations are governed by the streak-line equations for the vortices and by the satisfaction of the tangency boundary condition on the solid surfaces. In their basic state, the vortices are assumed to be straight parallel filaments, near infinite two-dimensional steady surfaces that are represented by a potential source surface distribution. Small three-dimensional long wave perturbations, constructed of two orthogonal waves, are imposed on the vortex filaments, concurrently with fluctuations in the intensity of the source distribution, and with known unsteady perturbations along the shape of the solid surfaces. The singularity in the calculation of the self-induced velocity of a curved vortex line is treated by the 'Cut-off distance' model. A linearization of the flow-field equations followed by a Fourier transformation, results in a system of zero-order equations, for the two-dimensional dynamics of the vortices in their basic state, and first-order equations, that are constructed of Fredholm integral equations of the second kind for the source fluctuations distribution, and of the first-order linear differential equations that describe the time-history of the vortex perturbations. When the basic state is steady, or quasi-steady, the first-order equations result in an eigenvalue problem. Analysis shows that the perturbations development in time can never be asymptotically stable. The outcome of the model are the new concepts of 'Generalized Damping of a Vortex System' that govern its dynamic stability, and 'Rigidity' that governs the static divergence of a vortex system, which was never considered before. Also, a control approach is presented, together with the new concepts of 'Controllability' and 'Observability', that lead to the challenging idea of 'Active Control' of vortex stability.

Rusak, Z. and Wang, S.

"REVIEW OF THEORETICAL APPROACHES TO THE VORTEX BREAKDOWN PHENOMENON"

AIAA Paper No. 1996-2126, New Orleans, June 1996

We review in this paper theoretical and numerical studies of the nearly axisymmetric vortex breakdown in a pipe. Although several explanations of vortex breakdown have been proposed, a consistent description of this complicated phenomenon has not yet been provided. Also, the relations between the various theoretical and numerical solutions is not fully clear. We then describe a recent theory that has been developed by the authors. The theory is built of global analysis of the steady state solutions of the Euler equations that describe the motion of an axisymmetric and inviscid swirling flow in a pipe and of linear stability analysis of the various steady state solutions under certain boundary conditions that may reflect the physical situation. The theory unifies the major previous theoretical approaches and provides, for the first time, a consistent explanation of the physical mechanism leading to the axisymmetric vortex breakdown phenomenon, as well as the conditions for its occurrence.

Rusak, Z., Seginer, A. and Wasserstrom, E.

"CONVERGENCE CHARACTERISTICS OF A VORTEX-LATTICE METHOD FOR NONLINEAR CONFIGURATION AERODYNAMICS"

J. Aircraft, Vol. 15, No. 12, December 1978, pp. 861-863

The convergence characteristics of a vortex-lattice method for the high-angle-of-attack, nonlinear aerodynamics of aircraft and missile configurations are studied parametrically. The solution for the vortex intensities is determined by the tangency boundary condition on all of the configuration surfaces, including the three-dimensional, rolled-up wakes that characterize such flowfields. The a priori unknown position of the wake that renders this problem nonlinear is determined by an iterative process. Since there is no proof for the existence and uniqueness of this process, this paper investigates the effects of several geometrical and numerical parameters on the converged solution. It was found that the convergence of the iterative solution procedure is usually rapid and is not affected by initial conditions of the first iteration and by the integration method of the wake streamlines. Grid refinement leads to a converged solution, but its final values vary with wing surface paneling and wake discretization schemes within some range in the vicinity of the experimental data.

"TURBULENT DISSIPATION ESTIMATES FROM PULSE COHERENT DOPPLER INSTRUMENTS"

Proceedings of the IEEE/OES/CWTM Conference on Current Measurement Technology, March 2011, Monterey, CA, pp. 167-172.

Utilizing a commercially available acoustic Doppler velocimeter, the Nortek Vectrino with optional plus firmware, measurements of turbulence are made in a turbulent open channel flow in the 8m Research Flume of the DeFrees Hydraulics Laboratory. The measurements are used to estimate

dissipation from Kolmogorov's 2/3, 5/3 and 4/5 Laws as well as integration of the dissipation spectrum. Corrections to remove bias due to Doppler noise are carried out when appropriate. Results from the four methods are compared to judge the validity of each for use with single point velocity measurements from an acoustic Doppler Velocimeter. The 4/5 Law is the most consistent across each velocity component, but all methods produce reasonable estimates of dissipation from at least one velocity component.

Rutishauser, D.

"RECENT ANALYSIS AND STATUS OF DFW AND MEM WAKE VORTEX DATABASES IMPLICATIONS FOR WAKE MODELLING AND AVOSS PREDICTOR ALGORITHM REFINEMENTS"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

NASA Langley Research Center (LaRC) has collected large amounts of field data to support wake vortex research. These data include wake vortex position and strength information from a variety of research sensors, and corresponding meteorological parameters relevant to wake vortex behavior. The data was collected during field deployments from 1994 to 2000. The content and availability of the LaRC wake data will be summarized in this presentation, as well as the usefulness of the various types of data for wake modeling activities. Recent analysis of the data for wake modeling and wake mitigation concept development will also be discussed.

Rutishauser, D. K.

"PROGRESS TOWARDS THE INVESTIGATION OF TECHNICAL ISSUES RELEVANT TO THE DESIGN OF AN AIRCRAFT WAKE VORTEX ADVISORY SYSTEM (WakeVAS)"

AIAA Paper No. 2003-3808, Orlando, FL, June 2003.

Wake vortex separations applied to aircraft during instrument operations have been shown to potentially introduce inefficiencies in air traffic operations during certain weather conditions conducive to short duration wake hazards between pairs of landing aircraft. NASA Langley Research Center (LaRC) demonstrated an integration of technologies that provided real-time observations and predictions of aircraft wake behavior, from which reduced wake spacing from the current criteria was derived. To take this proof of concept to an operational prototype system, NASA has been working in cooperation with the FAA and other government and industry members to design operational concepts for a Wake Vortex Advisory System (WakeVAS). In addition to concept development, open research issues are being addressed and activities to quantify system requirements and specifications are currently underway. This paper describes the technological issues relevant to WakeVAS development and current NASA efforts to address these issues.

Rutishauser, D. K. and O'Connor, C. J.

"AIRCRAFT WAKE VORTEX SPACING SYSTEM (AVOSS) PERFORMANCE UPDATE AND VALIDATION STUDY"

NASA TM-2001-211240, October 2001, NASA Langley Research Center, Hampton, VA

An analysis has been performed on data generated from the two most recent field deployments of the Aircraft Wake VORtex Spacing System (AVOSS). The AVOSS provides reduced aircraft spacing criteria for wake vortex avoidance as compared to the FAA spacing applied under Instrument Flight Rules (IFR). Several field deployments culminating in a system demonstration at Dallas Fort Worth (DFW) International Airport in the summer of 2000 were successful in showing a sound operational concept and the system's potential to provide a significant benefit to airport operations. For DFW, a predicted average throughput increase of 6% was observed. This increase implies 6 or 7 more aircraft on the ground in a one-hour period for DFW operations. Several studies of performance correlations to system configuration options, design options, and system inputs are also reported. The studies focus on the validation performance of the system.

Rutishauser, D. K., Butler, P. and Riggins, J.

"A SENSITIVITY STUDY OF THE AIRCRAFT VORTEX SPACING SYSTEM (AVOSS) WAKE PREDICTOR ALGORITHM TO THE RESOLUTION OF INPUT METEOROLOGICAL PROFILES"

NASA TM-2004-213239, June 2004, NASA Langley Research Center, Hampton, VA

The AVOSS project demonstrated the feasibility of applying aircraft wake vortex sensing and prediction technologies to safe aircraft spacing for single runway arrivals. On average, AVOSS provided spacing recommendations that were less than the current FAA prescribed spacing rules, resulting in a potential airport efficiency gain. Subsequent efforts have included quantifying the operational specifications for future Wake Vortex Advisory Systems (WakeVAS). In support of these efforts, each of the candidate subsystems for a WakeVAS must be specified. The specifications represent a consensus between the high-level requirements and the capabilities of the candidate technologies. This report documents the beginnings of an effort to quantify the capabilities of the AVOSS Prediction Algorithm (APA). Specifically, the APA horizontal position and circulation strength output sensitivity to the resolution of its wind and turbulence inputs is examined. The results of this analysis have implications for the requirements of the meteorological sensing and prediction systems comprising a WakeVAS implementation.

"MEASUREMENTS OF AIRCRAFT WAKE VORTEX SEPARATION AT HIGH ARRIVAL RATES AND A PROPOSED NEW WAKE VORTEX SEPARATION PHILOSOPHY"

Fifth EUROCONTROL/FAA ATM R&D Seminar, June 2003, Budapest, Hungary

This paper presents data and a proposed new aircraft wake vortex separation standard that argues for a fundamental re-thinking of international practice. The current static standard, under certain atmospheric conditions, presents an unnecessary restriction on system capacity. A new approach, that

decreases aircraft separation when atmospheric conditions dictate, is proposed based upon the availability of new instrumentation and a better understanding of wake physics.

"WAKE VORTEX ADVISORY SYSTEM (WAKEVAS) CONCEPT OF OPERATIONS"

NASA/TM-2003-212176, April 2003, NASA Langley Research Center, Hampton, VA

NASA Langley Research Center has a long history of aircraft wake vortex research, with the most recent accomplishment of demonstrating the Aircraft Vortex Spacing System (AVOSS) at Dallas/Fort Worth International Airport in July 2000. The AVOSS was a concept for an integration of technologies applied to providing dynamic wake-safe reduced spacing for single runway arrivals, as compared to current separation standards applied during instrument approaches. AVOSS included state-of-the-art weather sensors, wake sensors, and a wake behavior prediction algorithm. Using real-time data AVOSS averaged a 6% potential throughput increase over current standards. This report describes a Concept of Operations for applying the technologies demonstrated in the AVOSS to a variety of terminal operations to mitigate wake vortex capacity constraints. A discussion of the technological issues and open research questions that must be addressed to design a Wake Vortex Advisory System (WakeVAS) is included.

Rutten, M.

"VORTEX AXIS CALCULATION BY USING VORTEX FEATURES"

AIAA Paper No. 2004-2353, Portland, OR, June-July 2004

For the development of highly maneuverable and high angle of attack aircraft flight, an essential point is to know the structure and behaviour of the vortical flow over delta wings. Vortex breakdown is one of the limiting factors of extreme maneuvers in flight and is a significant component of flight control. The demand of simulating the vortical flow behaviour has pushed the limits of current CFD Codes, but also the demand of advanced post processing tools. From an analysis point of view, the important

requirement is the capability to identify vortical flow patterns like vortex axis lines, vortex hull surfaces, and vortex interactions. This information is significant for a deeper physical understanding of various vortical flow phenomena and for flight control of aircrafts. Therefore, one goal of this paper is to compare typical vortex identification methods applied to the vortical flow over a generic 65 degrees swept delta wing. The overall goal of this paper is to use these methods as elements of a construction kit to define a fast algorithm to detect and calculate vortex axes.

Rutten, M., Alrutz, T. and Wendland, H.

"A VORTEX AXIS AND VORTEX CORE BORDER GRID ADAPTATION ALGORITHM"

International Journal for Numerical Methods in Fluids, Vol. 58, 2008, pp. 1379-1405.

In the design process of hydrodynamical and aerodynamical technical applications, the numerical simulation of massively separated vortical flow is crucial for predicting, for example, lift or drag. To obtain reliable numerical results, it is mandatory to accurately predict the physical behavior of vortices. Thus, the dominant vortical flow structures must be resolved in detail, which requires a local grid refinement and certain adaptation techniques. In this paper, a vortex flow structure adaptation algorithm is presented, which is particularly designed for local grid refinement at vortex axes positions and associated vortex core border locations. To this end, a fast and efficient vortex axis detection scheme is introduced and the algorithm for the vortex core border determination is explained. As the interaction between vortices makes the assignment of grid points to a certain vortex axis difficult, a helicity-based vortex distinction approach in combination with a geometrical rotational sensor is developed. After describing the combined different techniques in detail, the vortex feature adaptation algorithm is applied to analytical and more realistic examples, which show that the described grid adaptation algorithm is able to enhance the grid cell resolution locally such that all significant vortical flow phenomena are resolved.

"STABILITY CHARACTERISTICS OF A COUNTER-ROTATING UNEQUAL-STRENGTH BATCHELOR VORTEX PAIR"

Journal of Fluid Mechanics, Vol. 696, 2012, pp. 374-401.

A Batchelor vortex represents the asymptotic solution of a trailing vortex in an aircraft wake. In this study, an unequal-strength, counter-rotating Batchelor vortex pair is employed as a model of the wake emanating from one side of an aircraft wing; this model is a direct extension of several prior investigations that have considered unequal-strength Lamb-Oseen vortices as representations of the aircraft wake problem. Both solution of the linearized Navier-Stokes equations and direct numerical simulations are employed to study the linear and nonlinear development of a vortex pair with a circulation ratio of -0.5. In contrast to prior investigations considering a Lamb-Oseen vortex pair, we note strong growth of the Kelvin mode $[-2,0]$ coupled with an almost equal growth rate of the Crow instability. Three stages of nonlinear instability development are defined. In the initial stage, the Kelvin

mode amplitude becomes sufficiently large that oscillations within the core of the weaker vortex are easily observable and significantly affect the profile of the weaker vortex. In the secondary stage, filaments of secondary vorticity emanate from the weaker vortex and are convected around the stronger vortex. In the tertiary stage, a transition in the dominant instability wavelength is observed from the short-wavelength Kelvin mode to the longer-wavelength Crow instability. Much of the instability growth is observed on the weaker vortex of the pair, although small perturbations in the stronger vortex are observed in the tertiary nonlinear growth phase.

Ryan, K., Sheard, G. J. and Thompson, M. C.

"SHORT WAVE INSTABILITIES OF COUNTER-ROTATING BATCHELOR VORTEX PAIRS"

Fifth International Conference on CFD in the Process Industries, CSIRO, December 2006, Melbourne, Australia.

Recently, investigations have considered the cooperative elliptic instability which forms by the mutual co-existence of a counter-rotating Batchelor-type vortex pair. Such vortex pairs are observed in the wake of an aircraft and pose a significant danger to trailing aircraft. An aircraft flying through the wake of a lead aircraft can exhibit significant loss of lift and control forces; several accidents and near-misses have been recorded. Our investigation has identified that short-wave Kelvin-type instabilities may prematurely destroy the vortex pair. By inducing short-wave instabilities there is the potential to significantly improve safety in the aviation industry. The work has relied heavily on CFD to validate analytical estimates and provide data for future experimental investigations.

"SOUND RADIATION FROM ELLIPTIC VORTEX RINGS: EVOLUTION AND INTERACTION"

Journal of Sound and Vibration, Vol. 200, Issue 3, February 1997, pp. 231-252

Sound generation from the evolution and interaction of elliptic vortex rings is calculated numerically. An elliptic vortex ring emits a strong sound signal due to significant distortion and stretching of the vortex filament. At the far field, the acoustic pressure is linearly dependent on the third time derivatives of the vortex positions. Therefore, a numerical scheme of high resolution is employed to describe in detail the elliptic vortex ring motions, which are highly non-linear. Discretized vortex filaments are interpolated by using a parametric blending function to remove a possible numerical instability. The distorted vortex filament, owing to the self-induced velocity and the induced velocity from the other vortex segments, is redistributed at each time step. The accuracy and efficiency of the scheme are validated by comparisons with the analytic solution of circular vortex ring interaction. Acoustic signals from the evolution of a single elliptic vortex ring are obtained with various aspect ratios of the axes. Vortex motions and acoustic signals from two identical elliptic vortex rings, placed initially with selected separation distances, are calculated. Distinct periods are obtained from the evolution of each single elliptic vortex ring and the pairing process of two elliptic vortex rings. The calculated

periods in the acoustic signals depend to a significant degree on the initial aspect ratio of the ring and the separation distance.

Ryu, K.-W., Lee, D.-J. and Koo, S.-O.

"SOUND GENERATION DUE TO A SPINNING VORTEX PAIR NEAR THE FLAT AND CURVED WALL"

AIAA/CEAS-96-1748, State College, PA, May 1996

A numerical study of a two-dimensional acoustic field is carried out for a spinning vortex pair located near a wall to investigate the effect of the wall from the spinning quadrupole source in unsteady vortical flows. Based on the unsteady hydrodynamic information from the known incompressible flow field, the perturbed compressible acoustic terms derived from the Euler equations are calculated. Non-reflecting boundary conditions on the free field and the solid boundary conditions are developed for a generalized curvilinear coordinates system to investigate the effect of a curved wall. It is concluded that the sound generated by the quadrupole sources of unsteady vortical flows in the presence of a flat wall or a circular cylinder can be calculated by using the source terms of hydrodynamic flow fluctuations in both near and far acoustic fields simultaneously.

Saban, D.

"WAKE VORTEX MODELLING AND SIMULATION FOR AIR VEHICLES IN CLOSE FORMATION FLIGHT"

PhD Thesis, Jan. 2010, Cranfield University, Bedfordshire, UK.

The aim of this research is to develop realistic models of aerodynamic cross-coupling effects that can be incorporated in real-time or near real-time simulations of Unmanned Aerial Vehicles (UAV's) in close formation flight. These would permit the assessment of the risks and issues associated with wake vortex evolution and encounter and the analysis of their consequences on the design of automatic control systems and the development of safe and reliable operating procedures. Several wake vortex modeling techniques that can be used in formation flight simulations are reviewed. A novel Wake Vortex Model (WVM) is developed, implemented, verified, validated, and successfully integrated within a Matlab/Simulink simulation environment. The code, named ELL because it is based on Weissinger's extended lifting line theory, meets the following requirements: (i) it is generic and can easily be adapted to accommodate any wing planform and air vehicle configuration; (ii) it is computationally rapid enough to be used in real-time or near real-time simulations; (iii) and it is sufficiently representative to support studies of aerodynamic interaction between multiple air vehicles during formation reconfiguration and air-to-air refueling simulations. Simulink test scenarios of two Aerosonde UAVs are developed to test and validate the use of ELL within simulation models, and the simulation environment is interfaced with visualization tools to facilitate the evaluation of multiple air vehicle dynamic interaction.

Saban, D., Whidborne, J. F. and Cooke, A. K.

"SIMULATION OF WAKE VORTEX EFFECTS FOR UAVS IN CLOSE FORMATION FLIGHT"

The Aeronautical Journal, Vol. 113, No. 1149, 2009, pp. 727-738.

This paper addresses the development of multiple UAV deployment simulation models that include representative aerodynamic cross-coupling effects. Applications may include simulations of autonomous aerial refueling and formation flying scenarios. A novel wake vortex model has been developed and successfully integrated within a MATLAB/Simulink simulation environment. The wake vortex model is both sufficiently representative to support studies of aerodynamic interactions between multiple air vehicles, and straightforward enough to be used within real time or near real time air-to-air simulations. The model integration process is described, and computational results of a two-vehicle-formation flight are presented.

Sabelnikov, V.

"EXPERIMENTAL INVESTIGATION OF COMBUSTION STABILIZATION IN SUPERSONIC FLOW USING FREE RECIRCULATION ZONES"

Report SPC 96-4043, August 1997, Central Aerohydrodynamics Institute, Moscow, Russia.

Final report summarizes shortly main results of three quarterly reports and presents experimental results on self-ignition and combustion stabilization in supersonic flow using free circulation zone. Tests are conducted at hypersonic facility TsAGI T-131B. Measurements are performed in a nearly matched supersonic jet at the exit of two-dimensional channel over Mach number range $M = 2.0-2.8$ at stagnation temperature range $T = 1200-1400K$. Initial thickness of jet was equal 67 mm. Self-ignition and stabilization are obtained at $T = 1400K$. Self-ignition was absent at $T = 1200K, 1300K$. Thickness of free recirculation zone was about 25-30 mm.

Sabel'nikov, V. A., Korontsvit, Y. P., Ivanyushkin, A. K. and Ivanov, V. V.

"EXPERIMENTAL INVESTIGATION OF COMBUSTION STABILIZATION IN SUPERSONIC FLOW USING FREE RECIRCULATING ZONE"

AIAA Paper No. 98-1515, Jan. 1998, Reno, NV.

The paper presents experimental results on self-ignition and combustion stabilization of aerated by gas liquid kerosene in supersonic flow using free recirculating zone which was generated by the interaction of a concentrated vortex with a normal shock wave. Tests were conducted in hypersonic facility of TsAGI T-131B in a nearly matched to atmospheric pressure supersonic jet at the exit of two-dimensional channel over Mach number range $M = 2.0-2.8$ and total temperature range $T = 1200-1400K$. Initial thickness of jet was equal 67 mm. Self-ignition was not achieved at $T = 1400K$ and $1300K$. Thickness of free circulating zone was about 25-30 mm.

Saberi, H. A.

"ANALYTICAL MODEL OF ROTOR WAKE AERODYNAMICS IN GROUND EFFECT"

NASA-CR-166533, Stanford University, December 1983

The model and the computer program developed provides the velocity, location, and circulation of the tip vortices of a two-blade helicopter in and out of the ground effect. Comparison of the theoretical results with some experimental measurements for the location of the wake indicate that there is excellent accuracy in the vicinity of the rotor and fair amount of accuracy far from it. Having the location of the wake at all times enables us to compute the history of the velocity and the location of any point in the flow. The main goal of our study, induced velocity at the rotor, can also be calculated in addition to stream lines and streak lines. Since the wake location close to the rotor is known more accurately than at other places, the calculated induced velocity over the disc should be a good estimate of the real induced velocity, with the exception of the blade location, because each blade was replaced only by a vortex line. Because no experimental measurements of the wake close to the ground were available, quantitative evaluation of the theoretical wake was not possible. But qualitatively we have been able to show excellent agreement. Comparison of flow visualization with our results has indicated the location of the ground vortex is estimated excellently. Also the flow field is, however, well represented.

Sacks, A. H.

"BEHAVIOR OF VORTEX SYSTEM BEHIND CRUCIFORM WINGS - MOTIONS OF FULLY ROLLED-UP VORTICES"

NACA TN-2605, January 1952, Langley Aeronautical Laboratory, Langley Field, VA.

The motions of four fully rolled-up vortices representing the vortex system trailing behind cruciform wings are studied by theoretical and visual-flow methods. The analysis applies throughout the Mach number range. Equations are developed for the three-dimensional paths traced by the vortices behind a cruciform wing banked 45 deg., and calculations are made of the distance behind the wing at which the upper two vortices pass through the lower two. It is found that this 'leapfrog' distance depends upon the lift coefficient, aspect ratio, and span loading of the cruciform wing, and that for low-aspect-ratio cruciform wings leapfrogging may occur within two chord lengths of the trailing edges. The various types of vortex motion to be expected throughout the angle-of-attack range are considered in some detail, and the interaction of the two vortex sheets shed from the cruciform wing is taken into account. Results of some water-tank studies are also presented and compared with the theory.

Saffman, P. G.

"STRUCTURE AND STABILITY OF STREETS OF FINITE VORTICES"

Vortex Motion: Proceedings of a Colloquium Held at Goettingen on the Occasion of the 75th Anniversary of the Aerodynamische Versuchsanstalt in November 1982, edited by Hornung, H. G. and E. A. Muller

Results are presented for the steady motion of finite cored uniform vortices in an incompressible perfect fluid. The cases of single vortices, vortex pairs, single rows and the staggered double row are considered. The stability of the flows to two-dimensional disturbances is examined. In particular, it is shown that finite area stabilizes the Karman vortex street for a finite band of aspect ratio values about the Karman value of 0.281.

Saffman, P. G.

"THE VELOCITY OF VISCOUS VORTEX RINGS"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 9-10

The motion of vortex rings of small cross section is considered. A formula is given for the velocity of a ring in an ideal fluid with an arbitrary distribution of vorticity in the core and an arbitrary circumferential velocity. A definition of velocity is given for the unsteady diffusing ring in a viscous fluid, and the speed is found by the method used for rings in ideal fluids.

Saffman, P. G.

"THE MOTION OF A VORTEX PAIR IN A STRATIFIED ATMOSPHERE"

Studies in Appl. Math., June 1972, Vol. 51, No. 2, pp. 107-119

The movement of a horizontal vortex pair through an inhomogeneous fluid is considered. The problem is formulated first for the case when the ambient fluid is uniform, the fluid moving with the vortex pair has a different density, and the motion is supposed laminar and inviscid. An approximate solution is obtained, which predicts that the distance between the vortices stays constant and the vortices accelerate at a constant rate. This solution is then applied to motion in a stratified atmosphere and it is found that the vortices oscillate vertically with a frequency and amplitude depending on the initial conditions and the stratification. Finally, approximate equations are constructed to describe the effects of turbulent entrainment into the fluid moving with the vortex pair, and an estimate of the damping is obtained.

Saffman, P. G.

"THE STRUCTURE OF TURBULENT LINE VORTICES"

AFOSR-72-2283, October 1972, California Institute of Technology, Pasadena, CA

A theory is given to explain the observed dependence on Reynolds number of the decay of turbulent line vortices. The discussion considers first the self-similar vortex, in which all quantities are assumed to depend only on the circulation at infinity, the Reynolds number, and the time from a virtual origin. It is argued that the turbulent line vortex has a triple structure: an outer vortex of given radius, an inner vortex, and a viscous core. The axial velocity in the core, produced by growth of a trailing vortex, is shown to be Reynolds number dependent.

Saffman, P. G.

"STRUCTURE OF TURBULENT LINE VORTICES"

Phys. Fluids, Vol. 16, No. 8, August 1973, pp. 1181-1188

A theory is given to explain the observed dependence on Reynolds number of the decay of turbulent line vortices. It is argued that the turbulent vortex has a triple structure; an outer region with a logarithmic distribution of circulation; and an inner region and viscous core in both of which the motion is close to solid body rotation. The development of an overshoot of circulation in the outer region is discussed, and the axial velocities produced by growth of a trailing vortex are calculated.

Saffman, P. G.

"A MODEL OF VORTEX RECONNECTION"

J. Fluid Mech., Vol. 212, March 1990, pp. 395-402

A model is proposed to describe the breaking and rejoining of vortex lines which occurs when vortex filaments of equal and opposite strengths touch. It is based on the idea that viscosity cancels the vorticity where the filaments first touch. The weakening of the centrifugal force in the vortex core then leads to a local increase in the pressure which accelerates the fluid in the cores in the axial direction and convects the vorticity away from the initial contact and produces an apparent rejoining.

Saffman, P. G.

"VORTEX DYNAMICS"

Cambridge Monographs on Mechanics and Applied Mathematics, 1st edition, Cambridge University Press, New York, 1992

The emphasis in this monograph is on the classical theory of inviscid incompressible fluids containing finite regions of vorticity. The effects of viscosity, compressibility, inhomogeneity, and stratification are enormously important in many fields of application, from hypersonic flight to global environmental fluid mechanics. However, this volume focuses on those aspects of fluid motion which are primarily controlled by the vorticity and are such that the effects of the other fluid properties are secondary.

Saffman, P. G.

"APPROACH OF A VORTEX PAIR TO A RIGID FREE SURFACE IN VISCOUS FLUID"

Physics of Fluids, A - Fluid Dynamics, Vol. 3, No. 5, Pt. 1, May 1991, pp. 984-985

The motion in a viscous incompressible fluid of a vortex pair toward a rigid plane wall on which slip is allowed is considered. It is shown that the centroids of vorticity do not approach the wall monotonically, and there is some rebound at a rate depending upon the viscosity and initial separation of the vortices.

Saffman, P. G. and Schatzman, J. C.

"AN INVISCID MODEL FOR THE VORTEX-STREET WAKE"

Journal of Fluid Mechanics, Vol. 122, 1982, pp. 467-486.

An inviscid model for the Karman vortex street, containing vortices of uniform vorticity surrounded by irrotational fluid, is related to the wake behind a bluff body by a global analysis requiring the conservation of momentum, energy and vorticity. Some comparison is made with experimental results reported in the literature. A qualitative procedure is proposed whereby the slow evolution of the wake through viscous effects is approximated. Some comments are made regarding the relevance of the stability properties of the inviscid street. Some calculations are made for the 'secondary vortex street' that is observed after breakdown and rearrangement, and comparison is made with experiment.

Saito, T. and Takagi, M.

"WAKE SURVEY OF AN AIRPLANE MODEL WITH AND WITHOUT GROUND PLANE"

Proceedings of 9th International Symposium on Flow Visualization, Edinburgh, Scotland, August 2000, pp. 349-1 - 349-4

The tip vortices at the ends of the wing and the flap of a model airplane are investigated. The methods are force measurements and wake surveys. The balance is a strut type six component balance and the wake survey is done by a traversing rake of four simple total pressure (Pitot) probes. The measurements are carried out at various combinations of the angle of attack, the flap, and the ground plane. The results clearly show the relationship between aerodynamic characteristics and the flow field, and a possibility to improve the flap efficiency was suggested.

"DEVELOPMENT OF A WAKE VORTEX DETECTION ALGORITHM USING COHERENT LASER RADAR"

13th CLRC Proceedings, Oct. 2005, Tokyo, Japan, pp. 148-151

In the present paper, we have proposed a wake vortex detection algorithm using the template matching method. And the computer simulations with Doppler velocity distributions of the pseudo wake vortex have borne out that the proposing method operated properly. We have developed a wake vortex detection system using coherent laser radar, and have been evaluating this algorithm.

"STUDY OF THREE-DIMENSIONAL EFFECTS ON VORTEX BREAKDOWN"

ICAS 1988, Paper No. 5.4.2, August-September 1988, Jerusalem, Israel.

The incompressible, axisymmetric, steady Navier-Stokes equations in primitive variables are used to simulate vortex breakdown. The equations, discretized using a second-order, central-difference scheme, are linearized and then solved using an exact LU decomposition, Gaussian elimination, and Newton iteration. Solutions are presented for Reynolds numbers, based on vortex-core radius, as high as 1500. An attempt to study the stability of the axisymmetric solutions to three-dimensional perturbations is discussed.

Samant, S. S. and Gray, R. B.

"A SEMI-EMPIRICAL CORRECTION FOR THE VORTEX CORE EFFECT ON HOVERING ROTOR WAKE GEOMETRIES"

33rd Annual National V/STOL Forum of the American Helicopter Society, Washington, DC, May 1977

A semi-empirical correction for the vortex core effect on hovering rotor wake geometries is presented. The results show that with this effect included, the tip vortex geometry in the near wake can be calculated with much better accuracy for one-, two-, three-, and four-bladed rotors than has been previously possible. The method breaks down for six-bladed rotors and this appears to be due to the use of the lifting line rather than the lifting surface model for the blade.

Samet, M. and Einav, S.

"MEAN VALUE MEASUREMENTS OF A TURBULENT SWIRLING-JET"

AIAA Journal, Vol. 26, No. 5, May 1988, pp. 619-621.

Our knowledge of the swirling-jet in a coflowing stream is quite limited. The present study is an attempt to provide sufficiently complete and reliable information on swirling-jets in still and moving surroundings. The data obtained during the present study were restricted to mean values in the swirling-jet. The data showed that the longitudinal and radial distributions of mean-velocity components were strongly affected by the degree-of-swirl and velocity ratio.

Sammonds, R. I. and Stinnett, Jr., G. W.

"HAZARD CRITERIA FOR WAKE VORTEX ENCOUNTERS"

NASA TM X-62473, August 1975, NASA Ames Research Center, Moffett Field, CA

A piloted, motion-based simulation was conducted to evaluate the ability of simulators to produce realistic vortex encounters and to develop criteria to define hazardous encounters. A boundary for

encounter hazard based on subjective pilot opinion could be identified in terms of maximum bank angle. For encounter altitudes from 200 to 500 feet, tentative hazard criteria established for visual flight conditions indicated that the acceptable upset magnitude increased nearly linearly with increasing altitude.

Sammonds, R. I., Stinnett, Jr., G. W. and Larsen, W. E.

"WAKE VORTEX ENCOUNTER HAZARDS CRITERIA FOR TWO AIRCRAFT CLASSES"

FAA-RD-75-206, June 1976, NASA Ames Research Center, Moffett Field, CA

An investigation was conducted using a piloted, motion-base simulator to determine wake vortex hazard criteria for two classes of jet transport aircraft. A light business jet and a large multiengine jet transport were represented respectively. The hazard boundaries were determined in terms of the maximum bank angle due to the vortex encounter. Upsets as small as 7 deg in bank angle were considered to be hazardous at breakout altitude (200 ft (61.0 m)) for Instrument Flight Rule (IFR) and at 50 ft (15.2 m) for Visual Flight Rule (VFR) for both aircraft classes. Proximity to the ground was the primary reason for a hazardous rating. This was reflected in the reduction in the maximum bank angle at the hazard boundary and in more consistent ratings as altitude was decreased.

Sammonds, R. I., Stinnett, Jr., G. W. and Larsen, W. E.

"CRITERIA RELATING WAKE VORTEX ENCOUNTER HAZARD TO AIRCRAFT RESPONSE"

J. Aircraft, Vol. 14, No. 10, October 1977, pp. 981-987

Piloted six-degree-of-freedom motion simulator investigations were conducted at the NASA Ames Research Center to determine criteria relating the hazard posed by a wake vortex encounter to the response of the encountering airplane. These investigations demonstrated that wake vortex encounters can be reproduced realistically on a simulator, established that the maximum bank angle due to the encounter provides the best correlation with the pilot's subjective assessment of the hazard, and determined hazard boundaries in terms of maximum bank angle for two classes of jet transport aircraft.

Sampson, R. G.

"AN EXPERIMENTAL AND THEORETICAL INVESTIGATION OF THE STRUCTURE OF A TRAILING VORTEX WAKE"

Aviation Quarterly, Vol. 3, February 1977, pp. 39-50.

An improved technique for the use of a five-hole yaw probe has been used in determining velocity, vorticity, and pressure distributions over a transverse plane five chords downstream of a lifting wing. A well-defined tip vortex is shown to exist, together with a vortex sheet which contains a significant proportion of the total vorticity. The vorticity distribution is compared with that predicted by the

calculation of vortex sheet roll-up using a two-dimensional array of line vortices. Good agreement is obtained, and the validity of using time steps large enough to inhibit the chaotic motion found in some calculations of this type is demonstrated. The structure of the tip vortex is found to be well described by the turbulent vortex model of Hoffman and Joubert.

Sampson, R. G.

"TRAILING VORTEX WAKE STRUCTURE"

In: Deutsche Gesellschaft fuer Luft- und Raumfahrt, European Rotorcraft and Powered Lift Aircraft Forum, 2nd, Bueckeburg, W. Germany, September 20-22, 1976

The wake trailed by a half-wing mounted in an open-jet wind tunnel has been studied over a transverse plane five chords downstream. Vorticity contours show a well-defined tip vortex, together with a diffuse vortex sheet which contains a significant portion of the circulation. Calculations of the roll-up of a sheet of line vortices is shown to represent the shape of the experimental vorticity contours, and the tip vortex strength, very well. In addition, the velocity distribution within the tip vortex is shown to compare well with a logarithmic circulation distribution for a turbulent line vortex.

Sanders, N. D. and Stockman, N. O.

"NOISE FROM TWO-DIMENSIONAL VORTICES"

AIAA Paper No. 1972-0155, San Diego, CA, January 1972.

The fluctuating flow in an idealized model of a turbulent shear layer composed of many discrete vortices is analyzed. Computer solutions reveal irregular motions which are similar in many respects to observed flows in turbulent three-dimensional layers. The model is further simplified to a pair of equal co-rotating vortices and the noise generation is analyzed in terms of equivalent quadrupole oscillations. Results of the analysis in a uniform medium are consistent with Lighthill's results. New results are obtained for the effects of mean velocity gradients, compressibility, temperature inhomogeneities, and gradients of the mean Mach number.

Sanderse, B.

"AERODYNAMICS OF WIND TURBINE WAKES -- LITERATURE REVIEW"

ECN-E-09-016, 2009, Energy Research Centre of the Netherlands, Petten, The Netherlands.

This report reviews the available literature on the aerodynamics of wind turbines and wind farms. Firstly, two introductory chapters are devoted to the physics of the flow around a wind turbine and the existing engineering models for blade and wake aerodynamics. The focus of this work is however on the numerical modeling of wakes. The difficulties in solving the Navier-Stokes equations are discussed, and the different existing models for the description of the rotor and the wake are mentioned, along with problems associated with the choice of turbulence models and inflow conditions. The purpose of

this overview is to include the latest developments in the numerical computation of wind turbine aerodynamics.

Sankar, L. N and Yang, Z.

"RECENT IMPROVEMENTS TO MODELING ROTOR WAKES IN HOVER AND FORWARD FLIGHT"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

The goal of this study is to develop an efficient solution methodology that will accurately predict the aerodynamic loads on a rotor in forward flight. The model should simulate the complex blade dynamic motion in forward flight, include a trim process, have a self-consistent wake model, and account for the aeroelastic deformations of the blade. A hybrid method is used in this study, and is demonstrated to be an appropriate phenomenological methodology for capturing the unsteady flow phenomena over the rotor in different flow regions. A Navier-Stokes analysis is used for modeling the viscous flow and near wake in a small region surrounding the single rotor blade. A finite volume form of the Navier-Stokes equations is solved using Roe's approximate Riemann solver with third order or fifth order spatial accuracy. In the outer zones of the computational domain, a potential flow analysis is used to solve the inviscid isentropic flow and carry the acoustic and pressure waves generated by the blade to the far field. A velocity decomposition approach is implemented that consists of a superposition of the freestream velocity, disturbance potential velocity, and induced velocity caused by the far wake. The grid velocity terms in the viscous and inviscid zones are implemented in a general form to consider the fact that the cell faces are moving with respect to an inertial observer, and are deforming because of aeroelastic effects in forward flight. A Lagrangean wake approach is implemented to capture the effects of the tip vortex once it leaves the viscous zone, and convect it without diffusion in the inviscid zone and the far field. The present approach is complete in that there is no need to link the analysis to an external rotor wake simulation code to include the far wake effects. This transonic, potential-based method with a Lagrangean wake model can convect the wake vorticity in the far field without numerical dissipation. This strategy also permits the use of a sparse grid in the far wake.

"AN APPROACH FOR THE VERIFICATION AND VALIDATION OF ROTOR AERODYNAMICS CODES BASED ON FREE-WAKE VORTEX METHODS"

31st European Rotorcraft Forum, September 2005, Florence, Italy, pp. 56.1-56.15.

This paper presents an approach to verify and validate a newly developed free-wake lifting line vortex code to model the wake generated by a wind turbine in axial flow conditions. Although the code is intended to simulate wind turbine wakes, it may be readily applied to propellers and helicopter rotors. The Delft University of Technology model wind turbine is used for this case study. Detailed hot-film inflow measurements in the near wake and smoke visualizations of tip vortex cores are used as a basis for validating the free-wake model. A parametric analysis was carried out to investigate how different

levels of blade/wake discretizations and viscous modeling influence the accuracy of the inflow results. The tip vortex locations were compared with those predicted by the vortex model. In general, very good agreement was obtained. It was found that the middle sections of the blades are rather insensitive to the choice of the viscous modeling parameters. However, high sensitivity to these parameters was observed at the blade tip and root regions.

"THE DEVELOPMENT OF HELICAL VORTEX FILAMENTS IN A TUBE"

Physics of Fluids, Vol. 17, April 2005, pp. 044104-1-044104-9

We study the formation of helical vortex filaments in a tube. The helical flow is assumed to be potential except in a very slender core. The boundary conditions are satisfied by introducing a helical image vortex. By assuming an axisymmetric flow upstream and imposing conservation laws, we obtain a set of conditions that must be satisfied by the helical flow downstream. We obtain that, when a generalized swirl parameter reaches a critical value, a bifurcation occurs and there are two solutions for the helical filamentary vortex. Such a bifurcation can be produced by increasing the swirl level of the inlet flow or the radius of the outlet tube, in agreement with experiments. We have discussed the influence of the core size and the Reynolds number on the generalized swirl parameter and with these results we have explained some experimental observations.

"TOWARDS THE CREATION OF A PHYSICS-BASED GROUND EFFECT MODEL"

AIAA Paper No. 2006-1072, Reno, NV, January 2006

It has been evident for quite some time that the development of a physics-based real-time prediction algorithm depends on the aircraft, on a clear understanding of the characteristics of the resulting vortices, atmospheric input, and the prevailing (unsteady, turbulent) boundary layer on the ground. The previous efforts on vortices have been directed towards the design of a single velocity-profile (valid within some probabilistic limits), regardless of the type of the originating aircraft. The IGE models were based on the use of several discrete vortices or many particles to mimic the field tests. These efforts led to satisfactory comparisons (mostly with flights out of ground effect) between the model predictions and the generating aircraft, but lacked physics. The present paper introduces two radically different concepts regarding the modeling of the aircraft vortices and the ground effect in view of several facts: the vortices of all aircraft are not created equal, the orbiting of secondary and tertiary vortices around the primary vortex in ground effect has never been observed in the field, and the physics content of the existing models leaves much to be desired. It is hoped that the concepts advanced herein will enhance the accuracy of the definition of the vortices entering the ground effect, the quantification of the turbulent boundary layer (or the displacement thickness), and the physics content of the IGE models.

Sarpkaya, T.

"COMPUTATIONAL METHODS WITH VORTICES -- THE 1988 FREEMAN SCHOLAR LECTURE"

Journal of Fluids Engineering, Vol. 111, March 1989, pp. 5-52.

A comprehensive review is presented of the computational methods based upon Helmholtz's powerful concepts of vortex dynamics, making use of Lagrangian or mixed Lagrangian-Eulerian schemes, the Biot-Savart law or the Vortex-in-Cell methods. The ingenious approximations and smoothing schemes developed in search of predictive models, qualitative solutions, new insights, or just some inspiration in the simulation of often two-dimensional, occasionally three-dimensional, and almost always incompressible fluids are described in detail. The challenge is to produce results in the face of ever accumulating errors within a time scale appropriate for the investigation. The review is organized around two major sections: Theoretical foundations and practical applications of vortex methods.

Sarpkaya, T.

"AN EXPERIMENTAL INVESTIGATION OF THE VORTEX-BREAKDOWN PHENOMENON"

NPS-59SL0071A, July 1970, Naval Postgraduate School, Monterey, CA.

The results of an experimental investigation of the characteristics of stationary and travelling vortex breakdowns in swirling flow in a diverging cylindrical tube are presented and discussed. Basically, three types of vortex breakdown were observed, viz, double helix, spiral and axisymmetric breakdown. The type and location of the stationary breakdowns were found to be dependent upon the Reynolds and circulation numbers of the flow. The breakdown bubble responded to gradual and abrupt changes in the upstream and downstream flow conditions in a manner analogous to the hydraulic jump in open-channel flow. The observations reported and the evidence presented herein revealed unmistakably that the vortex breakdown is a finite transition from a uniform state of swirling flow (supercritical) to one (subcritical) featuring a large standing wave, followed by standing wavelets, of finite amplitude.

Sarpkaya, T.

"TURBULENT VORTEX BREAKDOWN"

Phys. Fluids, Vol. 7, No. 10, October 1995, pp. 2301-2303.

Reported herein is a cone-shaped turbulent vortex breakdown in noncavitating swirling flows at high Reynolds numbers in a slightly diverging cylindrical tube. The turbulent conical form is in addition to the well-known double-helix, spiral, and nearly axisymmetric or 'bubble'-type breakdowns.

Sarpkaya, T.

"DECAY OF WAKE VORTICES OF LARGE AIRCRAFT"

AIAA Paper No. 1998-0592, January 1998, Reno, NV.

A summary of the previous works is followed by an in-depth analysis of velocities, circulations, and decay histories of several trailing vortices generated by large aircraft during field tests in Memphis, TN. The results suggest that the decay of trailing vortices is governed by the mutual straining of vortices; intermittent exchange of mass, momentum, and vorticity across the core boundary; rotational damping and restructuring of turbulence in the core; stretching of large turbulent structures, turbulent diffusion, the interaction of oppositely-signed vorticity in the overlapping regions of the vortex pair, and the draining of vorticity from the Kelvin oval.

Sarpkaya, T.

"EFFECT OF CORE SIZE ON THE RISE AND DEMISE OF TRAILING VORTICES"

NPS-69-82-010, December 1982, Naval Postgraduate School, Monterey, CA.

Experiments were conducted with five lifting surfaces to investigate the evolution of trailing vortices in stratified and unstratified water. The vortex trajectories were determined as a function of the relative depth, normalized time, stratification parameter, and the relative vortex core size. The results have shown that the vortices rise only to a finite height as they gradually demise under the influence of turbulence, sinusoidal instability, and vortex breakdown. The effect of stratification is to reduce the lifespan of vortices and the maximum height attained by them. Various approximate analyses have been examined and new ones have been proposed to determine the lifespan of the trailing vortices.

Sarpkaya, T.

"ON STATIONARY AND TRAVELLING VORTEX BREAKDOWNS"

J. Fluid Mech., Vol. 45, No. 3, February 1971, pp. 545-559

This paper describes some experiments in swirling flows in a diverging cylindrical tube in which various types of vortex breakdowns were observed. In one set of experiments, the position of the breakdown, axial component of the velocity of the vortex core, swirl angle distribution ahead of the breakdown, and the pressure distribution along the tube were determined for various flow rates for various values of circulation imparted to the fluid (water). Basically, three types of vortex breakdown were observed, viz. mild (double helix) breakdown, spiral breakdown (followed by turbulent mixing), and axisymmetric breakdown (followed by a thicker vortex core, then a spiral breakdown, and finally turbulent mixing). The type and the location of the stationary breakdowns were found to be dependent, for the vortex tube being used, upon the Reynolds and circulation numbers of the flow. In a spiral breakdown, the vortex core filament maintained the same sense of rotation as the upstream fluid elements. In an axisymmetric breakdown, the bubble included an inclined vortex-ring axis gyrated about the axis of the tube.

Sarpkaya, T.

"VORTEX BREAKDOWN IN SWIRLING CONICAL FLOWS"

AIAA Journal, Vol. 9, No. 9, September 1971, pp. 1792-1799

This paper describes some experiments in swirling flows in a mildly diverging cylindrical tube in which three types of vortex breakdown were observed: double-helix and spiral forms (followed by turbulent mixing), and axisymmetric form (often followed by a spiral breakdown, then by turbulent mixing). The type and location of the breakdowns were found to be dependent upon the Reynolds and circulation numbers of the flow. The observations reported and the evidence presented herein revealed that the axisymmetric breakdown is basically a finite transition between two separate states of flow, from a uniform state of swirling flow (supercritical) to one (subcritical) featuring a series of standing waves of finite amplitude. The double-helix and spiral forms, which occur in a region well defined by Reynolds and circulation numbers, appear to be a consequence of the instability of the vortical viscous flow to spiral disturbances.

Sarpkaya, T.

"EFFECT OF THE ADVERSE PRESSURE GRADIENT ON VORTEX BREAKDOWN"

AIAA Journal, Vol. 12, No. 5, May 1974, pp. 602-607

The present work examines in detail the effect of the degree of divergence on the type and location of the vortex breakdown in swirling flows in tubes of various angles of divergence, compares the results with those predicted using the analytical models proposed by Randall and Leibovich and by Mager, and illustrates the role played by the flow separation and reversal on the tube wall.

Sarpkaya, T.

"TRAILING VORTICES IN HOMOGENEOUS AND DENSITY-STRATIFIED MEDIA"

J. Fluid Mech., Vol. 136, November 1983, pp. 85-109

Experiments were conducted with three delta wings and two rectangular wings to investigate the evolution of trailing vortices in stratified and unstratified water. The vortex trajectories were determined as a function of the normalized time Vt/b , stratification parameter Nb/V and an effective vortex-core size r/b . The results have shown that the vortices rise only to a finite height as they decay gradually at first and rapidly thereafter under the influence of turbulence, sinusoidal instability, and core bursting. The effect of stratification is to reduce the lifetime of vortices and the maximum height attained by them.

Sarpkaya, T.

"DECAY OF WAKE VORTICES OF LARGE AIRCRAFT"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 61-74

Some of the data obtained during the Memphis Field Program has been evaluated. The results suggest that the decay of trailing vortices is governed by the mutual straining of vortices; intermittent exchange of mass, momentum, and vorticity across the core boundary; turbulent diffusion; and the stretching of large turbulent structures. The molecular diffusion is inconsequential and inconsistent with the time scales and the high Reynolds numbers encountered.

Sarpkaya, T.

"DECAY OF WAKE VORTICES OF LARGE AIRCRAFT"

AIAA Journal, Vol. 36, No. 9, September 1998, pp. 1671-1679

A summary of the previous works is followed by an in-depth analysis of velocities, circulations, and decay histories of several trailing vortices generated by large aircraft during field tests in Memphis, TN. The results suggest that the decay of trailing vortices is governed by the mutual straining of vortices; intermittent exchange of mass, momentum, and vorticity across the core boundary; rotational damping and restructuring of turbulence in the core; stretching of large turbulent structures, turbulent diffusion, the interaction of oppositely-signed vorticity in the overlapping regions of the vortex pair, and the draining of vorticity from the Kelvin oval.

"THREE-DIMENSIONAL INTERACTIONS OF VORTICES WITH A FREE SURFACE"

AIAA Paper No. 1992-0059, Reno, NV, January 1992

The interaction of a single turbulent trailing vortex and its image with a deformable free surface has been undertaken for the purpose of exploring the origins of scars, striations, and three-dimensional instabilities. The experiments were conducted in a low turbulence water tunnel through the use of various vertically-mounted hydrofoils. The distance between the top of the test foil and the water surface was systematically varied. The principal measurements were photographic observations of the vortices and free surface through the use of laser induced fluorescence. Certain unusual characteristics of the vortex - evolution of U-shaped structures and turbulent patches - and their role in the creation of whirls have been investigated. The numerical part of the investigation used the vortex dynamics and explored the evolution of whirls, energy spectrum, and the fractal dimensions of the two-dimensional turbulence field.

Sarpkaya, T.

"NEW MODEL FOR VORTEX DECAY IN THE ATMOSPHERE"

J. Aircraft, Vol. 37, No. 1, January-February 2000, pp. 53-61

1889

A new vortex decay model for the prediction of the descent of aircraft trailing vortices subjected to realistic environmental conditions (stratification, turbulence, crosswind, headwind, shear effects, and ground effect) is presented, and the model is applied to field data obtained with Lidar in Memphis and Dallas-Fort Worth airports. Although the model has not yet been fully optimized, the predictions and field data compare reasonably well. Some flights, particularly in unstable environments, exhibit behavior unexplainable in terms of the assumed, measured, and/or indirectly calculated input parameters, for example, vortex separation, uncertainties in Lidar measurements, stratification, shear, gravity currents, head- and crosswinds, turbulent kinetic energy, and/or the eddy dissipation rate.

Sarpkaya, T.

"A NEW MODEL FOR VORTEX DECAY IN THE ATMOSPHERE"

AIAA Paper No. 1999-0761, Reno, NV, January 1999.

The purpose of this paper is (a) to present a new vortex decay model for the prediction of the descent of aircraft trailing vortices subjected to realistic environmental conditions (stratification, turbulence, cross wind, headwind, shear effects, and ground effect), and (b) to apply the model to field data obtained with Lidar in Memphis and Dallas-Fort Worth airports. Although the model has not yet been optimized, the predictions and field data compare reasonably well. Some flights, particularly in unstable environments, exhibit behavior unexplainable in terms of the assumed, measured and/or indirectly-calculated input parameters (e.g., vortex separation, uncertainties in Lidar measurements, stratification, shear, head and cross winds, turbulent kinetic energy and/or the eddy dissipation rate.

"EFFECTS OF AMBIENT TURBULENCE AND STRATIFICATION ON THE DEMISE OF TRAILING VORTICES"

NPS69-86-006, July 1986, Naval Postgraduate School, Monterey, CA.

A series of experiments was carried out with two streamlined foils at different speeds in a towing tank. The ambient turbulence (nearly isotropic) was generated by means of a bi-planar grid. The model-grid separation distance was varied systematically in order to subject the trailing vortices to varying degrees of turbulence. The data have been expressed in terms of a normalized turbulence parameter and the relative rise of the vortices. The results have shown that the ultimate height to which the vortices rise prior to their demise is controlled by the two parameters cited, irrespective of the shape and the aspect ratio of the lifting surfaces. A numerical analysis has been initiated to analyze the motion of the trailing vortices and the propagation of internal waves in density stratified medium with the ultimate objective of incorporating the effect of turbulence into the numerical model.

Sarpkaya, T. and Daly, J. J.

"EFFECT OF AMBIENT TURBULENCE ON TRAILING VORTICES"

J. Aircraft, Vol. 24, No. 6, June 1987, pp. 399-404

The effects of ambient turbulence (generated by a biplanar grid) on the migration and lifespan of trailing vortices are investigated in a towing tank using two NACA-0012 foils moving at a constant angle of attack. The results show that the rise and demise of the vortices are controlled primarily by the rate of dissipation of the background turbulence. The integral scale of turbulence plays only a minor role. In both a quiescent or weakly-turbulent fluid the sinusoidal instability and in a fluid with stronger turbulence, the vortex bursting precedes the subsequent instability events which brings about the eventual destruction of the vortices. Both forms of the large-scale instability are often accompanied by the roll of the vortex pair onto its side. Shear is not necessary for the roll but may enhance it under atmospheric conditions.

Sarpkaya, T. and Henderson Jr., D. D.

"SURFACE DISTURBANCES DUE TO TRAILING VORTICES"

NPS-69-84-004, March 1984, Naval Postgraduate School, Monterey, CA.

The characteristics of the surface signatures resulting from the interaction of the trailing vortices with the free surface have been investigated both theoretically and experimentally. The vortices were created using three lifting surfaces of different shape and aspect ratio (two Delta wings and a rectangular foil). The surface disturbances have been classified into two groups (striations and scars) and the evolution of each type has been expressed in terms of the governing parameters such as the depth of generation of vortices, mutual induction velocity, and the initial vortex spacing. It has been shown that the surface signatures are a consequence of the strain field resulting from the nonuniform surface-velocity distribution and that they are not simple capillary-gravity waves. A turbulence model has been used to establish reasonable correlation between the theoretical and experimental results.

Sarpkaya, T. and Johnson, S. K.

"EVOLUTION OF AIRCRAFT TRAILING VORTICES IN A STRATIFIED FLUID"

AIAA Paper No. 1983-0564, Reno, NV, January 1983

The evolution of trailing vortices in stratified and unstratified water was experimentally investigated for the cases of two rectangular and three delta wings, determining vortex trajectories as a function of relative depth, normalized time, stratification parameter, and relative vortex core size. Results obtained show that vortices rise only to a finite height as they gradually decay under the influence of turbulence, sinusoidal instability, and vortex breakdown, where the effect of stratification is to reduce vortex lifespan and maximum attained height. The determination of trailing vortex lifespan is attempted through several approximate analyses.

Sarpkaya, T. and Johnson, S. K.

"TRAILING VORTICES IN STATIFIED FLUIDS"

NPS-69-82-003, June 1982, Naval Postgraduate School, Monterey, CA

Experiments were conducted with two delta wings and a streamlined body with lifting surfaces to investigate the evolution of turbulent trailing vortices in stratified and unstratified water. The vortex trajectories were determined as a function of the relative depth, normalized time, and the stratification parameter. The results have shown that the vortices rise only to a finite height as they gradually demise under the influence of turbulence, sinusoidal instability, and the vortex breakdown. The effect of stratification is to reduce the lifespan of vortices and the maximum height attained by them. Various approximate analyses have been examined and new ones have been proposed to determine the lifespan of the vortices. Finally, an exploratory numerical analysis of the two-dimensional, unsteady laminar vortices has been carried out with encouraging results.

Sarpkaya, T. and Suthon, P.

"INTERACTION OF A VORTEX COUPLE WITH A FREE SURFACE"

Experiments in Fluids, Vol. 11, 1991, pp. 205-217.

The characteristics of three-dimensional flow structures (scars and striations) resulting from the interaction between a heterotrophic vortex pair in vertical ascent and a clean free surface are described. The flow features at the scar-striation interface (a constellation of whirls or coherent vortical structures) are investigated using flow visualization, a motion analysis system, and the vortex-element method. The results suggest that the striations are a consequence of the short wavelength instability of the vortex pair and the helical instability of the tightly spiraled regions of vorticity. The whirls result from the interaction of striations with the surface vorticity. The whirl-merging is responsible for the reverse energy cascade leading to the formation and longevity of larger vortical structures amidst a rapidly decaying turbulent field.

"WAKE-VORTEX EDDY-DISSIPATION MODEL PREDICTIONS COMPARED WITH OBSERVATIONS"

J. Aircraft, Vol. 38, No. 4, July-August 2001, pp. 687-692.

The purpose of this paper is to describe the latest version of a wake-vortex eddy-dissipation model devised by Sarpkaya, and to compare its predictions with lidar observations obtained at Memphis and Dallas/Fort Worth airports. The model simulates the evolution of aircraft-generated trailing vortices in an atmospheric environment defined by vertical profiles of potential temperature, eddy-dissipation rate, and crosswind. Visual and quantitative comparisons of the time histories of altitude, circulation, and lateral position of such vortices are presented.

Sarrat, C., Paugam, R., Paoli, R., Cariolle, D. and Nyblen, L.

"HIGH RESOLUTION SIMULATIONS OF AIRCRAFT CONDENSATION TRAILS: CONTRAILS EVOLUTION AND DIFFUSION"

Proceedings of the 2nd International Conf. on Transport, Atmosphere and Climate (TAC-2), edited by Sausen, R., van Velthoven, P. F. J., Bruning, C. and Blum, A., June 2009, Aachen, Germany and Maastricht, The Netherlands, pp. 108-111.

This study describes a high-resolution numerical simulation of the evolution of an aircraft condensation trail (contrail) and its transition into a contrail-cirrus. The results show the extension of the contrail over 3200m width during a few hours. In particular, we show that the vertically integrated optical thickness is maintained in the core of the contrail during four hours.

Sathe, A. and Mann, J.

"A REVIEW OF TURBULENCE MEASUREMENTS USING GROUND-BASED WIND LIDARS"

Atmospheric Measurement Techniques, Vol. 6, 2013, pp. 3147-3167.

A review of turbulence measurements using ground-based wind lidars is carried out. Work performed in the last 30 yr, i.e., from 1972-2012 are analyzed. More than 80 percent of the work has been carried out in the last 15 yr, i.e., from 1997-2012. New algorithms to process the raw lidar data were pioneered in the first 15 yr, i.e., from 1972-1997, when standard techniques could not be used to measure turbulence. Obtaining unfiltered turbulence statistics from the large probe volume of the lidars has been and remains the most challenging aspect. Until now, most of the processing algorithms that have been developed have shown that by combining an isotropic turbulence model with raw lidar measurements, we can obtain unfiltered statistics. We believe that an anisotropic turbulence model will provide a more realistic measure of turbulence statistics. Future development in algorithms will depend on whether the unfiltered statistics can be obtained without the aid of any turbulence model. With the tremendous growth of the wind energy sector, we expect that lidars will be used for turbulence measurements much more than ever before.

Sathe, A. and Mann, J.

"MEASUREMENT OF TURBULENCE SPECTRA USING SCANNING PULSED WIND LIDARS"

Journal of Geophysical Research, Vol. 117, 2012, pp. D01201-1 to D01201-11.

Turbulent velocity spectra, as measured by a scanning pulsed wind lidar (WindCube), are analyzed. The relationship between ordinary velocity spectra and lidar derived spectra is mathematically very complex, and deployment of the three-dimensional spectral velocity tensor is necessary. The resulting scanning lidar spectra depend on beam angles, line-of-sight averaging, sampling rate, and the full three-dimensional structure of the turbulence being measured, in a convoluted way. The model captures the attenuation and redistribution of the spectral energy at high and low wave numbers very well. The model and measured spectra are in good agreement at two analyzed heights for the u and w components of the velocity field. An interference phenomenon is observed, both in the model and the

measurements, when the diameter of the scanning circle divided by the mean wind speed is a multiple of the time between the beam measurements. For the v spectrum, the model and the measurements agree well at both heights, except at very low wave numbers, less than 0.005/m. In this region, where the spectral tensor model has not been verified, the model overestimates the spectral energy measured by the lidar. The theoretical understanding of the shape of turbulent velocity spectra measured by scanning pulsed wind lidar is given a firm foundation.

Sathe, A., Mann, J., Gottschall, J. and Courtney, M. S.

"CAN WIND LIDARS MEASURE TURBULENCE?"

Journal of Atmospheric and Oceanic Technology, Vol. 28, July 2011, pp. 853-868.

Modeling of the systematic errors in the second-order moments of wind speeds measured by continuous-wave (ZephIR) and pulsed (WindCube) lidars is presented. These lidars use the conical scanning technique to measure the velocity field. The model captures the effect of volume illumination and conical scanning. The predictions are compared with the measurements from the ZephIR, WindCube, and sonic anemometers at a flat terrain test site under different atmospheric stability conditions. The sonic measurements are used at several heights on a meteorological mast in combination with lidars that are placed on the ground. Results show that the systematic errors are up to 90 percent for the vertical variance, whereas they are up to 70 percent for the horizontal velocity variance. For the ZephIR, the systematic errors increase with height, whereas for the WindCube, they decrease with height. The systematic errors also vary with atmospheric stability and are low for unstable conditions. In general, for both lidars, the model agrees well with the measurements at all heights and under different atmospheric stability conditions. For the ZephIR, the model results are improved when an additional low-pass filter for the 3-s scan is also modeled. It is concluded that with the current measurement configuration, these lidars cannot be used to measure turbulence precisely.

Sathe, A., Mann, J., Vasiljevic, N. and Lea, G.

"A SIX-BEAM METHOD TO MEASURE TURBULENCE STATISTICS USING GROUND-BASED WIND LIDARS"

Atmospheric Measurement Techniques, Vol. 8, 2015, pp. 729-740.

A so-called six-beam method is proposed to measure atmospheric turbulence using a ground-based wind lidar. This method requires measurement of the radial velocity variances at five equally spaced azimuth angles on the base of a scanning cone and one measurement at the center of the scanning circle, i.e. using a vertical beam at the same height. The scanning configuration is optimized to minimize the sum of the random errors in the measurement of the second-order moments of the components (u , v , w) of the wind field. We present this method as an alternative to the so-called velocity azimuth display (VAD) method that is routinely used in commercial wind lidars and which usually results in significant averaging effects of measured turbulence. In the VAD method, the high frequency radial velocity measurements are used instead of their variances. The measurements are performed using a pulsed lidar (WindScanner), and the derived turbulence statistics (using both

methods) such as the u and v variances are compared with those obtained from a reference cup anemometer and a wind vane at 89 m height under different atmospheric stabilities. The measurements show that in comparison to the reference cup anemometer, depending on the atmospheric stability and the wind field component, the six-beam method measures between 85 and 101 percent of the reference turbulence, whereas the VAD method measures between 66 and 87 percent of the reference turbulence.

"THREE-DIMENSIONAL STRUCTURE AND DECAY PROPERTIES OF VORTICES IN SHALLOW FLUID LAYERS"

Physics of Fluids, Vol. 13, No. 7, July 2001, pp. 1932-1945.

Recently, several laboratory experiments on vortex dynamics and quasi-two-dimensional turbulence have been performed in thin (stratified) fluid layers. Commonly, it is tacitly assumed that vertical motions, giving rise to a three-dimensional character of the flow, are inhibited by the limited vertical dimension. However, shallow water flows, which are vertically bounded by a no-slip bottom and a free surface, necessarily possess a three-dimensional structure due to the shear in the vertical direction. This shear may lead to significant secondary circulations. In this paper, the three-dimensional (3D) structure and the decay properties of vortices in shallow layers of fluid, both homogeneous and stratified, have been studied in detail by 3D direct numerical simulations. The quasi-two-dimensionality of these flows is an important issue if one is interested in a comparison of experiments of this type with purely two-dimensional theoretical models. The influence of several flow parameters, like the depth of the fluid and the Reynolds number, has been investigated. In general, it can be concluded that the flow loses its two-dimensional character for larger fluid depth and larger Reynolds number. Furthermore, it is possible to construct a regime diagram that allows the assessment of the parameter regime, where the flow can be considered as quasi-two-dimensional. It is found that the presence of secondary circulations within a planar vortex flow results in a deformation of the radial profile of axial velocity. In the limiting case of quasi-two-dimensional flow, the vorticity profiles can be scaled according to a simple diffusion model. In a two-layer stratified system, the decay is reduced and three-dimensional motions are significantly inhibited compared to the corresponding flows in a homogeneous layer.

"VORTEX RESEARCH FACILITY IMPROVEMENTS AND PRELIMINARY DENSITY STRATIFICATION EFFECTS ON VORTEX WAKES"

AIAA Paper No. 1985-0050, Reno, NV, January 1985.

The Vortex Research Facility at NASA's Langley Research Center has recently completed a facility modernization. This modernization has involved replacing the data acquisition hardware and software as well as upgrading the research vehicle. The Vortex Research Facility is a unique experimental facility in which the research model is towed the length of the facility instead of moving air past the research model as is done in conventional wind tunnels. Modern data acquisition hardware and software have

been incorporated into the facility to provide rapid acquisition of large amounts of data and efficient data reduction and presentation. The hardware improvements include a pulse coded modulation (PCM) system for acquiring model aerodynamic data and vehicle data, a change from a back-scatter to an enhanced forward-scatter laser velocimeter (LV) system for acquiring detailed wake measurements, and a minicomputer for the data acquisition and reduction for the PCM and LV systems. The improved experimental capabilities of this facility were used in a study of atmospheric stratification effects on wake vortex decay. Density stratification was produced by a test section temperature gradient resulting in a significant effect on the decay of the wake vortex system. The stratification results indicate that temperature gradient effects must be considered to avoid misleading conclusions in wake vortex research.

Satti, R., Li, Y., Shock, R. and Duncan, B.

"COMPUTATIONAL ANALYSIS OF A WINGTIP VORTEX IN THE NEAR-FIELD USING LBM-VLES APPROACH, AIAA Paper No. 2011-0679"

In recent years, the near-field flow behavior of the tip vortex originating from airfoils has been widely studied to provide insight into the complex physics governing the growth and propagation of wingtip vortices. For this purpose, extensive experiments on a semi-span NACA0012 airfoil were recently conducted in the low-speed wind tunnel at NASA Ames Research Center to provide data for benchmarking CFD codes. In the current study, a Lattice Boltzmann Method based very large eddy simulation (LBM-VLES) approach was used to simulate flow past a semi-span NACA0012 airfoil with rounded wingtip. Time-dependent, three-dimensional simulations were conducted to compute the span wise distribution of mean pressure coefficient and the mean velocity field distributions around the tip vortex region. The computed results for the mean flow field, including surface pressure distribution, flow field velocity through the vortex core, and the location of the vortex core were found to agree well with experimental data. Further, an in-depth analysis of the unsteady flow field and the comparison and validation of computational results for the Reynolds stress tensor is planned for future work.

Sau, R. and Mahesh, K.

"DYNAMICS AND MIXING OF VORTEX RINGS IN CROSSFLOW"

Journal of Fluid Mechanics, Vol. 604, 2008, pp. 389-409.

Direct numerical simulation is used to study the effect of crossflow on the dynamics, entrainment and mixing characteristics of vortex rings issuing from a circular nozzle. Three distinct regimes exist, depending on the velocity ratio (ratio of the average nozzle exit velocity to free-stream crossflow velocity) and stroke ratio (ratio of stroke length to nozzle exit diameter). Coherent vortex rings are not obtained at velocity ratios below approximately 2. At these low velocity ratios, the vorticity in the crossflow boundary layer inhibits roll-up of the nozzle boundary layer at the leading edge. As a result, a hairpin vortex forms instead of a vortex ring. For large stroke ratios and velocity ratio below 2, a series of hairpin vortices is shed downstream. The shedding is quite periodic for very low Reynolds numbers. For velocity ratios above 2, two regimes are obtained depending upon the stroke ratio. Lower stroke

ratios yield a coherent asymmetric vortex ring, while higher stroke ratios yield an asymmetric vortex ring accompanied by a trailing column of vorticity. These two regimes are separated by a transition stroke ratio whose value decreases with decreasing velocity ratio. For very high values of the velocity ratio, the transition stroke ratio approaches the 'formation number'. In the absence of trailing vorticity, the vortex ring tilts towards the upstream direction, while the presence of a trailing column causes it to tilt downstream. This behavior is explained. In the absence of crossflow, the trailing column is not very effective at entrainment, and is best avoided for optimal mixing and entrainment. However, in the presence of crossflow, the trailing column is found to contribute significantly to the overall mixing and entrainment. The trailing column interacts with the crossflow to generate a region of high pressure downstream of the nozzle that drives crossflow fluid towards the vortex ring. There is an optimal length of the trailing column for maximum downstream entrainment. A classification map which categorizes the different regimes is developed.

"PASSIVE SCALAR MIXING IN VORTEX RINGS"

J. Fluid Mech., Vol. 582, 2007, pp. 449-461

Direct numerical simulation is used to study the mixing of a passive scalar by a vortex ring issuing from a nozzle into stationary fluid. The 'formation number' (Gharib et al. J. Fluid Mech. Vol. 360, 1998, p. 121), is found to be 3.6. Simulations are performed for a range of stroke ratios (ratio of stroke length to nozzle exit diameter) encompassing the formation number, and the effect of stroke ratio on entrainment and mixing is examined. When the stroke ratio is greater than the formation number, the resulting vortex ring with trailing column of fluid is shown to be less effective at mixing and entrainment. As the ring forms, ambient fluid is entrained radially into the ring from the region outside the nozzle exit. This entrainment stops once the ring forms, and is absent in the trailing column. The rate of change of scalar-containing fluid is found to depend linearly on stroke ratio until the formation number is reached, and falls below the linear curve for stroke ratios greater than the formation number. This behavior is explained by considering the entrainment to be a combination of that due to the leading vortex ring and that due to the trailing column. For stroke ratios less than the formation number, the trailing column is absent, and the size of the vortex ring increases with stroke ratio, resulting in increased mixing. For stroke ratios above the formation number, the leading vortex ring remains the same, and the length of the trailing column increases with stroke ratio. The overall entrainment decreases as a result.

Sau, R. and Mahesh, K.

"THE EFFECT OF CROSSFLOW ON VORTEX RINGS"

AIAA Paper No. 2007-1316, Reno, NV, January 2007

DNS is performed to study passive scalar mixing in vortex rings in the presence, and absence of crossflow. For vortex rings without crossflow, the 'formation number' (Gharib et. al 1998) is found to be

3.6. Simulations are performed for a range of stroke ratios encompassing the formation number. In the absence of crossflow, the optimal stroke ratio for mixing and entrainment is shown to be at the formation number; the trailing column is not seen to be as beneficial as the ring itself. However, in the presence of crossflow, the trailing column is shown to contribute significantly because of the high-pressure gradient created by deformation of the column upon interacting with crossflow. It is shown that the crossflow reduces the stroke ratio beyond which the trailing column forms. This reduction in stroke ratio is due to entrainment of crossflow fluid during formation of the ring, and depends on the velocity ratio.

"CHARACTERIZATION OF EXTENDED NEAR-FIELD AND CROW INSTABILITY IN THE FAR-FIELD OF A REALISTIC AIRCRAFT WAKE"

European Congress on Computational Methods in Applied Sciences and Engineering ECCOMAS 2004, Jyväskylä, Finland, July 2004

Experimental data is used to generate the initial condition for a computation that predicts the wake evolution from the near-field to extended near-field. The Large-Eddy Simulation approach was followed to simulate the roll-up of the vorticity sheet and the subsequent merging of the primary co-rotating vortices. It leads to the formation of a wake that is primarily composed of a counter-rotating vortex pair. The final vortex structure appears to be best described by at least a two-scale velocity profile. A simulation of a generic configuration composed of a counter-rotating vortex pair was carried out to investigate the Crow instability in the far-field. For this purpose, the generic configuration is generated using the characteristics of the vortex structure that is recovered at the end of the extended near-field simulation. The results have shown that the natural development of the Crow instability is insufficient to reduce the strength of the realistic aircraft wake considered in this study at approximately 100 spans behind the aircraft.

"HIGH-ORDER ACCURATE CARTESIAN PARTITIONING METHODS. APPLICATION TO ROTOR FLOWS"

TP-2007-147, September 2007, 33rd European Rotorcraft Forum - ERF 2007, Kazan, Russia

In the present article, a coupling between the mesh adaptation technique of Meaking and high-order numerical schemes is proposed. Several schemes for introducing an artificial dissipation into a high-order central finite volume approximation to the Euler equations are considered. Transfers in overlap regions are completed by high-order interpolations. The methods applied to the computation of 2D parallel blade-vortex interaction and to the simulation of a 3D flow around a hovering blade of the ONERA 7A helicopter rotor exhibiting an improvement in the wake capture.

"PREPARATION OF WAKE VORTEX DETECTION TECHNOLOGY CASE"

EEC/TRS-C52, March 2005, Eurocontrol, France

The objective of the Eurocontrol project WAKESEP is to propose extensions to the current ICAO separations with a set of separations based on an understanding of wake vortex behavior under different atmospheric conditions. For ATC operations, four critical areas with respect to Wake Vortex (WV) encounter risk (2 areas for arrivals, 2 areas for departures) have been defined.

Savas, O.

"EXPERIMENTAL INVESTIGATIONS ON WAKE VORTICES AND THEIR ALLEVIATION"

C. R. Physique, Vol. 6, 2005, pp. 415-429

Recent wake vortex research in the laboratory has benefited considerably from concurrent analytical and numerical research on the instability of vortex systems. Tow tank, with dye flow visualization and particle image velocimetry is the most effective combination for laboratory research. Passive and active wake alleviation schemes have been successfully demonstrated in the laboratory. The passive alleviation systems exploit the natural evolution of vortex instabilities while the active systems rely on hastening selected instabilities by forcing the vortices individually or as a system. Their practical applicability, however, will have to meet further criteria beyond those dictated by fluid dynamics.

Savas, O.

"EXPERIMENTAL STUDY OF COMPLEX VORTEX INTERACTIONS IN THE WAKE OF HIGH ASPECT RATIO WINGS"

NASA/CR-112556, August 1997, Univ. of California, Berkeley, CA

The dynamics of trailing vortex wakes from flapped airfoils are investigated in a towing tank and a wind tunnel. In this work, parallel experiments are conducted in a wind tunnel with a five-hole probe for near wake measurements and in a tow tank with particle image velocimetry for mid- and far-wake measurements. The wind tunnel allows detailed time-averaged measurements of the near-wake in a plane fixed relative to the wing while the tow tank allows measurements of the entire evolving wake in a plane fixed relative to an observer. The wakes from a lifting rectangular circular arc airfoil with an aspect ratio of 6 and flap-spans of 30% and 67% and a NACA 0012 with an aspect ratio of 8 and flap-spans of 40% and 50% are studied as the wake evolves downstream. Chord-based Reynolds number $Re(\text{sub } c)$, ranged from 15000 to 80000. A traversing five-hole pitot probe and Lagrangian Parcel Tracking are used to measure the velocity field in a cross-stream plane behind the wing in the wind tunnel and the towing tank, respectively. The interaction of the tip and flap vortices are studied. Merger of the flap and tip vortices usually occurs within one orbit, leading to a shorter descent distance to merger for the longer flap-spans. The strut wake significantly affects the vortex strength, hence merger characteristics, by disrupting the vortex sheet.

Savas, O., Green, R. B. and Caradonna, F. X.

"COUPLED THRUST AND VORTICITY DYNAMICS DURING VRS"

American Helicopter Society Specialists' Conf. on Aeromechanics, Jan. 2008, San Francisco, CA.

The focus is on the vortex ring state (VRS) observed at rapid descent rates. At VRS, the helical vortex filaments coming off the blades amalgamate around the rotor disk forming a vortex ring, which periodically detaches into the wake, causing extreme oscillations in thrust, with periods on the order of several tens of rotor revolutions. We discuss here the phase relation between the thrust cycle and vorticity distribution at the rotor disk. Maxima of the VRS thrust oscillations correlate well with the maxima of circulation, enstrophy, and minima of enstrophy dispersion radius observed in the vicinity of the rotor disk.

Savas, O., Ortega, J. M. and Bristol, R. L.

"WAKE ALLEVIATION THROUGH CONTROL VORTEX INSTABILITIES"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

A series of experiments are carried out in the vortex wakes of wings with outboard flaps, which are used to generate control vortices. A rapidly growing instability is observed to develop between unequal strength, counter-rotating vortex pairs in the wakes of airfoils with outboard triangular flaps. Unlike the wake of a simple rectangular airfoil, the wakes of the triangular-flapped airfoils become highly unsteady and complex as the result of this instability. The qualitative features of the instability, such as its wavelength and non-linear evolution, are examined by flow visualization measurements that are made in a towing tank at a chord-based Reynolds number of 100,000. This sinuous instability is seen to develop on the weaker flap vortices and have a wavelength of order one wingspan. Typically, the instability requires about 15 wingspans to become finite in amplitude. Planar velocity field measurements of the vortex wakes are made with a PIV technique, allowing the vortex structure, trajectories, kinetic energy, and distribution to be assessed up to several hundred wingspans downstream of the airfoils. For angles of attack ranging from -1.0 to 2.0 degrees, the circulation strength ratio of the flap and tip vortices ranges from -0.7 to -0.4. Additionally, the circulation-based Reynolds number is seen to be of order 100,000. The PIV data indicate that the wake's two-dimensional kinetic energy decreases substantially as the instability transforms the two-dimensional nature of the wake into a three-dimensional one. The wake alleviation properties of these wings are estimated using the PIV data, following Rossow (1976). The non-linear interactions between the vortices result in a wake that is highly three-dimensional and incoherent. These effects are reflected in large decreases in both the rolling moment and downwash on a simulated following wing. The results are compared to those of a rectangular wing. For all the experimental runs, the wakes of the triangular-flapped wings have a maximum rolling moment and downwash that are substantially less than those of the rectangular wing. In particular, non-dimensional rolling moment and downwash are about 1/3 of those of a comparable rectangular wing. The results of this study indicate that the triangular-flapped wing design offers a possible solution to the wake hazard problem.

Sayers, W. H.

"VORTICISM IN AERONAUTICS"

NACA TM-222, August 1923, NACA Langley Aero. Lab., Langley Field, VA

Since the war there has been a considerable advance in knowledge about the airfoil and its behavior. The theory is now sufficiently advanced to make it possible to predict and to calculate certain results which previously could only be attained by direct experiment. The vortex theory receives special attention.

Scarano, F., van Wijk, C. and Veldhuis, L. L. M.

"TRAVERSING FIELD OF VIEW AND AR-PIV FOR MID-FIELD WAKE VORTEX INVESTIGATION IN A TOWING TANK"

Experiments in Fluids, Vol. 33, 2002, pp. 950-961.

Wake vortex flow experiments are performed in a water tank where a 1:48 scaled model of a large transport aircraft A340-300 is towed at a speed of 3 and 5 m/s with several values of the angle of attack (2, 4, 8 degrees). Particle image velocimetry (PIV) measurements are performed in a plane perpendicular to the towing direction describing the streamwise component of the wake vorticity. The instantaneous field of view (I-FOV) is traversed vertically with an underwater moving-camera device tracking the vortex core during the downward motion. An adaptive resolution (AR) image-processing technique is introduced that enhances the PIV interrogation in terms of spatial resolution and accuracy. The main objectives of the investigation are to demonstrate the applicability of PIV diagnostics in wake vortex research with towing-tank facilities. The specific implementation of the traversing field-of-view (T-FOV) technique and the AR image processing are driven by the need to characterize the vortex wake global properties as well as the vortex decay phenomenon in the mid- and far-field. Relevant aerodynamic information is obtained in the mid-field where the time evolution of the vortex structure (core radius and tangential velocity) and of the overall vortex wake (vortex trajectory, descent velocity, circulation) are discussed.

Scarano, F., van Wijk, C. and Veldhuis, L. L. M.

"TRAVERSING FIELD-OF-VIEW AND AR-PIV FOR MID FIELD WAKE VORTEX INVESTIGATION IN A TOWING TANK"

4th International Symposium on Particle Image Velocimetry, Gottingen, Germany, September 2001.

Wake vortex flow experiments are performed in a water tank where a 1/48 scaled model of an Airbus A340-300 is towed at a speed of 3 and 5 m/s with several values of the angle of attack (2, 4, 8 degrees). PIV measurements are obtained in a fixed plane perpendicular to the towing direction to measure the streamwise component of the wake vorticity. An underwater moving camera device is used to keep the

moving vortex in the field of view during the vortex whole downward motion. An adaptive resolution (AR) image processing technique is employed to further enhance the technique capability in terms of spatial resolution and accuracy. An extensive measurement campaign yields the wake vortex behavior described during a period that extends from the vortex formation stage up to the mid-field (200 wingspans). Results show a constant vortex downward motion up to about 100 wingspans. Further, the vortex wake interaction with the bottom wall constitutes the main limitation to the investigation of vortex decay phenomena in the far-field. The analysis of the vortex structure yields important insights on the time evolution of the vortex velocity distribution. The maximum tangential velocity, the peak vorticity and the vortex core radius are the main parameters addressed in the discussion of the time evolution of the wake vortex properties.

"AN EXPERIMENTAL STUDY OF THE BULK PROPERTIES OF VORTEX RINGS TRANSLATING THROUGH A STRATIFIED FLUID"

European Journal of Mechanics, B/Fluids, Vol. 25, 2006, pp. 302-320

Experiments are carried out to find the bulk properties and some structural properties of vortex rings in a stratified fluid. Previous theoretical descriptions of vortex ring propagation speed in a homogeneous fluid are compared to experiment and developed for use in stratified fluids. Vortex rings are fired at oblique angles to the horizontal and at different speeds through a stratified fluid. The buoyancy frequency of the fluid is varied between different series of experiments. New models are proposed which predict the speeds and trajectories of vortex rings fired through a stratified fluid and these are compared to experiment. It is shown that these models perform well in high Froude number flows, but less well in low Froude number flows.

"NONLINEAR DYNAMICS OF THE SHORT-WAVELENGTH ELLIPTIC INSTABILITY"

International Workshop on Fundamental Issues Related to Aircraft Trailing Wakes, Marseille, France, May 2008

The nonlinear dynamics of the elliptic instability has been studied by Direct Numerical Simulation with a pseudo-spectral code. As the main objective was to analyze the effect of the axial flow, we have first performed a series of simulations to better characterize the nonlinear dynamics of the elliptic instability without axial flow. We have considered the configurations of a single strained Lamb-Oseen vortex and of a system of two counter-rotating Lamb-Oseen vortices. For both cases, we have demonstrated that both weakly nonlinear and strongly nonlinear evolution of the elliptic instability were possible. The weakly nonlinear dynamics which has been observed very close to threshold is characterized by a limit cycle behavior. The strongly nonlinear dynamics, which has been obtained in most simulations, is much more violent but possesses some universal characteristic features. We have shown that it always follows the following steps: (1) concentration of the vorticity in thin layers at the

periphery of the vortex, (2) expulsion of vortex loops, (3) breakdown of the whole structure, (4) laminarization process leading to the reformation of a weaker and larger vortex. The instability can start again and the process can repeat several times leading to larger and larger vortices.

Schaffer, A.

"A STUDY OF VORTEX CANCELLATION"

Journal of Aerospace Sciences, Vol. 27, No. 3, 1960, pp96.

The cancellation of a vortex by means of another concentric vortex of equal strength but opposite spin is investigated. When such a cancellation occurs, there is a recovery of static pressure. The vortices are generated by means of two three-dimensional airfoils cantilevered from the duct wall, one being situated in the wake of the other. The airfoils have opposite effective angles of attack and therefore have trailing vortices of opposite spin, as required. It is documented experimentally that there exists an optimum angle of attack for the second airfoil which cancels the vortex from the first airfoil and restores uniform flow downstream of the two airfoils. A theoretical solution of this optimum angle of attack is presented, and it is found to depend upon the angle of attack of the first airfoil and upon the geometrical properties of the wings. The pressure recovery accompanying the vortex cancellation is also studied. Theoretical considerations, based on the model of a vortex filament in the center of a circular tube show that a maximum of 62 per cent of the static pressure drop across the first airfoil can be recovered. This maximum is imposed, irrespective of skin friction and separation losses, by the irreversibility associated with establishing a vortex field. Experimental pressure recoveries of 50 per cent are realized.

"SIMULATING AIRCRAFT WAKE VORTICES WITH OVERFLOW"

AIAA Paper 2015-3301, June 2015, Dallas, TX.

Low dissipation methods were used to simulate wake vortex generation using the OVERFLOW computational fluid dynamics solver. The study involved varying parameters such as grid spacing, time step, high order spatial and temporal methods, turbulence modeling, and automatic grid adaption. A two-dimensional inviscid vortex was analyzed to assess numerical dissipation, then the practices learned were applied to a finite wing and a full aircraft. Comparisons were made to idealized vortex models, the finite wing compared closest to the Hallock-Burnham model and the full aircraft to the Proctor model.

Schauerhamer, D. G. and Robinson, S. K.

"A VALIDATION STUDY OF OVERFLOW FOR WING-TIP VORTICES"

AIAA Paper 2016-1782, January 2016, San Diego, CA.

A validation study of the computational fluid dynamics flow solver OVERFLOW simulating wing-tip vortices was conducted using data from two wind tunnel tests. The first test was of a semi-span wing conducted in the NASA Ames Research Center Fluid Mechanics Laboratory, and included surface pressure measurements and measurements of the trailing vortex using a pressure probe. Best practices of the OVERFLOW solver were established through grid and time step sensitivity studies and comparing to test data. Methods include high-order accurate spatial methods and detached eddy simulation turbulence modeling. The best practices from the first test were applied to a second wind tunnel test of a generic wing/body aircraft with slat and flap extended. For both tests, comparisons with test data and with algebraic vortex models are presented and sources of uncertainties and any deviations are discussed.

Schauerhamer, D. G. and Robinson, S. K.

"TOWARDS SIMULATING THE EVOLUTION OF AIRCRAFT WAKE VORTICES WITH OVERFLOW"

AIAA Paper 2017-0956, January 2017, Grapevine, TX.

Best practices towards simulating the evolution of aircraft wake vortices were developed with a systematic approach using two-dimensional simulations. The simulations were initialized with either idealized vortex models or a simulated wake system produced by the NASA Common Research Model. Simulations evolved the vortex system to over 8 times the wing span downstream from the wing trailing edge. Sensitivity studies were completed to establish time accurate methods and convergence, as well as the use of automatic mesh refinement. Errors involved in using symmetry boundary conditions and running on a different number of processors were also addressed. The resulting evolved wake vortices were compared to idealized vortex models.

Schauerhamer, D. G. and Robinson, S. K.

"AIRCRAFT EFFECTS IN WAKE VORTEX DECAY SIMULATIONS"

AIAA Paper 2017-3035, June 2017, Denver, CO.

Aircraft wake vortex decay simulations were carried out that included aircraft effects. Low dissipation Reynolds Averaged Navier-Stokes Computational Fluid Dynamics were used to generate wing tip vortices from the NASA Common Research Model with and without a generic winglet. The wake was propagated with two-dimensional evolution and coarse-mesh three-dimensional simulations. Vortex decay simulations were initialized with results from the aircraft simulations and compared to decay simulations initialized with idealized vortex models. Some numerical artifacts existed in the decay simulations. Comparisons between decay simulations with aircraft effects and decay simulations initialized with idealized vortex models had differences in vortex position, descent rate, and circulation..

Schauerhamer, D. G. and Robinson, S. K.

"COMPUTATIONAL-FLUID-DYNAMICS BEST PRACTICES FOR AIRCRAFT WING-TIP VORTEX ROLL-UP"

Journal of Aircraft, Vol. 54, No. 4, July-August 2017, pp. 1552-1565.

Best practices for simulating aircraft wing-tip vortex roll-up with Reynolds-averaged Navier-Stokes computational fluid dynamics were developed using a build-up approach with the NASA OVERFLOW flow solver. Methods were tested for accuracy and computational expense beginning with a simple case, then building up step by step in complexity toward a realistic aircraft geometry. The cases tested were started two-dimensionally with an inviscid vortex, then a viscous vortex, then three-dimensionally with a basic rectangular finite wing, a semispan wing that included validating wind-tunnel test data, and finally to a realistic wing/body aircraft configuration that also included wind-tunnel data. Comparisons were also made with algebraic vortex models used to initialize large-eddy simulations of wake decay.

Schauerhamer, D. G. and Robinson, S. K.

"SENSITIVITY STUDY OF AIRCRAFT WAKE VORTICES USING OVERFLOW"

AIAA Paper 2016-3137, June 2016, Washington, DC.

A sensitivity study on aircraft wing tip vortices was conducted with low dissipation computational fluid dynamics. Using the OVERFLOW flow solver, simulations of full aircraft were conducted. An aircraft in high lift configuration with slat and flap extended was used, and the effect of varying degrees of geometric fidelity was tested. Also, a cruise configuration aircraft was used with and without a generic winglet. Validation of the simulations was conducted with data from wind tunnel tests. The wake vortices were sensitive to the aircraft state. Of the aircraft in this study, the aircraft with the slat and flap extended with the lowest geometric fidelity produced the strongest vortex, and the cruise configuration with the generic winglet produced the weakest. Comparisons were made with algebraic vortex models used to initialize Large Eddy Simulations. No model accurately portrayed the vortices from the OVERFLOW simulations, but for the aircraft and conditions tested, the Proctor model was the closest.

Scheiman, J. and Shivers, J. P.

"EXPLORATORY INVESTIGATION OF THE STRUCTURE OF THE TIP VORTEX OF A SEMISPAN WING FOR SEVERAL WING-TIP MODIFICATIONS"

NASA TN D-6101, February 1971, NASA Langley Research Center, Hampton, VA

Wind-tunnel tests were performed on a semispan wing with rather radical wing-tip modifications. These modifications were chosen in an attempt to deform, displace, or modify the cross-sectional characteristics of the trailing tip vortex. The wing-tip modifications test did not grossly affect the spanwise lift distribution and did not produce a noticeable change in the position of the downstream tip vortex. Tip-vortex cross-sectional variations were obtained such that the outer flow field was no longer potential flow.

Scheiman, J., Shivers, J. P. and Megrail, J. L.

"EXPLORATORY INVESTIGATION OF FACTORS AFFECTING THE WING TIP VORTEX"

NASA TM X-2516, April 1972, NASA Langley Research Center, Hampton, VA

An investigation was conducted in the Langley full-scale tunnel to study some factors affecting the tip vortex of a wing. It was found that there was a pronounced effect of Reynolds number on the tip-vortex core size. An attempt was made to determine what aerodynamic parameters - such as lift, drag, or induced drag - influence the size of the vortex core, but no function of the parameters was found to be superior to all others. Various spoilers placed on the upper and lower surfaces of the wing to increase the boundary-layer thickness resulted in a reduction in the vorticity as determined from the tuft grid. Various solid objects placed in the vortex core downstream of the wing tip seemed to decrease the vorticity within the vortex core.

Schell, I., Ozger, E. and Jacob, D.

"INFLUENCE OF DIFFERENT FLAP SETTINGS ON THE HAZARD POSED TO FOLLOWING AIRCRAFT"

In New Results in Numerical and Experimental Fluid Mechanics III, Notes on Numerical Fluid Mechanics, Vol. 77, Eds. Wagner, et al., Springer-Verlag, Berlin Heidelberg, 2002, pp. 66-73.

In the present paper the influence of different flap settings of the wake generating aircraft on the hazard posed to a following aircraft is investigated. The near wake region of a rectangular wing with flaps is computed by means of a 3D panel method while the far wake region is simulated by a 2D Navier Stokes scheme in vorticity form. The hazard posed to a following aircraft is quantified by the value of the maximum induced rolling moment which is calculated by means of 2D strip theory. A preceding experimental investigation showed that the maximum induced rolling moment on the following aircraft related to the wing lift of the generating aircraft is decreased by deflecting the flaps. This result is confirmed by the numerical simulation for moderate flap deflections whereas higher flap angles lead to an increase of the maximum induced rolling moment related to the wing lift. The computation of the far wake region shows that in these cases the merger of the wing tip and flap vortex leads to a reconcentration of circulation and a reduction of the alleviating effect of the flap deflection.

Schell, I., Ozger, E. and Jacob, D.

"INFLUENCE OF DIFFERENT FLAP SETTINGS ON THE WAKE-VORTEX STRUCTURE OF A RECTANGULAR WING WITH FLAPS AND MEANS OF ALLEVIATION WITH WING FINS"

Aerospace Science and Technology, Vol. 4, No. 2, February 2000, pp. 79-90

This paper presents the results of an experimental investigation of the wake-vortex structure behind a flapped rectangular wing. The wind-tunnel test is to investigate the flow structure in the wake of wings with different flap extensions. The purpose of this investigation is to study the main features of lift generated vortices to find ways to alleviate hazardous wake vortex encounters for following airplanes during start and approach such that an increase in airport capacity can be achieved. First, the wake

structure at different flap settings is investigated by measuring the velocity field at different positions in the near field behind the wing. The measured data are evaluated in terms of vortex parameters such as core radius, maximum tangential velocities, circulation distributions, turbulence levels and maximum induced rolling moments on a following aircraft. Then additionally, for one flap setting, means of alleviation are examined with a wing fin mounted at different positions on the wing. Alleviation is judged by the decrease of the maximum induced rolling moment. A significant reduction is achieved for a wing fin placed near the outboard edge of the flap.

"SHOCK EFFECTS ON DELTA WING VORTEX BREAKDOWN"

Journal of Aircraft, Vol. 46, No. 3, May-June 2009, pp. 903-914.

It has been observed that delta wings placed in a transonic freestream can experience a sudden movement of the vortex breakdown location as the angle of incidence is increased. The current paper uses computational fluid dynamics to examine this behavior in detail. The study shows that a shock/vortex interaction is responsible. The balance of the vortex strength and axial flow and the shock strength are examined to provide an explanation of the sensitivity of the breakdown location. Limited experimental data are available to supplement the computational fluid dynamics results in certain key respects, and the ideal synergy between computational fluid dynamics and experiments for this problem is considered.

Schick, F. V. and Reichmuth, J.

"EVALUATION OF OPERATIONAL CONCEPTS OF A WAKE VORTEX WARNING SYSTEM"

Z. Flugwiss. Weltraumforsch., Vol. 18, 1994, pp. 54-59

In an Air Traffic Control (ATC) simulation study with 15 ATC controllers as subjects, three different operational concepts of utilizing a Wake Vortex Warning System (WVWS) were investigated. Traffic flow data, operational data and controller judgments which were obtained from real-time simulations were analyzed, and discussed in terms of operational performance, controller workload and controller acceptance of the concepts tested. In the simulation environment, an increase of landing capacity was realizable. Based on detailed findings specific for the various concepts, some conclusions were drawn, regarding display layout and operational procedures of a future advanced WVWS concept. [In German.]

Schilling, V.

"MOTION AND DECAY OF TRAILING VORTICES WITHIN THE ATMOSPHERIC SURFACE LAYER"

Beitr. Phys. Atmosph., Vol. 65, No. 2, May 1992, pp. 157-169

Results of investigations of aircraft induced trailing vortices within the atmospheric surface layer (ASL) are presented. Using a two-dimensional numerical model, the influence of stratification and wind shear on the motion, structure and decay of those vortices has been studied. It is depicted, for example, that the shifting of vortex wakes is weakly influenced by the thermal stratification of the atmosphere (in accordance with measurements of Franke, Kopp & Tetzlaff (1991) (FKT '91)), while the background wind and wind shear are found to be more important factors. Special attention is directed to formation and influence of secondary vortices. An attempt is made to describe, in which way they are responsible for the observed 'rebounding' of the primary vortices. It is found, that the development of this phenomenon depends strongly on the background crosswind and may also occur in the absence of any wind shear within the ASL. Without doubt, these secondary vortices are responsible for a possible spiral path of the vortex trajectories. These phenomena have to be taken into consideration (as an important factor), when problems of landing and take-off frequencies of different aircraft will be studied. Comparisons of the computed results with the measurements of FKT '91 at the Frankfurt International Airport (FIA) show corresponding movement and a maximum lifetime (3 min.) of the trailing vortices as well as the same critical crosswind velocity ($U_{min} = 2.5 \text{ m/s}$), which is necessary to transport vortices to a parallel runway at the FIA.

Schilling, V. and Etling, D.

"DISPERSION OF AIRCRAFT EMISSIONS DUE TO WAKE VORTICES"

In: Impact of Emissions from Aircraft and Spacecraft Upon the Atmosphere, Proceedings of International Scientific Colloquium, Cologne, Germany, 1992, pp. 315-320

The development of the wake vortex system behind a B-747 airplane and the dispersion of the aircraft emissions due to these vortices have been studied numerically by using a 2D model including a dynamic (Eulerian) and a dispersion (Lagrangian) part. Representing one of the simulation experiments, we demonstrate the influence of a strong temperature inversion on the development of the vortex-emission system. We found the lifetime of the wake vortices limited to about one minute, and the dispersion efficiency of the whole process is quantified by a scale dependent vertical diffusion coefficient.

Schilling, V., Siano, S. and Etling, D.

"DISPERSION OF AIRCRAFT EMISSIONS DUE TO WAKE VORTICES IN STRATIFIED SHEAR FLOWS: A TWO-DIMENSIONAL NUMERICAL STUDY"

J. Geophysical Research, Vol. 101, No. D15, September 1996, pp. 20965-20974

The development of the wake vortex system behind an airplane (B-747) at cruising altitude (8-15 km) and the dispersion of the aircraft emissions due to this vortex system have been studied by means of a two-dimensional numerical model. Simulation experiments are presented which examine the influence of atmospheric stratification and vertical wind shear on the combined vortex-emission system. Although the development of the vortex wake system can be influenced by three-dimensional effects

(e.g., Crow instabilities), the undisturbed process can be approximated as a two-dimensional phenomenon, which allows the study of details of the vortex structures at small scales (length L about 1 m) and the dispersion of engine exhausts at larger scales (L about 100 m). The results of simulation experiments show that the maximum lifetime of the wake vortices (120 s to 300 s) as well as the descending rate (1.2 m/s to 2.4 m/s) and the dispersion of the emitted substances depend on the atmospheric stratification as well as vertical wind shear, but buoyancy forces seem to dominate over shear forces. The overall dispersion of aircraft emissions due to the wake vortex system can be quantified by a vertical standard deviation for the entire process of less than or equal to 70 m.

Schillings, J. J., Ferguson, S. W., Brand, A. G., Mullins, B. R. and Libby, J.

"WAKE VORTEX MEASUREMENTS OF THE XV-15 TILTROTOR USING A MOBILE GROUND-BASED LIDAR SYSTEM"

57th Annual Forum, American Helicopter Society, May 2001, Washington, DC.

The paper presents initial results of a research program to measure trailing wake vortices of tiltrotor aircraft. Wake measurements of the Bell XV-15 were made using the MIT Lincoln Laboratory Lidar system. Measured data include time histories of vortex positions, circulation strengths, and wake velocities. Selected data from each of the XV-15's modes of flight are included in the paper. In airplane mode, the trailing wake resembles the wake of a fixed-wing aircraft of equal weight. In helicopter mode, the wake consists of a pair of vortices separated by the distance between the advancing blade tips. In conversion mode, the separation distance of the vortices is approximately a linear function of nacelle angle. Initial circulation is calculated using an analytical method and compared to flight test. This analytical method suggests that during helicopter and conversion mode flight the wing tip vortex combines with the vortex from the advancing blades, while the vorticity from the retreating blades has a weaker influence.

"WIND SPEED FORECASTING FROM 1 TO 30 MINUTES"

Theoretical and Applied Climatology, Vol. 60, 1998, pp. 191-198

The long lifetime and high intensity of vortex trails generated by landing large-capacity aircraft may cause a risk to subsequently landing planes. A wake vortex warning system can help to avoid such hazards by forecasting the time intervals permitting safe operation on the landing strip. This information provides the basis for an appropriate landing schedule based on reduced succession distances. An essential element of the warning system is the prediction of wind across the landing strip and this is commonly determined by a method based on the principle of persistence. This study shows that autoregressive (AR) modelling can improve the accuracy of crosswind forecasts. To this end, the measurements are analyzed to estimate model parameters. Unlike the more simplistic previously used method, AR forecasting, as part of the vortex trail warning system, allows longer intervals for safe

operation and can avoid forecast discontinuities (leaps) which are inherent problems of all forecasts in which boundary layer processes must be considered.

Schmid, P. J. and Rossi, M.

"THREE-DIMENSIONAL STABILITY OF A BURGERS VORTEX"

J. Fluid Mech., Vol. 500, 2004, pp. 103-112

The evolution of infinitesimal three-dimensional perturbations superimposed on a Burgers vortex is studied. By a sequence of variable transformations and scalings this linear evolution problem is reduced to a time-dependent system which is nearly identical to the stability equations governing a Lamb-Oseen vortex. The maximum amplification reached by perturbations over a finite time interval is computed through an iterative scheme based on the direct and adjoint governing equations, and results on the asymptotic stability of the Burgers vortex are deduced. The Burgers vortex is shown to be asymptotically stable, although significant short-term amplification may occur.

"WING INDUCED DRAG"

AIAA Paper No. 2002-4878, Monterey, CA, August 2002

The purpose of this study is to show that modern computational power using an elementary lifting surface theory is in accord with the oft-quoted statement that the minimum induced drag due to angle of attack on a wing occurs when the wing span load distribution is elliptical. However, the caveat must be introduced that the classical studies applied to a wing with an unswept quarter chord line. It will subsequently be shown by analyzing a straight-tapered wing with an 0.40 taper ratio that wing sweep angle has a significant effect upon the wing's induced drag.

"A340 FLIGHT TEST RESULTS OF A DIRECT DETECTION ONBOARD UV LIDAR IN FORWARD-LOOKING TURBULENCE MEASUREMENT CONFIGURATION"

Proceedings of the 15th Coherent Laser Radar Conference, June 2009, Toulouse, France, pp. 169-172.

A direct detection short pulse UV Doppler LIDAR onboard aircraft sensor for forward looking air speed / turbulence measurement was developed and flight tested. This detection schemes allows measurements even in aerosol-depleted air at distances of 50 m, which is necessary for reliable and high-frequency measurements of clear air turbulence at cruise altitude. A fringe-imaging technique was used applying an intensified CCD camera, allowing fast gating for longitudinal measure volume reduction (as necessary for real-time control purposes) and in-flight re-calibration by image processing. Algorithms have been developed and applied to determine the wind speed around 1 m/s accuracy. The forward measured air speed / turbulence data shall later be directly fed forward into the flight control

of an aircraft. The paper describes the results achieved in flight tests using an Airbus A340-300 aircraft used as test-bed with the forward-looking direct detection LIDAR to measure turbulences ahead, which was integrated in a fairing below the aircraft nose.

"RECENT DEVELOPMENT IN THE ASYMPTOTIC THEORY OF VORTEX BREAKDOWN"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

This lecture will summarize the generalized asymptotic theory involving axial core structure variations on a three-dimensional slender vortex filament. It will describe in some detail the critical layer theory. Results include a comparison with direct numerical simulations done at Aerodynamisches Institut, RWTH Aachen.

Schmitz, S., Bhagwat, M., Moulton, M. A., Caradonna, F. X. and Chattot, J.-J.

"THE PREDICTION AND VALIDATION OF HOVER PERFORMANCE AND DETAILED BLADE LOADS"

Journal of the American Helicopter Society, Vol. 54, No. 3, July 2009, pp. 32004-1 - 32004-12.

This paper focuses on the validation of a hybrid computational fluid dynamics (CFD) method for the prediction of isolated rotor hover performance of the model UH-60A and tapered-tip variant rotors by comparison with available data sets. The hybrid method combines a local Reynolds-averaged Navier-Stokes solver to resolve the near-blade flow, with a vorticity-embedding potential flow solver for the wake flow field. The comparisons entail wake trajectories, surface pressures, integrated sectional thrust and torque, and rotor performance. The wake and loads comparisons demonstrate that the current method has a predictive accuracy and speed that is unusual to most CFD methods. The resulting performance comparisons are inconclusive owing partially to the fact that two available data sets do not agree to the level of accuracy required for validation. It appears therefore that development of hover CFD methods requires validation and test data in greater detail and variety than currently exists.

Schneemann, J., Trabucchi, D., Trujillo, J. J. and Kuhn, M.

"COMPARING MEASUREMENTS OF THE HORIZONTAL WIND SPEED OF A 2D MULTI-LIDAR AND A CUP ANEMOMETER"

The Science of Making Torque from Wind 2012, published in IOP Journal of Physics: Conference Series Vol. 555, 2014, pp. 012091-1 - 012091-8.

Wind measurements of a 2D Multi-Lidar and a mast mounted cup anemometer are compared in this study. Average wind speed and direction as well as the turbulence intensity of the wind speed are considered. Data analysis is mainly performed using standard regression analysis on 10-minute average data and the calculation of the power spectral density. The results show a good agreement regarding wind speed and direction and the turbulence intensity of the horizontal wind.

Schoenfeld, T., Corjon, A., Rudnik, R., Ronzheimer, A, Elphick, G. and Galpin, S.

"WAKE VORTEX ANALYSES OF A HIGH-LIFT AIRCRAFT CONFIGURATION ON STRUCTURED AND UNSTRUCTURED GRIDS"

AIAA Paper No. 2000-2218, Denver, CO, June 2000

The numerical simulation of the vortical flow field behind a generic high-lift wing-fuselage-flaps-slat aircraft configuration is presented. Vortex formation at the trailing edge and the wing tips and their spatial evolution in the near field are investigated. The 3D Euler equations are solved on both block-structured and unstructured grids. The evaluation of the computational results is done by assessing the simulation quality through comparison with experimental PIV data and computational results between the different partners of the European EuroWake project.

Schoenhals, S., Steen, M. and Hecker, P.

"TOWARDS WAKE VORTEX SAFETY AND CAPACITY INCREASE: THE INTEGRATED FUSION APPROACH AND ITS DEMANDS ON PREDICTION MODELS AND DETECTION SENSORS"

ICAS 2010 Paper 2010-11.6.3, Sept. 2010, Nice, France.

The integrated concept for collaboration of wake vortex prediction and measurement is introduced in this paper. This approach can increase airport and air space capacity while maintaining or even improving current wake vortex safety. The aspect of requirements resulting for the prediction model and measurement sensor is presented in detail. Implementation examples are given for ease of understanding.

Schoennhals, S., Steen, M. and Hecker, P.

"ENHANCING WAKE VORTEX SURVEILLANCE CAPABILITY USING INNOVATIVE FUSION APPROACHES"

Paper EN-048, Second ENRI International Workshop on ATM/CNS, EIWAC 2010, November 2010, Tokyo, Japan.

A new concept for collaboration of wake vortex prediction and measurement is introduced in this paper. This approach can enhance wake vortex surveillance capability of both airborne and ground wake vortex warning or avoidance systems. Thus, a significant step towards the increase of airport and air space capacity while maintaining or even improving current wake vortex safety could be achieved. Following an overview of the model and sensor components the fusion concept is being described. Implementation examples are given for ease of understanding.

Scholl, R. H., Buxel, C. and Neuwerth, G.

"INFLUENCE OF SPANWISE LOADING AND FINS ON EXTENDED NEAR-FIELD VORTEX WAKE"

AIAA Paper No. 2006-62, Reno, NV, January 2006.

The hazard imposed on aircraft by the wake vortices of leading aircraft persists to be a problem for airplane operations on highly-frequented airstrips. To develop a better understanding of the roll-up process of the vortices shed by a transport aircraft wing in different high-lift configurations, experimental investigations in a water tunnel are conducted. The wing is also equipped with a fin on the suction side. Velocities in the extended near-field up to four spans downstream of the wing are measured with Stereo Particle Image Velocimetry (SPIV). Different flap and fin settings are employed, and the effects on roll-up and meandering of the vortices are observed. Data are captured in a time-resolved fashion, and flow properties are determined from instantaneous as well as averaged velocity fields. The effect of vortex meandering on those properties is examined. It is found that the influence of fins on statical induced rolling moment is minimal. However, fins do prove to increase the meandering amplitude of the wake vortices, which decreases the actual hazard to following aircraft through dynamic effects.

Scholl, R., Henke, R. and Neuwerth, G.

"VORTEX SHEETS OF AIRCRAFT IN TAKEOFF AND LANDING"

Flow Modulation and Fluid-Structure Interaction, Notes on Numerical Fluid Mechanics and Multidisciplinary Design, Vol. 109, 2010, pp. 1-21.

In the present paper the development of vortex wake starting from the vortex sheet at the trailing edge of a transport aircraft wing up to the far field over 60 spans downstream is investigated. Different configurations of a half model were investigated in wind and water tunnels as well as in a towing tank by hot-wire anemometry and particle image velocimetry. In addition to an understanding of the development of the wake, means for the attenuation of the impact on following aircraft were investigated. A fin was installed on the suction side of the wing to investigate the impact on the vortex system downstream. The possibility of exploiting short-wave cooperative instabilities to accelerate vortex decay were investigated as well. This included active excitation of instabilities via ailerons oscillated in antiphase.

Scholte, J. J., van Baren, G. B. and Stroeve, S. H.

"QUALITATIVE SAFETY ASSESSMENT OF THE ATC-WAKE OPERATION"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

New and advanced Air Traffic Management systems and procedures are being developed for busy airports to cope with the increase in air traffic. The ATC-Wake project for the European Commission proposes an operation in which airport capacity is improved using dynamic weather-based aircraft separation standards, using an advanced ATC-Wake system. The current study lays a foundation for the

safety and capacity analysis of the ATC-Wake operation by providing a qualitative safety assessment of potential risks associated with the proposed operations. Potential safety bottlenecks identified in this study give early-stage feedback to operation designers and provide focusing points for subsequent safety modelling and quantitative safety assessment in the ATC-Wake project. The risks associated with the ATC-Wake operation were assessed using NLR's qualitative safety assessment methodology. This methodology is largely based on structured use of operational experts' judgement. The applied risk criteria are based on ESARR 4 requirements, using the ESARR 4 severity classification scheme and the ESARR 4 maximum tolerable probability of an accident, plus some additional assumptions that had to be made for this qualitative risk assessment. The risks of the proposed ATC-Wake operations were assessed for single runway arrivals, single runway departures and closely spaced parallel runway arrivals. In various brainstorming sessions with operational experts, 228 hazards were identified that might occur in the considered operations. These hazards were structured into 11 conflict scenarios, which aim to cover all imaginable ways in which the hazards can lead to or worsen a conflict situation. Using operational experts' judgement and knowledge from other studies, for each of these conflict scenarios the severity and the frequency of occurrence were assessed. Based on these severity and frequency assessments, and the risk criteria, an evaluation of the acceptability of the risk of each conflict scenario was given. The presentation will give a broad overview of the steps of the qualitative safety assessment, the safety criteria adopted and the main risk assessment results of the conflict scenarios identified.

Schonfeld, A., Luckner, R. and Efremov, A. V.

"A METHOD FOR INVESTIGATION OF PILOT-VEHICLE SYSTEM DYNAMICS IN WAKE VORTEX ENCOUNTERS"

1st CEAS European Air and Space Conference, Berlin, Germany, CEAS-2007-332, September 2007, pp. 1323-1332

One of the most hazardous external disturbances for civil and military aircraft is a severe wake vortex encounter. Primary effect on a trailing aircraft is the induced rolling moment. Depending on the encounter conditions also a noticeable reaction around the pitch axis can occur. Investigation of such incidents in flight tests depends on environmental conditions and can be quite expensive. For minimizing these factors and to reduce development time, it is desired to simulate the pilot-vehicle system reaction in ground simulation first. In this paper an approach is presented to model dual-axis pilot behavior during a wake vortex encounter in manual flight. The Modified Optimal Control Model (MOCM) was chosen to represent the pilot dynamics and for prediction of pilot-vehicle system responses in such a surprising case. Since the model requires a continuous input signal for parameterization, the assumption was made that manual control is carried out first in turbulent atmosphere. Adapted to the turbulence signal, the aircraft flies into the wake vortex and the pilot starts reacting to the turbulence, not changing his stereotype immediately. Experimentally obtained operator results successfully demonstrate the applicability of this extrapolation for the first half oscillation of the wake vortex signal. Besides linear aircraft dynamics, experiments have been executed for nonlinear actuator dynamics, too.

Schonfeld, T.

"12 YEARS OF EUROPEAN WAKE VORTEX RESEARCH AN OVERVIEW"

ECCOMAS CFD 2006: Proceedings of the European Conference on Computational Fluid Dynamics, September 2006, Egmond aan Zee, Netherlands.

This note contains the opening remarks for the dedicated wake vortex session held in the ECCOMAS CFD 2006 conference. A high-level description and associated background of the European wake turbulence research from 1994 to 2006 were provided. A few industry-wide focused research efforts provided tremendous physical insight on the physics of wake turbulence, but also the recognition of the limitation of classical wind tunnel techniques for advancing knowledge of the full wake life span. From there on, the European Commission launched several pan-European programs to understand topics ranging from the physical aspects for wake flows, verification of the level of safety in the system, wake instrumentation and detection techniques and stakeholder engagement forum.

"FUNDAMENTAL VORTEX PHENOMENA: INSTABILITIES AND INTERACTIONS WITH JETS AND WAKES"

1st CEAS European Air and Space Conference, Berlin, Germany, CEAS-2007-007, September 2007, pp. 1017-1025.

In this contribution, a synthesis of the recent results obtained in the frame of the ongoing European FP6 project FAR-Wake (Fundamental Research on Aircraft Wake Phenomena, 2005-2008), is presented. The main objective of this upstream research project is to gain better knowledge about open issues of vortex dynamics relevant to aircraft wakes, by investigating the following main topics, each treated in a separate work package: 1) the role of vortex instabilities on wake decay, 2) the influence of engine jets and of the turbulent wakes behind different aircraft components, and 3) the influence of ground effects, relevant for the wake evolution in the airport environment. The present paper deals with the first two topics, results from the work package on ground effects are shown in a different CEAS 2007 session on 'Wake Vortex Advisory Systems'.

Schonhals, S., Steen, M. and Hecker, P.

"WAKE VORTEX PREDICTION AND DETECTION UTILISING ADVANCED FUSION FILTER TECHNOLOGIES"

The Aeronautical Journal, Vol. 115, No. 1166, April 2011, pp. 221-228.

Because of its aerodynamic lift, each aircraft is generating wake vortices that can become a serious hazard for the succeeding aircraft and in the worst case lead to loss of control. Separation standards were introduced to prevent dangerous wake encounters that have proven sufficiently safe but also very conservative, thus limiting airspace and airport capacity. The objective of contemporary wake vortex research is regaining capacity in favorable atmospheric conditions, at the same time preserving or even improving the current safety level. The wake vortex advisory systems developed for this purpose are nearing experimental implementation and all include a forecasting component and additional online

detection sensors, with both elements having their benefits and limitations. The wake vortex research objectives at the Institute of Flight Guidance of the Technische Universität Braunschweig focus on a close coupling approach between model predictions and sensor measurements. Using the complementary capabilities of each, the aim of improved performance of the overall system shall be reached. After giving a short overview on the wake vortex phenomenon and current approaches to wake vortex alerting and advisory systems, this paper will introduce the fusion concept. The benefits of this approach will be demonstrated by means of examples. An outlook on further development and envisaged advanced implementation concepts will be given.

Schönhals, S., Steen, M. and Hecker, P.

"ENHANCING WAKE VORTEX SURVEILLANCE CAPABILITY USING INNOVATIVE FUSION APPROACHES"

ENRI International Workshop on ATM/CNS, Paper EN-048, Nov. 2010, Tokyo, Japan.

A new concept for collaboration of wake vortex prediction and measurement is introduced in this paper. This approach can enhance wake vortex surveillance capability of both airborne and ground wake vortex warning or avoidance systems. Thus, a significant step towards the increase of airport and air space capacity while maintaining or even improving current wake vortex safety could be achieved. Following an overview of the model and sensor components the fusion concept is being described. Implementation examples are given for ease of understanding.

Schönhals, S., Steen, M. and Hecker, P.

"SURVEILLANCE SYSTEMS ON-BOARD AIRCRAFT: PREDICTING, DETECTING AND TRACKING WAKE VORTICES"

8th Innovative Research Workshop and Exhibition, December 2009, EuroControl Experimental Centre, Bretigny-sur-Orge, France.

Capacity limitations due to conservative wake vortex separations can only be avoided by changes of the existing regulations. For the future, even the complete delegation of separation responsibility to the pilot is projected. This is only possible if safe operations are still guaranteed. For this purpose, methods for detection and prediction of wake vortices are developed. This paper presents a concept that allows taking advantage of the two different approaches by means of collaboration and use of fusion filters. The introduction of the fusion approach is subject of this article. Examples and results of the implemented possibilities are given and an implementation in an airborne environment is depicted. Future work and further developments of the system is addressed.

Schönhals, S., Steen, M. and Hecker, P.

"TOWARDS WAKE VORTEX SAFETY AND CAPACITY INCREASE: THE INTEGRATED FUSION APPROACH AND ITS DEMANDS ON PREDICTION MODELS AND DETECTION SENSORS"

Proceedings of the Institution of Mechanical Engineers, Part G: Journal of Aerospace Engineering, Vol. 227, No. 1, January 2013, pp. 199-208.

Wake vortices and the prevention of wake vortex encounters are both an issue of safety and capacity in today's air transportation system. Current wake vortex separations are safe but also very conservative and thus have an adverse effect on capacity of airports. This article deals with the concept of fused wake vortex prediction and detection with the objective to deliver wake vortex strength and position with a high level of accuracy and reliability. The collaboration approach aims at fusion of models and sensors available for forecast and detection of hazardous wake turbulence to improve the overall system performance using the complementary capabilities of the single components. Different methods of coupling models with measurements are introduced and resulting the aspect of requirements for the prediction model and measurement sensor is presented. The implementation of an error-state system is presented and compared to sole prediction and sole sensor results. The results indicate that the fusion approach delivers benefits like reduced uncertainty of prediction and increased availability of detection and thus has the ability to increase airport and air space capacity while maintaining or even improving current wake vortex safety.

Schooley, A. H.

"WAKE COLLAPSE IN A STRATIFIED FLUID"

Science, Vol. 157, No. 3787, July 1967, pp. 421-423

A two-dimensional model is used to obtain quantitative data on characteristics of turbulently mixed wakes of bodies submerged in stratified fluids. The time between turbulent mixing and maximum expansion of the wake before vertical collapse starts is $0.44T$, where T is the local Vaisala-Brunt period. Time after mixing for maximum rate of horizontal spreading is about $2.0T$. Qualitative observations of aircraft vapor trails tend to confirm that the phenomenon does occur at full scale.

Schoppa, W.

"GENESIS OF LONGITUDINAL VORTICES IN NEAR-WALL TURBULENCE"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany.

Using direct numerical simulations of turbulence near one wall of a channel flow, we present a new linear instability mechanism for generation of near-wall longitudinal vortices in turbulent boundary layers. We formulate a two-dimensional base flow, containing no x -dependence or streamwise vorticity, to represent the streaks of low-speed fluid known to be prevalent near the wall. Linear instability is indicated by sustained exponential growth of low-amplitude perturbations; evidence suggests that this streak instability is inviscid in nature, despite the proximity of a no-slip wall. We demonstrate that the instability mechanism is inherently 3D, driven by sinuous streak displacement (along the span) induced by elliptical streamwise vorticity layers and quite analogous to oblique instability in free shear flow. The 3D features of the generated vortices, including counterrotation, tilting in the (x,z) plane and staggering in x , also agree well with the deduced (dominant) coherent structures, suggesting that this mechanism is

a dominant agent of longitudinal vortex regeneration near the wall. These results suggest strategies for realistic, large-scale (in contrast to fragile MEMS) control of drag and heat transfer over bodies.

Schouten, G.

"MOMENTUM, PRESSURE, AND ENERGY IN THE TREFFTZ-PLANE"

J. Aircraft, Vol. 32, No. 5, September-October 1995, pp. 943-95.

The distributions of momentum and energy generated by a force working in a fluid together with the associated pressure distributions are discussed in detail. The momentum generated by an impulsive point force in a compressible atmosphere is identified for two-thirds in a moving virtual sphere of fluid and for one-third in a front expanding with the velocity of sound. In a transverse section of an incompressible atmosphere the net momentum is identically zero when boundary conditions are left out of the considerations. It is discussed where and how net momentum is imparted to the atmosphere by impulsive and steady, moving force distributions. The analogy between an actuator surface and a viscous boundary layer on a flat plate, both involving the generation of momentum in a definite jet or wake region, is discussed in the same frame of reference as the induced drag of a lifting wing. The boundary conditions on and the dimensions of the control box both play a role in the answer to the question if and where net momentum is to be found. The statement that the net momentum in a transverse section remains zero proves to be only approximately valid in a free atmosphere. An important conclusion is that at an overall scale the unsteady pressures in any model, viscous or nonviscous, dominate the momentum balance.

"THE SENSITIVITY OF LARGE-EDDY SIMULATION TO LOCAL AND NONLOCAL DRAG COEFFICIENTS AT THE LOWER BOUNDARY"

NASA-CR-198310, April 1996, North Carolina State University, Raleigh, NC

This work is part of a program to predict aircraft wake vortex behavior under various meteorological conditions within the planetary boundary layer. It was found that the homogeneity of the surface drag coefficient plays an important role in the large-scale structure of turbulence in large-eddy simulation of the convective atmospheric boundary layer. Particularly when a ground surface temperature was specified, large horizontal anisotropies occurred when the drag coefficient depended upon local velocities and heat fluxes. This was due to the formation of streamwise roll structures in the boundary layer. In reality, these structures have been found to form when shear is approximately balanced by buoyancy. The present cases, however, were highly convective. The formation was caused by particularly low values of the drag coefficient at the entrance to thermal plume structures.

Schowalter, D. G., DeCroix, D. S., Switzer, G. F., Lin, Y.-L., and Arya, S. P.

"TOWARD THREE-DIMENSIONAL MODELING OF A WAKE VORTEX PAIR IN THE TURBULENT PLANETARY BOUNDARY LAYER"

AIAA Paper No. 1997-0058, Reno, NV, January 1997

A method for large-eddy simulation of aircraft wake vortices embedded in planetary boundary turbulence is outlined. A nested grid scheme and three-dimensional initial and boundary conditions are described and demonstrated. The nested grid scheme allows multiple one-way or two-way simulations using mass-conservative interpolation and averaging schemes along with radiative boundary conditions which lets unwanted wave energy pass out of the finer mesh domains. The three-dimensional wake vortex initial and boundary conditions force fully-developed wake vortices on the upstream boundary but permit the vortices within the domain to develop spatially and temporally. Future work will entail combining the two schemes for simulations of wake vortices embedded within the convective planetary boundary layer.

Schrader, M. L.

"CALCULATIONS OF AIRCRAFT CONTRAIL FORMATION CRITICAL TEMPERATURES"

Journal of Applied Meteorology, Vol. 36, 1997, pp. 1725-1729.

Forecasts of condensation trail (contrail) formation are an extremely important consideration in military aircraft operations, particularly in the operation of stealth aircraft. Some recently published works have claimed improvements in the time-tested forecast technique of H. Appleman, but the results are called into question by errors in the basic physics. This note provides a brief explanation of contrail formation theory and presents a simple derivation of the critical temperature of contrail formation for representative jet engine types.

Schram, C., Hirschberg, A. and Verzicco, R.

"SOUND PRODUCED BY VORTEX PAIRING: PREDICTION BASED ON PARTICLE IMAGE VELOCIMETRY"

AIAA Journal, Vol. 42, No. 11, Nov. 2004, pp. 2234-2244.

In some cases, the prediction of the sound generated by flows is impaired by inaccuracies in the available flow data. These inaccuracies can be due to the degree of approximation of a flow model, or to the uncertainty of a measurement technique. A particular crucial point for sound prediction is the conservation of the flow invariants. The sound radiated by vortex pairing in a subsonic excited jet is deduced from experimental data obtained by particle image velocimetry. The performance is compared of different formulations of vortex sound theory to predict the corresponding sound production. It is shown that assuming several times the conservation of the momentum and kinetic energy in the implementation of the vortex sound theory improves considerably the robustness of the prediction. In fact, a prediction in good agreement with both a theoretical model of leapfrogging and numerical simulations of merging is obtained, although the basic data do not respect precisely these conservation laws.

Schroder, A. and Konrath, R.

"REDUCING CIRCULATION IN A WAKE TURBULENCE BEHIND AN AIRPLANE FLYING AT LOW ALTITUDE"

US Patent 2011/0210202 A1, September 2011.

For reducing a circulation of wake vortexes in a wake turbulence behind an airplane flying over ground at low altitude, at least one ring vortex of airflow is generated at the ground on each side of a vertical middle plane of the airplane. Each ring vortex has a vortex axis and a direction of propagation, wherein the vortex axis is oriented at an angle with respect to the ground and wherein the propagation direction is oriented upwards from the ground, and each ring vortex disturbs at least one wake vortex to induce its decay.

Schroder, A. and Konrath, R.

"REDUCING CIRCULATION IN A WAKE TURBULENCE BEHIND AN AIRPLANE FLYING AT LOW ALTITUDE"

US Patent 8,528,858 B2, September 2013.

For reducing a circulation of wake vortexes in a wake turbulence behind an airplane flying over ground at low altitude, at least one ring vortex of airflow is generated at the ground on each side of a vertical middle plane of the airplane. Each ring vortex has a vortex axis and a direction of propagation, wherein the vortex axis is oriented at an angle with respect to the ground, and wherein the propagation direction is oriented upwards from the ground; and each ring vortex disturbs at least one wake vortex to induce its decay.

"STRONG SHOCK -- VORTEX INTERACTION -- A NUMERICAL STUDY"

ICTAM04 Proceedings, Mechanics of the 21st Century, August 2004, Warsaw, Poland.

The intersection of a longitudinal vortex by a normal shock is studied with a numerical solution of the Euler and Navier-Stokes equations for time-dependent, three-dimensional, laminar flow. The study is concerned with the destruction of the vortex core, usually referred to as vortex breakdown or bursting, by letting the shock intersect the vortex normal to its axis. Results are presented for a Mach number about 1.6. The calculations were performed on a Cartesian mesh with approximately 2 million grid points. The computations show noticeable differences between the two solutions, and viscous forces become important in the burst part of the vortex. Visualization studies clearly reveal the time-dependent, three-dimensional nature of the flow after breakdown.

Schroeder, N.

"ANALYSIS OF POTENTIAL WAKE TURBULENCE ENCOUNTERS IN CURRENT AND NEXTGEN FLIGHT OPERATIONS"

MS Thesis, January 2011, Virginia Polytechnic Institute and State University, Blacksburg, VA.

Wake vortices pose a threat to a following aircraft, because they can induce a roll and compromise the safety of everyone on board. Caused by a difference in pressure between the upper and the lower part of the wings, these invisible flows of air are a major hazard and must be avoided by separating the aircraft at considerable distances. One of the known constraints in airport capacity for both departure and arrival operations is the large headway resulting from the wake spacing separation criteria. Reducing wake vortex separations to a safe level between successive aircraft can increase capacity in the National Airspace System (NAS) with corresponding savings in delay times. One of the main goals of the Wake Encounter Model (WEM) described in this thesis is to assess the outcome from future reduced separation criteria in the NAS. The model has been used to test probable encounters in today's operations, and can also be used to test NextGen scenarios, such as Close Parallel Approaches and reduced in-trail separation flights. This thesis presents model enhancements to account for aircraft turning maneuvers, giving the wake a more realistic shape. Three major airspaces, New York, Southern California, and Atlanta, were analyzed using the original and the enhanced WEM to determine if the enhanced model better represents the conditions in today's operations. Additionally, some analysis on the wake lateral travel for closely spaced runways is presented in this thesis. Finally, some extension tools for post-analysis, such as animation tool and various graphs depicting the interactions between wake pairs were developed.

Schumann, U.

"FORMATION, PROPERTIES AND CLIMATIC EFFECTS OF CONTRAILS"

C. R. Physique, Vol. 6, 2005, pp. 549-56.

Condensation trails (contrails) are aircraft induced cirrus clouds, which may persist and grow to large cirrus cover in ice-supersaturated air, and may cause a warming of the atmosphere. This paper describes the formation, occurrence, properties, and climatic effects of contrails. The global cover by lined-shaped contrails and the radiative impact of line-shaped contrails is smaller than that assessed in an international assessment in 1999. Contrails trigger contrail cirrus with far larger coverage than observed for line-shaped contrails, but still unknown radiative properties. Some model simulations indicate an impact of particles and particle precursors emitted from aircraft engines on cirrus clouds properties. However, the magnitude of this effect cannot yet be assessed. Contrail formation can be avoided only by flying in sufficiently warm and dry air. The formation of contrail cirrus can be reduced by avoiding flights in ice-supersaturated regions of the atmosphere, e.g., by raising the flight level into the lower-most stratosphere.

Schumann, U.

"A CONTRAIL CIRRUS PREDICTION MODEL"

A new model to simulate and predict the properties of a large ensemble of contrails as a function of given air traffic and meteorology is described. The model is designed for approximate prediction of contrail cirrus cover and analysis of contrail climate impact, e.g. within aviation system optimization processes. The model simulates the full contrail life-cycle. Contrail segments form between waypoints of individual aircraft tracks in sufficiently cold and humid air masses. The initial contrail properties depend on the aircraft. The advection and evolution of the contrails is followed with a Lagrangian Gaussian plume model. Mixing and bulk cloud processes are treated quasi analytically or with an effective numerical scheme. Contrails disappear when the bulk ice content is sublimating or precipitating. The model has been implemented in a 'Contrail Cirrus Prediction Tool' (CoCiP). This paper describes the model assumptions, the equations for individual contrails, and the analysis-method for contrail-cirrus cover derived from the optical depth of the ensemble of contrails and background cirrus. The model has been applied for a case study and compared to the results of other models and in-situ contrail measurements. The simple model reproduces a considerable part of observed contrail properties. Mid-aged contrails provide the largest contributions to the product of optical depth and contrail width, important for climate impact.

"AIRCRAFT WAKE-VORTEX ENCOUNTER ANALYSIS FOR UPPER LEVELS"

Journal of Aircraft, Vol. 52, No. 4, July-August 2015, pp. 1277-1285.

The frequency of aircraft encountering the wake of other aircraft is analyzed for given aircraft, movement, and meteorological data. The method considers the descent and decay of wake vortices for a given stratification and turbulence-kinetic-energy dissipation rate, and the advection with ambient horizontal and vertical wind. An encounter is characterized in this study by the distance between the position of a follower aircraft and the centerline of a wake vortex behind the vortex generator, and by the wake-induced lift forces or roll moments on the encountering aircraft. A linear model is used for an efficient identification of potential wake-vortex encounters for all flight segments in dense traffic regions. The method is applied to radar-observed traffic over North America in 46 days in 2010/2011, and validated against pilot-reported wake encounters and automated in situ turbulence reports. Most upper-level encounters are found for medium-size aircraft on nearly parallel flight routes during descent. En route encounters of wakes from heavy aircraft flying 1000 ft higher occur relatively rarely. The frequency of wake-vortex encounters increases with the square of air-traffic density.

"LARGE-EDDY SIMULATION OF TURBULENCE IN THE FREE ATMOSPHERE AND BEHIND AIRCRAFT"

Fluid Dynamics Research, Vol. 20, Issues 1-6, February 1997, pp. 1-10

The method of large-eddy simulation has been used for a wide variety of atmospheric flow problems. This paper gives an overview on recent applications of this method to turbulence in the free

atmosphere under stably stratified conditions. In particular, flows in the wake of aircraft are studied considering the potential impact of aircraft exhausts on the chemical and climatological state of the atmosphere. It is shown that different profiles of heat and moisture in the initial conditions of a jet representing engine exhaust gases may cause larger water saturation and hence earlier contrail formation than assumed up to now. The instability of trailing vortices in the wake of an aircraft is simulated up to the fully turbulent regime. The vertical diffusivity of aircraft exhaust is large in the vortex regime and much smaller than horizontal diffusivities in the later diffusion regime. The three-dimensional formation of a critical layer and breaking of gravity waves is simulated.

"CONTRAILS: VISIBLE AVIATION INDUCED CLIMATE IMPACT"

In: Atmospheric Physics, Research Topics in Aerospace, U. Schumann (editor), Springer-Verlag Berlin Heidelberg, 2012, pp. 239-257.

Contrails are aircraft induced linear ice particle clouds. In ice-supersaturated air masses, contrails persist and develop into contrail cirrus. Aviation changes cloudiness also by soot emissions and other aerosols. In the global mean, contrail cirrus warms the atmosphere. The local warming induced by a contrail varies strongly relative to the global mean, and may be positive or negative, depending on aircraft, route, solar and Earth-atmosphere parameters. Here we summarize present knowledge on contrails with respect to aviation and atmospheric research.

"MEASUREMENT OF THE WAKE BEHIND A BAT-LIKE FLAPPER AND THE INFLUENCE OF THE FLAPPING FREQUENCY ON LIFT GENERATION"

AIAA Paper No. 2011-3116, June 2011, Honolulu, Hawaii.

The wake structure behind a simplified flapping model based on the Lesser short-nosed fruit bat *Cynopterus brachyotis* was examined at a Reynolds number $Re \sim 30000$ and four Strouhal numbers between 0.014 and 0.126 using high speed PIV in the Trefftz plane. Besides the tip vortex, three other vortex structures were observed at higher Strouhal numbers: a proximal counter rotating vortex, indicating that over the body temporarily no lift is produced, and a distal vortex dipole, showing that the distal part of the wing is generating negative lift during the upstroke at higher Strouhal numbers. Even though real bats cruise at higher Strouhal numbers (greater than or equal to 0.2), the same four vortices were described for the wake structures of three different bat species.

Schutte, A.

"NUMERICAL INVESTIGATIONS OF VORTICAL FLOW ON SWEEPED WINGS WITH ROUND LEADING EDGES"

Journal of Aircraft, Vol. 54, No. 2, March-April 2017, pp. 572-601.

The present work is investigating the vortex-dominated flow physics as well as the aerodynamic behavior of swept wing configurations with round leading edges. The research is based on numerical simulations using the computational fluid dynamics method DLR TAU. The target configurations are swept wings of constant aspect ratio, variable leading-edge contours, and leading-edge sweep angles. The work deals with the onset of the vortical flow at the leading edge for constant and variable leading-edge nose radii, the influence of the angle of attack, the leading-edge sweep, and the onflow Mach number. Furthermore, the aerodynamic behavior is analyzed and assessed, as well as the specific flow physics in the vicinity of the vortical flow separation at round leading edges. The objective of the present work is to provide a contribution for the design and assessment of the physical characteristics of swept wing configurations. Furthermore, sensitivities will be given for the design process. In addition, the current investigation provides a deeper understanding of the separation onset process and the flow physics of swept wing configurations with round leading edges.

"AVO-G2S: A MODIFIED, OPEN-SOURCE GROUND-TO-SPACE ATMOSPHERIC SPECIFICATION FOR INFRASOUND MODELING"

Computers & Geosciences, Vol. 125, April 2019, pp. 90-97.

To facilitate infrasound propagation studies, we present AVO-G2S, an open-source, Ground-to-Space model which provides temperature and wind specifications from the surface to an altitude of 225km. This model provides a means of smoothly characterizing atmospheric conditions using multiple numerical weather prediction forecast and reanalysis products, along with upper-atmospheric empirical models. Regional atmospheric reconstructions only require a limited domain and can utilize high-resolution numerical weather prediction forecasts typically provided on a projected grid. The use of a projected grid allows for faster spectral transform libraries to be employed. The AVO-G2S software can also provide global reconstructions that rely on global numerical weather prediction products and spherical harmonic decompositions. AVO-G2S is inspired by a global Ground-to-Space model developed by the Naval Research Laboratory, and relies on their empirical descriptions of upper-atmospheric conditions. Alaska Volcano Observatory has implemented this model for near-real-time infrasound monitoring of volcanic eruptions and historical research projects.

"A COMPARISON OF TEMPERATURE AND WIND MEASUREMENTS FROM ACARS-EQUIPPED AIRCRAFT AND RAWINSONDES"

Weather and Forecasting, Vol. 10, September 1995, pp. 528-544.

A comparison was made of temperature and wind observations reported by rawinsonde and Aircraft Communications, Addressing, and Reporting System (ACARS)-equipped commercial aircraft separated by less than 150 km in distance and 90 min in time near Denver, Colorado, in February and March 1992. Only data made on aircraft ascents and descents reported automatically were used. A total of 4440

matched data pairs were obtained for this period. The sample was analyzed in total but also as a function of time and distance separation, height, time of day, and ascent versus descent. A standard deviation temperature difference of 0.97 degrees C and rms vector wind difference of 5.76 m/s were found for the entire sample but were reduced, respectively, to 0.59 degrees C and 4.00 m/s when only data pairs separated by less than 25 km and 15 min were used. The study provides an upper limit to the combination of rawinsonde and ACARS observation and reporting errors and mesoscale variability, but it is not possible to distinguish the exact combinations from each of these sources. However, overall, these statistics indicate that the rawinsonde data used were more accurate than that reported in a previous study and that the accuracy of the ACARS data was somewhat higher still.

"SCENARIO DEFINITIONS"

CREDOS Report D3-3, September 2007, DLR, Oberpfaffenhofen, Germany.

CREDOS subtask 3.1.3 and this report provide a definition of wake vortex encounter scenarios during the takeoff phase as a basis for the simulations carried out in CREDOS. The parameters of influence for wake vortex encounters during takeoff are discussed and offline wake vortex encounter simulations are conducted to derive tendencies for the impact of relevant parameters.

Schwarz, C. and Fischenberg, D.

"ANALYSIS OF TWO 2005 WAKE VORTEX ENCOUNTER INCIDENTS"

ICAS 2010, Paper 2010-10.2.1, Sept. 2010, Nice, France.

Two potential wake vortex encounter incidents (medium behind heavy) are subject to investigation (radar data, FDR data, meteo data). The wake vortex behavior is simulated to estimate the closest proximity to the wake vortex indicating that a wake encounter with considerable vortex strength is likely in both cases.

Schwarz, C. and Fischenberg, D.

"WAKE TURBULENCE HAZARD ANALYSIS FOR A GENERAL AVIATION ACCIDENT"

Document 340177, December 2014, DLR, Braunschweig, Germany.

Whereas wake turbulence is commonly a topic within commercial aviation which is involving large/heavy transport aircraft, there can also be a hazard for general aviation flight operations. This has been investigated for a specific case of an accident where an aircraft of class E (one engine with a maximum takeoff weight up to 2 tons) took off behind an aircraft with 5.5 tons maximum takeoff weight. Based on available information and several assumptions the potential wake turbulence situation for the specific aircraft combination has been assessed. The roll axis was the dominating factor in this case. Accordingly, the wake induced rolling moment was analyzed and related to the

assumed available roll control power. Furthermore, the wake vortex behavior was simulated. The results indicate that wake turbulence can likely be the main reason for the accident.

"AUTOMATED PILOT ASSISTANCE FOR WAKE VORTEX ENCOUNTERS"

Aerospace Science and Technology, Vol. 15, 2011, pp. 416-421.

Wake vortices pose a possible hazard for encountering aircraft in all phases of flight. Hence wake vortex encounters are to be avoided in any case. In case of an unintended wake vortex encounter, special aircraft controllers can act as a safety net. Such an active wake vortex control system is being developed by the DLR Institute of Flight Systems based on feed-forward disturbance compensation. The control system has been tested with offline and pilot-in-the-loop investigations as well as with flight tests. It can be shown that the aircraft response can be improved significantly if the pilots are supported by an automatic wake assistance system. For the subjective assessment of the wake vortex encounters a dedicated pilot rating scale has been developed. The results show a clear tendency that the wake vortex controller improves the situation.

"GEFAHRDUNG BEIM EINFLOGEN IN WIRBELSCHLEPPEN"

Deutsche Luft- und Raumfahrt-Kongress, Munich, Germany, November 2003

Estimation of the risk assessment for flying into wake vortices will be determined at the DLR Institute for Flight Technical Systems by developing a simulation system of the aircraft reaction. It will introduce a risk zone concept that will be checked against a completely nonlinear simulation system. The definition of the risk zone is made possible by determining at any given time the necessary minimum distance from the leading aircraft, allowing for a safe crossing of the wake flow. [In German.]

Schwarz, C. and Hahn, K.-U.

"HAZARD AREAS FOR WAKE VORTEX ENCOUNTER AVOIDANCE"

German Aerospace Congress 2004, Dresden, Germany, DGLR-JT2004-014 (in German)

For the hazard assessment of wake vortex encounters hazard zones are defined. If these are not violated a safe and undisturbed flight operation is possible. For the determination of the hazard zones the required roll control power is used. Its limit must be chosen in such a way that outside the hazard zone all wake vortex effects are noncritical. For the determination of such limits offline as well a full-flight simulator studies were conducted. By means of the 'Simplified Hazard Area Prediction (SHAPE)' method simplified hazard zones are calculated. By parameterization of the input values the hazard zone concept is applicable universally to different aircraft types. SHAPE represents an essential

element of the wake vortex prediction and observation system within the DLR project Wirbelschlepp II, for the generation of safe dynamic wake vortex separations.

"IMPACT OF INDIVIDUAL AND DYNAMIC WAKE VORTEX SEPARATIONS ON AIRPORT CAPACITY"

25th International Congress of the Aeronautical Sciences (ICAS-2006), Sept. 2006, Hamburg, Germany.

For many airports the capacity is limited by minimum separation distances especially for approach and landing due to the possible hazard generated by wake vortices. To alleviate capacity limitations, separation rules must be improved without reducing safety. Based on simplified hazard areas dynamic wake vortex separations can be derived considering atmospheric conditions and actual aircraft pairing. This concept is applied to parallel runways in comparison to the single runway case for cross wind and headwind conditions.

"SIMPLIFIED HAZARD AREAS FOR WAKE VORTEX ENCOUNTER AVOIDANCE"

AIAA Paper No. 2005-5903, San Francisco, CA, August 2005

Simplified hazard areas (SHA) can help to master the wake vortex problem. Avoiding these zones allows safe and undisturbed flight operations. The definition of the hazard areas is based on the nominal required roll control power. The limit for this value must be chosen carefully to ensure that outside the hazard area all wake vortex effects are noncritical. To identify such a limit, offline simulations, full flight simulator studies, and in-flight simulations were conducted. The hazard area dimensions for a specific roll control limit are derived with the 'Simplified Hazard Area Prediction' method (SHAPE). Parameterization of the input parameters makes this method universally applicable to different aircraft types. SHAPE represents a fundamental element of the wake vortex prediction and observation system within the interdisciplinary DLR project Wirbelschlepppe II, for the generation of safe dynamic wake vortex separations.

Schwarz, C. W. and Hahn, K.-U.

"FULL-FLIGHT SIMULATOR STUDY FOR WAKE VORTEX HAZARD AREA INVESTIGATION"

Aerospace Science and Tech., Vol. 10, 2006, pp. 136-143

Simplified hazard areas (SHA) can help to overcome the wake vortex problem. Avoiding these zones allows safe and undisturbed flight operations. The definition of the hazard areas is based on the nominal required roll control power. The nominal limit for this value must be chosen carefully to ensure that outside the hazard area all wake vortex effects are noncritical. For the determination of such a limit offline simulations and full flight simulator studies were conducted. For a given roll control limit the hazard area dimensions are established with the 'simplified hazard area prediction' method (SHAPE). Parameterization of the input parameters makes this method universally applicable to different aircraft types. SHAPE represents an essential element of the wake vortex prediction and observation system within the DLR project Wirbelschlepppe II, for the generation of safe dynamic wake vortex separations.

"WAKE TURBULENCE EVOLUTION AND HAZARD ANALYSIS FOR A GENERAL AVIATION TAKEOFF ACCIDENT"

AIAA Paper 2018-3019, June 2018, Atlanta, GA.

Wake turbulence is commonly a commercial aviation topic involving relatively heavy transport aircraft. However, wake turbulence is also safety relevant for business and general aviation flight operations. A detailed analysis has been conducted for a specific accident involving two aircraft of the wake turbulence category light. A four-seat aircraft with one-ton maximum takeoff weight took off behind a biplane with 5.5 tons maximum takeoff weight. This led to a fatal accident. Based on available information and several assumptions the wake turbulence aspects for the specific accident scenario have been assessed. The roll axis was the dominating factor in this case. Accordingly, the wake induced rolling moment was analyzed and related to the assumed available roll control power. Furthermore, the wake vortex behavior was simulated and analyzed in detail. The results indicate that wake turbulence can be considered to be the cause for the accident. The theoretical results and the conclusions regarding the accident are also supported by the results of flight tests, which were conducted in the context of the accident investigation.

Schwarz, C. W., Hahn, K.-U. and Fischenberg, D.

"WAKE ENCOUNTER SEVERITY ASSESSMENT BASED ON VALIDATED AERODYNAMIC INTERACTION MODELS"

AIAA Paper No. 2010-7679, Toronto, Canada, August 2010.

Wake encounter severity criteria based on validated models are of great importance for any wake vortex related severity assessment. The aerodynamic interaction model 'strip method' describes the vortex-induced aircraft reaction. The model quality is validated with wake encounter flight test data. Model shortcomings are improved with dedicated refinements. A simplified hazard area approach is developed employing validated simulation models. With one simple criterion, the roll control ratio, safe and undisturbed flight operations can be ensured. A limit value for manually flown (non-fly-by-wire) aircraft is derived from piloted trials. With the simplified hazard area prediction method, this can be universally applied for wake vortex advisory systems like DLR's wake vortex prediction and monitoring system.

"WAKE CHARACTERIZATION OF A FREE-FLYING MODEL HELICOPTER IN GROUND EFFECT"

AHS International 74th Annual Forum & Technology Display, May 2018, Phoenix, Arizona.

Measurements of the flow field around a free-flying model helicopter in ground effect for both quasi-steady and unsteady maneuvering flights were performed using stereoscopic particle image velocimetry (PIV). The wake features for hover and forward flight at low advance ratios were

characterized and changing flow patterns like circulation and ground vortex flow were observed to be in good agreement with existing wind tunnel data. Parameters describing both general flow patterns and single blade tip vortices were extracted and showed significant dependence on the forward flight velocity. Landing approaches were performed and large vortical structures were observed close to the rotor disk, which contained high amounts of vorticity due to entrained blade tip vortices. The vortex structures developing for unsteady landing approaches contained distinctly higher velocities and momentum fluxes than expected from quasi-steady conditions at the same advance ratios. For a vertical takeoff maneuver with a rapid increase of collective pitch, the bundling of blade tip vortices into a 'starting vortex' with circulation values up to 6 times higher than for a single blade tip vortex was observed. These results show the significance of experimental data on free-flying helicopters in unsteady maneuvering flight because the resulting flow fields cannot be predicted using steady-state experiments or simulations.

Schweiger, R. N.

"PULSED ACOUSTIC VORTEX SENSING SYSTEM, VOLUME IV: PAVSS PROGRAM SUMMARY AND RECOMMENDATIONS"

FAA-RD-74-19.4, June 1977, Avco, Wilmington, M.

An engineered Pulsed Acoustic Vortex Sensing System (PAVSS) was developed. This system is capable of real-time detection, tracking, recording, and graphic display of aircraft trailing vortices. This volume of the report summarizes the background and accomplishments of the PAVSS program carried out by Avco, and presents Avco's recommendation that further work on the PAVSS would not be economically sound.

Schweiger, R. N.

"PULSED ACOUSTIC VORTEX SENSING SYSTEM, VOLUME II: STUDIES OF IMPROVED PAVSS PROCESSING TECHNIQUES"

FAA-RD-74-19.2, June 1977, Avco, Wilmington, M.

AVCO Corporation's System Division designed and developed an engineered Pulsed Acoustic Vortex Sensing System (PAVSS). This system is capable of real-time detection, tracking, recording, and graphic display of aircraft trailing vortices. This volume of the report presents the results of two subcontractor studies directed toward development of improved vortex tracking software techniques for the PAVSS. The volume recommends the incorporation of several improvements in the software.

Schweiger, R. N.

"PULSED ACOUSTIC VORTEX SENSING SYSTEM, VOLUME III: PAVSS OPERATION AND SOFTWARE DOCUMENTATION"

FAA-RD-74-19.3, June 1977, Avco, Wilmington, M.

AVCO Corporation's System Division designed and developed an engineered Pulsed Acoustic Vortex Sensing System (PAVSS). This system is capable of real-time detection, tracking, recording, and graphic display of aircraft trailing vortices. This volume of the report presents the operation of the pulsed acoustic vortex sensing system and the computer software documentation.

Schweiger, R. N.

"PULSED ACOUSTIC VORTEX SENSING SYSTEM, VOLUME I: HARDWARE DESIGN"

FAA-RD-74-19.1, June 1977, Avco, Wilmington, M.

An engineered Pulsed Acoustic Vortex Sensing System (PAVSS) was developed. This system is capable of real-time detection, tracking, recording, and graphic display of aircraft trailing vortices. This volume of the report presents hardware design aspects of the system. The design of the acoustic antenna and transducer is described. System control, computer hardware, and system/subsystem hardware interfaces are discussed.

Scorer, R. S. and Davenport, L. J.

"CONTRAILS AND AIRCRAFT DOWNWASH"

J. Fluid Mech., Vol. 43, Part 3, September 1970, pp. 451-464

Aircraft downwash consists initially of a vortex pair descending with its accompanying fluid through the atmosphere. Condensation trails are formed in exhaust emitted into the accompanying fluid and the shapes of them and their evolution depend on the positions of the engines in relation to the wing tip vortices. The atmosphere is stably stratified and so the descending accompanying fluid acquires upward buoyancy. Consequently, vorticity is generated at the outside of the accompanying fluid and the flow pattern in the vortex pair is altered to produce detrainment of its exterior part. So long as any air which is a mixture of accompanying fluid and exterior air is detrained, the vortices remain stable, but the width of the pair decreases and its downward velocity increases with time because of the buoyancy. Eventually the upper stagnation point in the motion relative to the vortices begins to move upwards relative to the vortices so that some mixed fluid is entrained into the circulation and the vortices immediately become unstable, mixing occurs, the pressure in the core rises, and any vortex core trails that may exist appear to burst. The motion produces downward-thrust blobs in trails from centrally placed engines, which correspond to the holes sometimes seen in cloud when distrails are formed.

Scott, G. A.

"NEW HORIZONS IN AIR TRAFFIC CONTROL"

AIAA Paper No. 1975-0569, Boston, MA, 1975

According to the FAA's latest air traffic forecasts, aviation in the United States will continue to grow into the indefinite future. To meet the demands of this continuing growth, the existing air traffic control (ATC) system must be improved. The goals of the future upgraded ATC system are: maintain or improve safety, constrain or reduce costs, and increase and improve performance. These goals will be met in part by the following new ATC features -Airport Surface Traffic Control System (ASTC), Discrete Address Beacon System (DABS), Air Traffic Control Automation, Intermittent Positive Control (IPC), Area Navigation (RNAV), Microwave Landing System (MLS), and Wake Vortex Avoidance System (WVAS).

"TRANSONIC BUFFET RESPONSE TESTING AND VORTEX CONTROL"

Proceedings of Symposium on Unsteady Aerodynamics, U.S. Air Force Office of Scientific Research and Univ. of Arizona, Vol. I, 1975, pp. 337-357

The basic theory of vortex stabilization by means of core wise blowing is presented as a vortex-lattice, source-induction (VLSI) computer simulation. An extension of Polhamus' leading-edge suction analogy to high aspect-ratio wing is derived, showing the effect of aspect ratio on near wake vortex burst.

Scully, M. P.

"A METHOD OF COMPUTING HELICOPTER VORTEX WAKE DISTORTION"

ASRL TR 138-1, June 1967, Massachusetts Institute of Technology, Cambridge, MA.

A method for computing the geometry of the tip vortex of a helicopter rotor in steady, forward flight, including the distortion due to the velocities induced by the vortex wake, has been developed. The relative importance of various parameters and approximations used by this method has been evaluated for one test case, including comparison with experimental results obtained from a flow visualization study.

Scully, M. P.

"COMPUTATION OF HELICOPTER ROTOR WAKE GEOMETRY AND ITS INFLUENCE ON ROTOR HARMONIC AIRLOADS"

PhD Thesis, February 1975, Massachusetts Institute of Technology, Cambridge, MA.

Efficient techniques are developed for the computation of helicopter rotor tip vortex geometry and helicopter rotor harmonic airloads. These techniques are designed to minimize the computational expense by the use of simplified wake models together with other devices which reduce the amount of integration over the wake of the Biot Savart relation for induced velocity. These techniques are designed for use in steady-state flight at advance ratios below 0.3; however, they could be readily extended to higher advance ratios and to transient flight conditions. The results of the tip vortex geometry computations show that, over the forward portion of the rotor, the tip vortex is much closer

to the rotor than the classical rigid wake assumption would indicate. This results in very intense, close blade-tip vortex interactions. These interactions must be modeled much more carefully than the less intense ones which occur when the rigid wake geometry assumption is used. The use of a lifting-surface solution for the airloads induced by these close blade-tip vortex interactions resulted in a substantial improvement in the agreement with measured airloads. Further improvement was obtained by the use of a very simplified model for tip vortex-core bursting and for the propagation of that bursting ahead of the blade which initiated it. This, together with the lifting-surface solution, brought the computed airloads into reasonable agreement with the measured airloads. A simple tip vortex roll-up model was used to test the effect of roll-up on the airloads computation and it was found to be significant in some cases. The effects of tangentially-induced velocity and local separation on airloads computations were also evaluated and found to be of limited importance. It is recommended that close blade-vortex interactions and tip vortex formation and roll-up be studied both experimentally and theoretically. The currently available knowledge of these phenomena is inadequate for accurate harmonic airloads computations.

Scully, M. P.

"COMPUTATION OF HELICOPTER ROTOR WAKE GEOMETRY AND ITS INFLUENCE ON ROTOR HARMONIC AIRLOADS"

ASRL TR 178-1, March 1975, Massachusetts Institute of Technology, Cambridge, MA.

Efficient techniques are developed for the computation of helicopter rotor tip vortex geometry and helicopter rotor harmonic airloads. These techniques are designed to minimize the computational expense by the use of simplified wake models together with other devices which reduce the amount of integration over the wake of the Biot Savart relation for induced velocity. These techniques are designed for use in steady-state flight at advance ratios below 0.3; however, they could be readily extended to higher advance ratios and to transient flight conditions. The results of the tip vortex geometry computations show that, over the forward portion of the rotor, the tip vortex is much closer to the rotor than the classical rigid wake assumption would indicate. This results in very intense, close blade-tip vortex interactions. These interactions must be modeled much more carefully than the less intense ones which occur when the rigid wake geometry assumption is used. The use of a lifting-surface solution for the airloads induced by these close blade-tip vortex interactions resulted in a substantial improvement in the agreement with measured airloads. Further improvement was obtained using a very simplified model for tip vortex-core bursting and for the propagation of that bursting ahead of the blade which initiated it. This, together with the lifting-surface solution, brought the computed airloads into reasonable agreement with the measured airloads. A simple tip vortex roll-up model was used to test the effect of roll-up on the airloads computation and it was found to be significant in some cases. The effects of tangentially-induced velocity and local separation on airloads computations were also evaluated and found to be of limited importance. It is recommended that close blade-vortex interactions and tip vortex formation and roll-up be studied both experimentally and theoretically. The currently available knowledge of these phenomena is inadequate for accurate harmonic airloads computations.

"WAKE SURVEY TECHNIQUES IN THE ONERA INDUSTRIAL WIND TUNNELS"

AIAA Paper No. 2002-2923, St. Louis, MO, June 2002

ONERA is currently pursuing both near-field and far-field wake survey techniques to better understand the components of aircraft drag, and how the wake of an aircraft persists in the atmosphere. Within the frame of national French research programs, ONERA has recently improved and validated its experimental techniques for near-field wake surveys in its industrial wind tunnels: the F1 low-speed wind tunnel; the SZMA transonic wind tunnel; and the large SIMA high-speed wind tunnel. Some of the different tests performed to validate these near-field techniques are presented. These wake survey techniques provide detailed descriptions of the flow downstream of the models under investigation. The drag can then be broken down into its basic terms (viscous, wave and induced drag), and the local sources of drag visualized. For far-field wake surveys, our catapult facilities at Lille are used for free-flight model tests. These test techniques rely on non-intrusive measurement techniques to study the propagation of a model's wake up to 80 wing spans downstream. We believe these wake survey techniques will be of great help in the understanding and analysis of local flow phenomena and wakes which will lead to better aircraft designs to minimize drag and more efficient air traffic procedures.

"FLOW FIELD INVESTIGATION OF A ROTATING HELICOPTER ROTOR BLADE BY THREE-COMPONENT LASER-DOPPLER-VELOCIMETRY"

Aerodynamics and Aeroacoustics of Rotorcraft, AGARD-CP-552, August 1995, pp. 23-1 to 23-12.

The measurement of three-dimensional local flow vectors of a blade tip vortex at positions near the helicopter rotor plane were performed with a three-component laser-Doppler-velocimeter (3D LDV). A 'position monitoring system' synchronized to the blade rotation gave access to blade motion parameters like lead-lag and pitching at the desired radial position of the blade. Mainly results concerning the structure of blade tip vortices were obtained. The measurements of a vortex generated at hover condition showed the correctness of 'time history' data acquisition, e.g. taking data during the time interval when one blade is passing the location of the measuring volume of the LDV. Vortex

structure measurements at two different blade tips, a regular square tip for reference and a non-planer tip called winglet, were carried out. First of all, the influence of the winglets on vortex structure and blade vortex interaction (BVI) has been investigated. Then in addition to the vortex parameters like vortex/blade miss distance, vortex core size, axial velocity deficit, vortex strength, and vorticity distribution with respect to the spatial orientation of the vortex axis, results on 3D-vorticity distribution and the temporal vortex roll up for the different blade tip vortices have been obtained.

"A SIMPLIFIED VORTEX MODEL OF PROPELLER AND WIND-TURBINE WAKES"

Journal of Fluid Mechanics, Vol. 725, 2013, pp. 91-116.

A new vortex model of inviscid propeller and wind-turbine wakes is proposed based on an asymptotic expansion of the Biot-Savart induction law to account for the finite vortex core size. The circulation along the blade is assumed to be constant from the blade root to the tip approximating a turbine with maximum power production for given operating conditions. The model iteratively calculates the tip-vortex path, allowing the wake to expand/contract freely, and is afterward able to evaluate the velocity field in the whole domain. The 'roller-bearing analogy', proposed by Okulov and Sorensen, is used to determine the vortex core size. A comparison of the main outcomes of the present model with the general momentum theory is performed in terms of the operating parameters (namely the number of blades, the tip-speed ratio, the blade circulation, and the vortex core size), demonstrating good agreement between the two. Furthermore, experimental data have been compared with the model outputs to validate the model under real operating conditions.

"UNCERTAINTY ANALYSIS OF THE VON KARMAN CONSTANT"

Experiments in Fluids, Vol. 11, 2013, pp. 1460-1468.

In 1930, von Karman presented an expression for the mean velocity distribution in channel and pipe flows that can be transformed into the today well-known logarithmic velocity distribution. At the same time, he also formulated the logarithmic skin friction law and obtained a value of 0.38 for the constant named after him through pipe flow pressure drop measurements. Different approaches to determine the von Karman constant from mean velocity measurements have been proposed over the last decades, sometimes giving different results even when employed on the same data, partly because the range over which the logarithmic law should be fitted is also under debate. Up to today, the research community has not been able to converge toward a single value and the favored values range between 0.36 and 0.44 for different research groups and canonical flow cases. The present paper discusses some pitfalls and error sources of commonly employed estimation methods and shows, using boundary layer data from Osterlund (1999) that von Karman's original suggestion of 0.38 seems to be valid for zero pressure gradient turbulent boundary layer flows. More importantly, it is shown that the uncertainty in

the determination of the von Karman constant can never be less than the uncertainty in the friction velocity, thereby yielding a realistic uncertainty for the most debated constant in wall turbulence.

"INSTALLATION EFFECTS ON HIGH SPEED PLUME EVOLUTION"

1997 ASME Fluids Engineering Division Summer Meeting, June 1997

An experimental and numerical study was conducted to examine the effect of the wing-tip vortex, wing wake, pylon wake, and angle-of-attack on the spatial distortion of an evolving high speed subsonic jet plume. One objective of the study was to evaluate the effect of this distortion on the radiated sound field. A generic powered nacelle was mounted with a generic pylon to a NACA 0012 airfoil. Both conventional probes and a planar laser light sheet were used to track the geometric center of the jet plume and wing-tip vortex. A cold resistance fine wire was used to measure total temperature fluctuations. Both the CRAFT and TTJET code were used for numerical simulations. Comparisons between experimental and numerical simulations were found to be in good agreement. Two supersonic rectangular nozzles, with aspect ratios of 1.56 and 2.0 were used to assess the non-azimuthal noise field. These convergent-divergent nozzles were designed for an exhaust Mach number of 1.5. The non-azimuthal sound field of the rectangular nozzles suggested, based on distortion of the installed plume flow field, that both angle-of-attack and wing tip vortex could lead to non-symmetric sound radiation for conventional aircraft at take-off.

"EVALUATION OF WIND ALGORITHMS FOR REPORTING WIND SPEED AND GUST FOR USE IN AIR TRAFFIC CONTROL TOWERS"

AMS 12th Conference on Aviation Range and Aerospace Meteorology, January - February, 2006, Atlanta, GA.

This paper examined several simple methods of evaluating short-term wind direction shift prediction, focusing on 2-min forward values derived from backward wind direction data. The results suggest that 2-min BW averaging for average wind direction and 10-min BW look-backs for wind range are reasonable standards for aviation reporting. The data provide evidence that 5-min BW averaging and look backs for both parameters may be optimum. The wind direction range was found to correlate with wind direction standard deviation, like results of Markee (1963) who analyzed wind data over 15-min, 30-min and 60-min time intervals. The findings here also agreed with his results that showed that the wind direction range is not correlated with wind speed standard deviation (not a good predictor). These limited results show that, irrespective of the many studies of winds that have been performed previously, much remains to be learned. In particular, more sophisticated approaches to analyzing winds should improve predictions, reducing both missed reports and false reports. Essentially, current methods may be considered naive compared to state-of-art time series and statistical analysis methods, including such topics as: time series filtering; neural networks; and fuzzy logic modeling.

"METER-SCALE OBSERVATIONS OF AIRCRAFT WAKE VORTICES IN PRECIPITATION USING A HIGH RESOLUTION SOLID-STATE W-BAND RADAR"

AMS 34th Conference on Radar Meteorology, Paper 10.25, October 2009, Williamsburg, VA.

Detection, tracking and characterization of wake vortices generated by aircraft during takeoff and landing are important to assess threats to aviation safety and ensuring that air traffic control procedures adequately account for the phenomenon. This paper reports on a radar technology that may provide valuable contributions to these efforts. Specifically, meter-scale detection of aircraft wake vortices in light rain has been demonstrated using a low power (100 mW), solid-state W-Band (94 GHz) radar system. The radar employs a 1.2 m diameter antenna on a scanning pedestal, providing a 1.5-m 6-dB cross track beam pattern at 500-m range. Range resolution as fine as 1.0-m is achieved using stretch processing, which also provides processing gain on the order of 30 dB. Additional coherent gain is achieved through FFT processing at each range gate. Range sidelobe suppression of greater than 40 dB makes this system suitable for high spatial and temporal resolution meteorological research such as the investigation of wake turbulence behavior during aircraft takeoff and landing operations.

"LASER DOPPLER ANEMOMETRY STUDY OF HELICOPTER ROTOR WAKE AIRFLOW"

International Symposium on Applications of Laser-Doppler Anemometry to Fluid Mechanics, Lisbon, July 1982

The equipment, instrumentation, and results of a laser Doppler anemometry study of helicopter rotor wake airflow are described. Azimuthal and radial distributions of vertical induced velocities and tip vortex paths are determined for the cases of hovering and forward flight. Attention is given to the arrangement of the laser velocimeter system and the data acquisition system, which can operate in both a 'wake' and a 'histogram' mode. The former simultaneously obtains the two induced velocities and the angular position of the blade, while the latter, velocities are measured for one given azimuthal blade location.

"COMPUTER MODELING OF TORNADO FORCES ON A CUBIC BUILDING USING LARGE EDDY SIMULATION"

Journal of the Arkansas Academy of Science, Vol. 57, 2003, pp. 140-146.

A tornado changes its wind speed and direction rapidly; therefore, it is difficult to study the effects of a tornado on buildings in a wind tunnel. The status of the tornado-structure interaction and various models of the tornado wind field found in literature are surveyed. Three-dimensional computer

modeling work using the turbulence model based on large eddy simulation is presented. The effect of a tornado on a cubic building is considered for this study. The Navier-Stokes (NS) equations are approximated by the finite difference method and solved by an implicit procedure. The force coefficients are plotted in time to study the effect of Rankine combined vortex model. The tornado is made to translate at a 0- and 45-degree angle, and the grid resolution is refined. Some flow visualizations are also reported to enhance understanding of the flow behavior around the cube.

Sen, R.

"VORTEX-OSCILLATION MODEL OF AIRFOIL SIDE-EDGE NOISE"

AIAA Journal, Vol. 35, No. 3, March 1997, pp. 441-449

Oscillation of the edge vortex is proposed as a mechanism for sound production at the lateral edge of a loaded airfoil. Flow in a spanwise cross section near the edge is idealized by potential flow around a square corner, and the time-averaged edge vorticity is represented by a single line vortex perpendicular to the plane of the flow. Based on a stability requirement, we calculate vortex oscillation modes with frequencies dependent on circulation, edge thickness, and mean distance from the edge. Realistic numbers for these parameters give frequencies that are consistent with measured noise and surface pressure frequencies. Reasonable surface pressure amplitudes are also predicted when experimental estimates of vortex oscillation amplitude are used. Interaction with large flow structures is simulated by perturbing the base vortex with a smaller vortex. This produces pressure spectra with broad peaks, as observed in experiments. The mechanism for broadening is nonlinear dynamics with transition to chaos. Far-field pressure is governed by the speed at which the center of vorticity moves normal to the wall. This previously obtained result is explained by a simple image argument. In a single-vortex model of the edge vorticity, noise production may be reduced by moving the equilibrium position far from the wall; this suppresses the normal component of the vortex-oscillation eigenvector. In multiple-vortex models, noise production may be suppressed by promoting antisymmetric motion. This occurs when the edge-vorticity field is compact or is positioned far from the wall.

Send, W.

"DOWNSTREAM VORTICITY MEASUREMENTS FROM ULTRASONIC PULSES"

J. Aircraft, Vol. 25, No. 11, November 1988, pp. 993-994

The vorticity distribution behind a profile is obtained from the measurement of the running-time shift, which an ultrasonic pulse experiences in wind tunnel flow. The spatial gradient of the running-time shift is related to the vorticity vector. The method is limited by the assumptions of incompressible flow and a high Reynolds number.

Serakawi, A. R. and Ahmad, K. A.

"EXPERIMENTAL STUDY OF HALF-DELTA WING VORTEX GENERATOR FOR FLOW SEPARATION CONTROL"

Journal of Aircraft, Vol. 49, No. 1, January-February 2012, pp. 76-81.

This paper describes an experimental study of the effects of passive half-delta wing vortex generators on a backward-facing ramp flow. Four models of vortex generators with aspect ratios of 0.4, 0.8, and 1.6 were tested in an open-circuit wind tunnel. The vortex generators were placed upstream of the backward-facing ramp where their heights were 24 and 48 percent of the boundary-layer thickness. Flow visualization and velocity measurements were conducted using a particle image velocimetry system. The results showed that an array of vortex generators with an aspect ratio of 1.6 had the highest efficiency in reducing the flow separation region.

Sereno, J. L. and Pereira, J. C. F.

"UNCERTAINTY QUANTIFICATION OF TWO-DIMENSIONAL WAKE VORTICES NEAR THE GROUND"

Journal of Aircraft, Vol. 49, No. 4, July-August 2012, pp. 1175-1178.

The objective of this work is to study the stochastic two-dimensional interaction of a vortex pair with a wall, under crosswind, considering different uncertainty sources: 1) vortex Reynolds number (circulation), 2) position of the vortices relative to each other, and 3) crosswind velocity. The stochastic solutions were obtained recurring to the polynomial chaos expansion method of random processes applied to the 2-D unsteady Navier-Stokes equations. The method quantifies the extent, dependence, and propagation of uncertainty through the model system, and particularly a methodology for the calculation of the vortex-trajectory variability (i.e., the confidence interval) could be obtained, provided that the randomness of the inputs is not sufficiently high to destroy the ensemble mean solution coherence.

Serrano-Aguilera, J. J., Garcia-Ortiz, J. H., Gallardo-Claros, A., Parras, L. and del Pino, C.

"EXPERIMENTAL CHARACTERIZATION OF WINGTIP VORTICES IN THE NEAR FIELD USING SMOKE FLOW VISUALIZATIONS"

Experiments in Fluids, Vol. 57, 2016, pp. 137-1 to 137-11.

In order to predict the axial development of the wingtip vortices strength, an accurate theoretical model is required. Several experimental techniques have been used to that end, e.g. PIV or hot-wire anemometry, but they imply a significant cost and effort. For this reason, we have performed experiments using the smoke-wire technique to visualize smoke streaks in six planes perpendicular to the main stream flow direction. Using this visualization technique, we obtained quantitative information regarding the vortex velocity field by means of Batchelor's model for two chord-based Reynolds numbers, $Re = 33,300$ and $100,000$. Therefore, this theoretical vortex model has been introduced in the integration of ordinary differential equations which describe the temporal evolution of streak lines as function of two parameters: the swirl number, S , and the virtual axial origin, z_{sub-0} . We have applied two different procedures to minimize the distance between experimental and theoretical flow patterns: individual curve fitting at six different control planes in the streamwise direction and the global curve fitting which corresponds to all the control planes simultaneously. Both

sets of results have been compared with those provided by del Pino et al. (Phys Fluids 23(013):602, 2001b. doi:10.1063/1.3537791), finding good agreement. Finally, we have observed a weak influence of the Reynolds number on the values S and z_0 at low-to-moderate Re . The experimental technique is proposed as a low-cost alternative to characterize wingtip vortices based on flow visualization.

Serre, E. and Bontoux, P.

"VORTEX BREAKDOWN IN A THREE-DIMENSIONAL SWIRLING FLOW"

Journal of Fluid Mechanics, Vol. 459, 2002, pp. 347-370.

Time-dependent swirling flows inside an enclosed cylindrical rotor-stator cavity with aspect ratio $H/R = 4$, larger than the ones usually considered in the literature, are studied. Within a certain range of governing parameters, vortex breakdown phenomena can arise along the axis. Very recent papers exhibiting some three-dimensional effects have simulated new interest in this topic. The study is carried out by a numerical resolution of the three-dimensional Navier-Stokes equations, based on high-order spectral approximations to ensure very high accuracy of the solutions. The first transition to an oscillatory regime occurs through an axisymmetric bifurcation (a supercritical Hopf bifurcation) at $Re = 3500$. The oscillatory regime is caused by an axisymmetric mode of centrifugal instability of the vertical boundary layer and the vortex breakdown is axisymmetric, being composed of two stationary bubbles. For Reynolds numbers up to $Re = 3500$, different three-dimensional solutions are identified. At $Re = 4000$, the flow supports the $k = 5$ mode of centrifugal instability. By increasing the rotation speed to $Re = 4500$, the vortex breakdown evolves to an S-shaped type after a long computational time. The structure is asymmetric and gyrates around the axis inducing a new time-dependent regime. At $Re = 5500$, the structure of the vortex breakdown is more complex: the upper part of the structure takes a spiral form. The maximum rotation speed is reached at $Re = 10000$ and the flow behavior is now chaotic. The upper structure of the breakdown can be related to the spiral-type. Asymmetric flow separation on the container wall in the form of spiral arms of different angles is also prominent.

"SUPERSONIC SHOCK WAVE/VORTEX INTERACTION"

NASA-CR-192209, Sept. 1991, Penn State University, University Park, PA.

The shock/vortex interaction is a basic and important fluid mechanics problem. Vortices are susceptible to bursting or breakdown when they encounter regions of high adverse pressure gradient. In supersonic flows, such a phenomenon can occur when vortices shed from delta wings of vehicles flying at high angles of attack interact with shock waves generated by the vehicle. In addition, vortices ingested into engine inlets may interact with the inlet shock system and adversely affect engine performance. However, very little research has been conducted on the topic of shock/vortex interaction. In one study, NASA Ames/Penn State University Consortium Agreement NCA2-235, the possibility of generating, controlling, and measuring supersonic streamwise vortices was confirmed.

This study also began to elucidate the phenomenology of the shock/vortex interaction. This research has continued over the last two years. The goals of the program are: to determine the structure of supersonic, streamwise, turbulent vortices; to thoroughly explore the phenomenology of the shock/vortex interaction; to determine the limits for the onset of supersonic vortex breakdown; to characterize the unsteadiness of the shock/vortex interaction; and to make detailed measurements of the interaction flowfield. Research activities of the past year have focused on mean flow measurements of the vortices and flow visualization experiments designed both to explore shock/vortex interactions and to determine the conditions for the onset of vortex breakdown. The results of the study should be of value in assessing the effect of shock/vortex interactions on high-speed flight and propulsion. Their immediate use will likely be in code validation exercises to test NASA-Ames' computational ability to model such complex turbulent flows. Our primary goal, of course, is to contribute new and fundamental knowledge in the field of high-speed fluid dynamics.

Sevil, H. E.

"AIRDATA SENSOR BASED POSITION ESTIMATION AND FAULT DIAGNOSIS IN AERIAL REFUELING"

PhD Thesis, August 2013, University of Texas, Arlington, TX.

Aerial refueling is the process of transferring fuel from one aircraft (the tanker) to another (the receiver) during flight. In aerial refueling operations, the receiver aircraft is exposed to a nonuniform wind field induced by the tanker aircraft, and this nonuniform wind field leads to differences in readings of air data sensors placed at different locations on the receiver aircraft. There are advantages and disadvantages of this phenomenon. As an advantage, it is used as a mechanism to estimate relative position of the receiver aircraft inside the nonuniform wind field behind the tanker. A model of the nonuniform wind field is used to construct maps of the wind field as functions of relative position in terms of airspeed, side slip angle and angle of attack. Several algorithms are developed that use measurements from three air data sensors placed at different locations on the receiver aircraft and the inverse of the maps to estimate the relative position of the receiver with respect to the tanker. The disadvantage of the phenomenon is that the differences in the readings of air data sensors cause false fault detections in a redundant-sensor-based Fault Detection and Isolation (FDI) system developed based on the assumption of identical sensor readings from three air data sensors. Such an FDI algorithm successfully performs detection and isolation of sensor faults when the receiver aircraft flies solo or outside the wake of the tanker aircraft. However, the FDI algorithm yields false fault detection when the receiver aircraft enters the tanker's wake. This problem is resolved by modifying the FDI algorithm. For robustness, the expected values of the sensor measurements are incorporated in the FDI algorithm, instead of the assumption of identical measurements from the sensors. The expected values, which depend on the position of the receiver relative to the tanker, are obtained from the maps of the nonuniform wind field as functions of the relative position. The new robust FDI detects and isolates sensor faults, as well as it eliminates the false fault detection in the nonuniform wind field induced by the tanker aircraft.

Sevil, H. R. and Dogan, A.

"FAULT DIAGNOSIS IN AIR DATA SENSORS FOR RECEIVER AIRCRAFT IN AERIAL REFUELING"

Journal of Guidance, Control, and Dynamics, Vol. 38, No. 10, October 2015, pp. 1959-1975.

Multiple air-data sensors placed on different positions on an aircraft are usually expected to provide identical measurements. This is because aircraft are assumed to fly in no-wind or uniform wind conditions. There are cases, however, where an aircraft flies in nonuniform wind vector field with significant variations in magnitude and direction over the dimensions of the aircraft. For example, in an aerial refueling operation, the receiver aircraft needs to fly within the nonuniform wind field induced by the wake of the tanker aircraft. This paper shows that an air-data sensor fault detection and isolation algorithm, if developed with an underlying assumption of identical sensor measurements, yields very high false detection rate when the aircraft enters the wake of another aircraft. This paper also presents a novel modification in the redundant-sensor-based fault detection and isolation algorithm that eliminates this problem. The new method is based on a model of the wind field as a function of relative position with respect to the tanker aircraft. This model is used to compute the expected values of air-data sensor measurements given the position of the receiver aircraft relative to the tanker.

Sezer-Uzol, N.

"HIGH-ACCURACY WAKE AND VORTEX SIMULATIONS USING A HYBRID EULER/DISCRETE VORTEX METHOD"

MS Thesis, May 2001, Dept. Aerospace Engineering, Penn State University, University Park, PA.

A new approach has been developed which preserves vortices over long distances. This new hybrid Computational Fluid Dynamics / Discrete Vortex (CFD/DV) method couples a Lifting-Line/Free-Wake method with an unstructured grid, parallel 3-D finite volume CFD flow solver. The total solution field is separated into two parts: the potential flow field from the DV solution and the deviation from this DV flow field. The modified Euler equations for the hybrid CFD/DV method are then solved and the total solution field is obtained. The tip vortex and wake of a fixed rectangular wing is investigated as a test case. Comparison of the wing surface pressure distributions to the available experimental data showed good agreement. The results obtained with the hybrid method are compared to those without the hybrid method. Simulation of the experiments done by Davenport et al., which have measurements on the vortex structure up to 30 chord lengths downstream, showed encouraging results. It is expected to preserve the tip vortex shed from the wing tip over longer distances when the hybrid CFD/DV method is applied. The wing tip vortex is quickly dissipated due to numerical diffusion in solutions without the hybrid method.

Sforza, P. M.

"SHOCK-VORTEX INTERACTION RESEARCH"

RTO-EN-4, November 1998, Research and Technology Organization, Neuilly-Sur-Seine, France

Supersonic cruise aircraft generate shock waves and vortices because of the flight speed and the forces generated, respectively. Interactions between these two produce flow disturbances which affect aircraft performance, stability, and control. Research in the field is reviewed to provide an understanding of the state of the art. The important parameters in the interaction are the Mach number and the swirl to axial velocity ratio of the vortex. The phenomenon of vortex breakdown is described and a criterion for determining if a shock-vortex interaction is strong enough to provoke it is given. Models developed thus far for evaluating such interactions are presented. Experimental investigations of shock-vortex interactions are also discussed.

Sforza, P. M.

"VORTEX-PLUME INTERACTION RESEARCH"

RTO EN-4, May 1998 RTO AVT, Rhode-Saint-Genese, Belgium, May 1998

The problem of the wake of an aircraft cruising at supersonic speed in the stratosphere is presented. The two major components of the flow field are the trailing vortex wake and the jet exhaust plumes. Accurate prediction of the dispersion of engine emissions resulting from interaction between the two has important consequences for determination of wake signatures. Research in the field is reviewed to provide an understanding of the present state of the art. Synthesis of these different jet and vortex studies provides a unified global description of aircraft wakes in terms of a length scale bA/CL , based on the span, aspect ratio, and cruise lift coefficient. A model is developed in which the jet plumes, being immersed in the trailing vortex wake downwash, are assumed to deform into twin vortices typical of jets in a cross-flow. This permits the development of the wake flow field to be assessed with the relatively simple tools of vortex filament analysis. Wakes of both conventional high subsonic and supersonic aircraft may be accommodated by this approach, as would the wakes of wing-jet combination injectors for scramjet applications. Experimental studies that would aid in the development of more accurate prediction methods are also described.

Sforza, P. M.

"AIRCRAFT VORTICES: BENIGN OR BALEFUL?"

Space/Aeronautics, April 1970, pp. 42-48

Vortices in aerodynamics are discussed with application to aircraft. The use of vortex lattice calculation techniques are described as are the effect of leading-edge vortices on the lift of low aspect ratio wings. Fuselage and wing tip vortices are shown to have a strong effect on stability and control of the generating aircraft as well as other aircraft operating in its wake.

Sforza, P. M.

"CIRCULATION DISTRIBUTION IN LEADING EDGE VORTICES"

AIAA Paper No. 2005-5161, June 2005, Toronto, Canada.

Data from a variety of experiments on leading edge vortices over sharp-edged delta wings are used to formulate an expression for the circulation distribution. A logarithmic region is shown to provide a transition between an exponential distribution in the viscous core and the spiral vortex outer flow. Pohlhamus's circulation function for the attached flow lift is found to scale the observed circulation characteristics in the primary vortex over the delta wing.

Sforza, P. M.

"ENTRAINMENT IN LEADING-EDGE AND TRAILING VORTICES"

AIAA Paper No. 2007-4362, Miami, FL, June 2007

Leading edge vortices from delta wings and trailing vortices from wings in general may be characterized as orderly vortex flows aligned with a mainstream flow. The nature of the axial flow in the core of the vortex determines the nature of the entrainment produced by the vortex. Jet-like, wake-like, or constant axial velocity distributions in the core of the vortex result in greatly differing entrainment characteristics. The mass entrainment by the vortex and its relationship to the variation of the axial flow in the vortex according to the continuity equation is described. It is shown that conventional trailing vortices do not entrain mass but rather diffuse into the constant outer flow while leading edge vortices have substantial entrainment properties. Then further analysis of the vortex according to momentum conservation illustrates the dependence of the entrainment on the circulation in the leading-edge vortex. Finally, the mass entrainment is related to the aerodynamic characteristics of the generating delta wing.

Sforza, P. M.

"INTERACTION OF WING VORTICES AND PLUMES IN SUPERSONIC FLIGHT"

IUTAM Symposium on Dynamics of Slender Vortices, Aachen, Germany, August 31-September 3, 1997

A model of the wake of an aircraft cruising at high speed in the stratosphere is presented. The two major components of the flow field are the trailing vortex wake and the jet exhaust plumes. The prospect of large fleets of supersonic airliners makes it important to accurately predict the dispersion of engine emissions resulting from interaction between the two. Here, synthesis of several different jet and vortex studies provides a unified description of aircraft wakes in terms of a length scale bA/CL , based on the span, aspect ratio, and cruise lift coefficient. The basic premise of the model is that jet plumes, being immersed in the trailing vortex wake downwash, deform into twin vortices typical of jets in a cross-flow. This permits the development of the wake flow field to be assessed with the tools of vortex filament analysis. The wakes of both conventional high subsonic and supersonic aircraft are shown to be accommodated by this approach, as would the wakes of wing-jet combination injectors for scramjet applications. Experimental studies which would aid in the development of more accurate prediction methods are also described.

Sforza, P. M. and Smorto, M. J.

"STREAMWISE DEVELOPMENT OF THE FLOW OVER A DELTA WING"

AIAA Paper No. 1980-0200, January 1980, Pasadena, CA.

An experimental investigation of the low-speed flow over a highly swept delta wing with sharp leading edges is presented. Velocity measurements in the separated leading-edge vortex which dominates the three-dimensional flow field are shown for several different chordwise stations, and serve to illustrate the streamwise development of the vortex. This data is also used to determine the trajectory of the vortex over the delta and to calculate the circulation distribution in the flow, and these results are compared to those of previous studies.

Sforza, P. M. and Smorto, M. J.

"STREAMWISE DEVELOPMENT OF THE FLOW OVER A DELTA WING"

AIAA Journal, Vol. 19, No. 7, July 1981, pp. 833-834.

An experimental investigation of the low-speed flow over a highly swept delta wing with sharp leading edges and at high angle of attack is presented. Velocity measurements in the separated leading-edge vortex are shown for several different chordwise stations, and serve to illustrate the streamwise development of the vortex. From these measurements the total vortex circulation has been calculated and is shown to compare well to that obtained theoretically by Polhamus. It is found that the vortex flowfield does not exhibit axisymmetry nor does it scale linearly with the half-span; a contradiction of two widely used assumptions in previous theoretical analyses. In the region of the axis of rotation, the viscous character of the flow becomes important and the core is found to grow linearly with downstream distance, while the maximum velocity is found to decrease with downstream distance.

Sforza, P. M., Sheerin, P. and Smorto, M.

"THREE-DIMENSIONAL WAKES OF SIMULATED WIND TURBINES"

AIAA Journal, Vol. 19, No. 9, September 1981, pp. 1101-1107.

An experimental and theoretical investigation of the wake behind a porous disk which simulates the effect of a wind turbine is presented. Modeling of the wake in an environmental wind tunnel is described and experimental results for the three-dimensional model wake flowfield are presented. A three-dimensional turbulent flow analysis is developed to deal with prediction of the wake characteristics. The theoretical results are shown to display the experimentally observed features of the wake.

Sforza, P. M., Stasi, W. and Gotkin, L.

"AN EXPERIMENTAL FACILITY FOR WIND ENGINEERING RESEARCH"

AIAA Paper No. 1978-813, April 1978, San Diego, CA.

Experimental research in wind engineering must rely on testing in a controlled laboratory environment as well as field testing in the uncontrolled natural wind. A facility for such research, developed in the Aerodynamics Laboratories of the Polytechnic Institute of New York, is described. This facility includes both a field test station and a laboratory test station for atmospheric boundary layer research. The utilization of this complex is discussed in terms of an ongoing project on wind energy conversion to illustrate the various capabilities that have been developed. Application of this facility to other problems in wind engineering are also described.

Sforza, P. M., Stasi, W., Pazienza, J. and Smorto, M.

"FLOW MEASUREMENTS IN LEADING EDGE VORTICES"

AIAA Paper No. 77-11, Los Angeles, CA, January 1977.

An experimental study of the vortex flow field over slender delta planforms with sharp leading edges is presented. Complete velocity measurements in this three-dimensional flow field are obtained by means of a Conrad type probe used in conjunction with a five-degree-of-freedom traversing mechanism and flow visualization is achieved by an oil fog technique. Effects of angle of attack, camber, sweepback, etc, are described. A new application of such flows, that of wind energy conversion by means of the Vortex Augmentor Concept developed by the first author, is discussed.

Sforza, P. M., Stasi, W., Smorto, M. and Sheerin, P.

"WIND TURBINE GENERATOR WAKES"

AIAA Paper No. 1979-0113, January 1979, New Orleans, LA.

An experimental and theoretical investigation of the wake behind wind turbine generators is presented. The general features of such flows are reviewed and the applicability of past work on more conventional aerodynamic wakes is discussed. Modeling of the wind turbine and the atmospheric boundary layer in an environmental tunnel is described. Experimental results for such models are given. Theoretical modeling of the three-dimensional mixing process in the wake-boundary layer interaction region is performed and numerical solutions for such flows are discussed and compared to the experiments.

Shadden, S. C., Katija, K., Rosenfeld, M., Marsden, J. E. and Dabiri, J. O.

"TRANSPORT AND STIRRING INDUCED BY VORTEX FORMATION"

J. Fluid Mech., Vol. 593, 2007, pp. 315-331

The purpose of this study is to analyze the transport and stirring of fluid that occurs owing to the formation and growth of a laminar vortex ring. Experimental data was collected upstream and downstream of the exit plane of a piston-cylinder apparatus by particle-image velocimetry. This data was used to compute Lagrangian coherent structures to demonstrate how fluid is advected during the transient process of vortex ring formation. Similar computations were performed from computational fluid dynamics (CFD) data, which showed qualitative agreement with the experimental results, although the CFD data provides better resolution in the boundary layer of the cylinder. A parametric study is performed to demonstrate how varying the piston-stroke length-to-diameter ratio affects fluid entrainment during formation. Additionally, we study how regions of fluid are stirred together during vortex formation to help establish a quantitative understanding of the role of vortical flows in mixing. We show that identification of the flow geometry during vortex formation can aid in the determination of efficient stirring. We compare this framework with a traditional stirring metric and show that the framework presented in this paper is better suited for understanding stirring/mixing in transient flow problems. A movie is available with the online version of the paper.

"TURBULENT TRANSPORT IN THE CORE OF A TRAILING HALF-DELTA-WING VORTEX"

Journal of Fluid Mechanics, Vol. 387, 1999, pp. 151-175.

The development of a turbulent streamwise vortex core in the wake of a half delta wing has been examined using high-resolution DPIV. The objective of this work was to gain understanding of the transport processes at work a short distance downstream of the wing trailing edge as the wake vortex developed. Experiments were conducted in the Rutgers Free Surface Water Tunnel using an in-house DPIV system. A turbulent streamwise vortex was generated by a half delta wing, with 44 cm chord length and 60-degree sweep angle, mounted at 30 degrees angle of attack. Reynolds number based on chord length was 65,000. Laser sheets oriented perpendicular to the flow direction were positioned 1, 3.5, and 7 chord lengths downstream of the wing trailing edge. Instantaneous vortex centers were identified to track vortex meandering as well as for better quantification of turbulence levels in the vortex core. Mean and fluctuating turbulence terms in the mean streamwise vorticity transport equation along with turbulent kinetic energy dissipation and production were evaluated relative to an inertial reference frame as well as relative to a vortex-centered frame. The results of this analysis highlight the importance of this near-wake region to the downstream evolution of the trailing vortices. There is a high degree of dissipation as well as streamwise vorticity convection in the near wake which increases rapidly with increasing distance from the trailing edge.

"INDUCTIVE PROPERTIES OF BENT VORTEX CORDS AND THEIR APPLICATION TO CONSTRUCTING A MODEL OF WAKE VORTEX HELICOPTER ROTOR"

Civil Aviation High Technologies, No. 223, 2016, pp. 84-92.

This article provides information about the properties of BENT inductive vortices capable of under the influence of self-induction to move at a speed independent of circulating gamma, the size of the nucleus and the local curvature of the individual sections of vortex tube. For numerical calculations the method of accounting for the self-induction at the nodal point of the vortex tube segments is provided. Formulas and recommendations for the construction of models of the free-vortex wake in the rotor blade theory is provided. [In Russian.]

"A VISCOUS FLOW ANALYSIS FOR THE TIP VORTEX GENERATION PROCESS"

NASA CR-3184, October 1979, Scientific Research Associates, Inc., Glastonbury, CT.

A three-dimensional, forward-marching, viscous flow analysis is applied to the tip vortex generation problem. The equations include a streamwise momentum equation, a streamwise vorticity equation, a continuity equation, and a secondary flow stream function equation. The numerical method used combines a consistently split linearized scheme for parabolic equations with a scalar iterative ADI scheme for elliptic equations. The analysis is used to identify the source of the tip vortex generation process, as well as to obtain detailed flow results for a rectangular planform wing immersed in a high Reynolds number free stream at 6-degree incidence.

"DIRECT NUMERICAL SIMULATION OF FLOW SEPARATION AROUND A NACA 0012 AIRFOIL"

Computers and Fluids, Vol. 34, Issue 9, November 2005, pp. 1096-1114

Direct numerical simulation (DNS) for the flow separation and transition around a NACA 0012 airfoil with an attack angle of 4 degrees and Reynolds number of 100,000 based on free-stream velocity and chord length is presented. The details of the flow separation, detached shear layer, vortex shedding, breakdown to turbulence, and re-attachment of the boundary layer are captured in the simulation. Though no external disturbances are introduced, the self-excited vortex shedding and self-sustained

turbulent flow may be related to the backward effect of the disturbed flow on the separation region. The vortex shedding from the separated free shear layer is attributed to the Kelvin-Helmholtz instability.

Shankar, S. and Van Dommelen, L.

"A NEW DIFFUSION PROCEDURE FOR VORTEX METHODS"

Journal of Computational Physics, Vol. 127, 1996, pp. 88-109

A new method is proposed for simulating diffusion in vortex methods for two-dimensional incompressible flows. The method resolves length scales up to the spacing of the vortices. The grid-free nature of vortex methods is fully retained and the distribution of the vortices can be irregular. It is shown for the Stokes equations that in principle, the method can have any order of accuracy. It also conserves circulation, linear, and angular momentum. The method is based on exchanging a conserved quantity between arbitrary computational points. This suggests that extensions to more general flows may be possible. For the two-dimensional incompressible flows studied, circulation is exchanged between vortices to simulate diffusion. The amounts of circulation exchanged must satisfy a linear system of equations. Based on stability considerations, the exchanged amounts should further be positive. A procedure to find a solution to this problem is formulated using linear programming techniques. To test the method, the decay processes of a single point vortex and of a counterrotating pair of point vortices are computed. Current limitations of the method are discussed.

Shapiro, A. R.

"LASER PROPAGATION IN AIRCRAFT WAKES"

Proceedings SPIE, Vol. 2005, Optical Diagnostics in Fluid and Thermal Flow, December 1993, pp. 139-154.

The use of lasers aboard aircraft is affected by the perturbed airflow in its vicinity. Therefore, an ability to predict the structure of aircraft-induced turbulence would be useful in system and performance analysis. PSR performed temperature and velocity fluctuation measurements in the wakes of an NRA-3B and a B-1B at trail distances of 50 to 5500 m, at two Mach numbers (0.5 and 0.75) and at two altitudes (0.9 and 6 km). Preliminary analysis of the data suggested significant differences with the predictions of the computational fluid dynamics code (CFD) WAKE developed for this application by ARAP for U.S. Air Force. These differences impact laser propagation. The principal difference between the data and the CFD predictions is that the temperature fluctuations which determine C_{θ}^2 are not isotropic and exhibit spectra and correlation scales which differ greatly from those of velocity. This paper reports the development of a hypothesis concerning the source of this temperature structure in aircraft wakes. Modifications to CFD models are suggested.

Shapiro, A. R. and Churnside, J. H.

"HOT JET/WAKE TURBULENT STRUCTURE AND LASER PROPAGATION, PART 3: LASER PROPAGATION MEASUREMENTS AND MODELING"

21st JANNAF Exhaust Plume Technology Meeting, Vol. 1, Oct. 1994, pp. 79-95.

The use of lasers aboard aircraft is affected by the perturbed airflow in its vicinity. Therefore, an ability to predict the structure of aircraft-induced turbulence would be useful in system and performance analysis. We performed temperature and velocity fluctuation measurements in the wakes of an NRA-3B and a B-1B at trail distances of 50 to 5500 m, at two Mach numbers (0.5 and 0.75) and at two altitudes (0.9 and 6 km). Analysis of the data suggested significant differences with the predictions of the computational fluid dynamics code (CFD) WAKE developed for this application. The magnitude and scales of the temperature fluctuations suggest that first order laser propagation models would not apply. The principal difference between the data and the CFD predictions is that the temperature fluctuations which determine C_{θ}^2 are not isotropic and exhibit spectra and correlation scales which differ greatly from those of velocity. This paper reports wind tunnel measurements to determine the source of this temperature structure in aircraft wakes and laser propagation measurements in this regime. Modifications to CFD and to propagation models are suggested.

Shariff, K.

"MAKING AIRCRAFT VORTICES VISIBLE TO RADAR BY SPRAYING WATER INTO THE WAKE"

Journal of Atmospheric and Oceanic Technology, Vol. 33, December 2016, pp. 2615-2638.

Aircraft trailing vortices pose a danger to following aircraft during takeoff and landing. This necessitates spacing rules, based on aircraft type, to be enforced during approach in instrument flight regulation (IFR) conditions; this can limit airport capacity. To help choose aircraft spacing based on the actual location and strength of the wake, it is proposed that wake vortices can be detected using conventional ground-based precipitation and cloud radars. This is enabled by spraying a small quantity of water into the wake from near the wing. The vortex strength is revealed by the Doppler velocity of the droplets. In the present work, droplet size distributions produced by nozzles used for aerial spraying are considered. Droplet trajectory and evaporation in the flow field is numerically calculated for a heavy aircraft, followed by an evaluation of radar reflectivity at 6 nautical miles (n mi) behind the aircraft. Small droplets evaporate, while larger droplets fall out of the wake. In the humid conditions that typically prevail during IFR, enough droplets remain in the wake and give good signal-to-noise ratios (SNR). For conditions of average humidity, higher-frequency radars combined with spectral processing give good SNR.

Shariff, K. and Leonard, A.

"VORTEX RINGS"

Annual Review, Fluid Mechanics, Vol. 24, 1992, 235-279

Saffman (1981), in encapsulating the vortex ring problem, said that 'one particular motion exemplifies the whole range of problems of vortex motion and is also a commonly known phenomenon, namely, the vortex ring. Their formation is a problem of vortex sheet dynamics, the steady state is a problem of existence, their duration is a problem of stability, and if there are several we have a problem of vortex interactions.' We shall do our best to follow this paradigm in organizing this article but sometimes we are forced to make a division along viscous/inviscid lines. The next section focuses on the problem of formation by discussing how rings are generated naturally and, in the laboratory, their resulting structure, and finally, what factors determine whether the rings are laminar or turbulent. Section 3 describes three stages in the life of a laminar ring. Section 4 discusses inviscid dynamics and begins with a discussion of how core dynamics influences overall ring motion (Section 4.1). There are examples of laminar vortices in two dimensions, which attain a balance of nonlinear terms in the inner core; the suggestion that this may be also true of laminar rings is a thread that connects laminar rings to Section 4.2, which discusses the theory of inviscid steady-state rings. Largely however, this body of work stands apart. Unsteady inviscid effects such as mutual straining are discussed in Section 4.3. In describing how two rings interact along a common axis of symmetry, Section 5 is happily able to unite viscous with inviscid thinking, and experimental with numerical results. Three types of interactions are considered: 'leapfrogging' head-on collisions, and collisions with a no-slip wall. The subject of azimuthal instabilities is taken up in Section 6: The linear instability theory has been reasonably successful in accounting for experimental observation but later stages in the breakdown are not well understood. The last section discusses turbulent vortex rings and puffs.

Shariff, K. and Wray, A.

"ANALYSIS OF THE RADAR REFLECTIVITY OF AIRCRAFT VORTEX WAKES"

J. Fluid Mech., Vol. 463, 2002, pp. 121-161

Radar has been proposed as a way of tracking wake vortices to reduce aircraft spacing and tests have revealed radar echoes from aircraft wakes in clear air. The mechanism causing refractive index gradients in these tests is thought to be the same as that for homogeneous and isotropic atmospheric turbulence in the Kolmogorov inertial range, for which there is a scattering analysis due to Tatarski. However, the structure of aircraft wakes has a significant coherent part superimposed with turbulence, about whose structure very little is known. Two simple mechanisms causing refractive index gradients are considered: (A) radial pressure (and therefore density) gradient in a columnar vortex arising from the rotational flow; (B) adiabatic transport of atmospheric fluid within a descending oval surrounding a vortex pair. In the scattering analysis, Tatarski's weak scattering approximation is kept but the usual assumptions of a far field and a uniform incident wave are dropped. For analytical insight, an approximate analysis that invokes, in addition to weak scattering, the far field and wide cylindrical beam assumptions, is also developed and compared with the more general analysis. Reflectivities calculated for the oval (mechanism B) are within 2-13 dBm squared of the measurements (approx. -70 dBm squared) of MIT Lincoln Laboratory at Kwajalein atoll. However, the present predictions have a cut-off away from normal incidence which is not present in the measurements. This implies that the two-dimensional picture is not entirely complete. Estimates suggest that the thin layer of vorticity which is baroclinically generated at the boundary of the oval is turbulent and this may account for

reflectivity away from normal incidence. The reflectivity of a vortex (mechanism A) is comparable to that of the oval (mechanism B) but occurs at a frequency (about 50 MHz) that is lower than those considered in all the experiments to date. This result may be useful because: (i) existing atmospheric radars (known as ST radars) already operate at this frequency and so the present prediction could be verified; (ii) rain clutter is not a problem at this frequency; (iii) mechanism A is more robust because it is independent of atmospheric stratification.

Shariff, K. and Wray, A.

"ANALYSIS OF THE RADAR CROSS-SECTION (RCS) OF AIRCRAFT VORTICES"

American Physical Society, Division of Fluid Dynamics Meeting, November 21-23, 1999, New Orleans, LA

Radar has been proposed as one way to track wake vortices to reduce aircraft spacing. Radar echoes from aircraft wakes are usually interpreted qualitatively using Tatarski's theory of scattering by isotropic atmospheric turbulence. The present work predicts RCS by (1) Keeping the weak scattering approximation but dropping the assumptions of a far-field and a uniform incident wave, neither of which is generally valid for a coherent wake (2) Considering three simple mechanisms for the structure and magnitude of refractive index variations: (i) Radial density gradient in each vortex (ii) Adiabatic transport of atmospheric fluid in the oval surrounding the vortices (iii) 3D fluctuations in the vortex cores. For mechanism (ii) the predictions agree with available data. However, the predictions have a cut-off away from normal incidence which is not present in the measurements due possibly to 3D fluctuations in the oval. The reflectivity of mechanism (i) is comparable but cuts-off at frequencies lower than those considered in the experiment. Finally, we suggest that hot engine exhaust could increase RCS by 40 dB and reveal vortex circulation, provided its mixing is prevented in the laminar vortex.

Shariff, K., Leonard, A., Zabusky, N. J. and Ferziger, J. H.

"ACOUSTICS AND DYNAMICS OF COAXIAL INTERACTING VORTEX RINGS"

Fluid Dynamics Research, Vol. 3, 1988, pp. 337-343.

Using a contour dynamics method for inviscid axisymmetric flow we examine the effects of core deformation on the dynamics and acoustic signatures of coaxial interacting vortex rings. Both 'passage' and 'collision' (head-on) interactions are studied for initially identical vortices. Good correspondence with experiments is obtained. A simple model which retains only the elliptic degree of freedom in the core shape is used to explain some of the calculated features.

Sharman, R.

"NATURE OF AVIATION TURBULENCE"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 1, 2016, Springer International Publishing Switzerland, pp. 3-30.

In-flight encounters with turbulence are a well-known hazard to aviation that is responsible for numerous injuries each year, with occasional fatalities and structural damage. Not only are turbulence encounters a safety issue, they also result in millions of dollars in operational costs to airlines and may cause schedule delays and air traffic management problems. For these reasons, pilots, dispatchers, and air traffic controllers attempt to avoid turbulence wherever possible. Despite these motivations, the accuracy of detection and forecasting turbulence for aviation application is insufficient for acceptable levels of avoidance. This chapter reviews the fundamental problems associated with understanding the properties of aviation-scale turbulence and provides an overview of the advances that are being made in the areas of detection and forecasting. References are included to other chapters in this volume which provide more detail on particular subjects.

Sharman, R. and Lane, T., editors

"AVIATION TURBULENCE"

1st edition, Springer International Publishing Switzerland, 2016.

This book provides a compilation of recent work in aviation turbulence research. The motivation for such a compilation was based on two highly successful internationally attended aviation turbulence workshops in the United States in 2013 and 2014 and four aviation meteorology workshops in Seoul, South Korea. These workshops make it clear that there has not been enough communication between the research community and users who need turbulence information to make operational decisions about where to fly. This book aims to foster that communication, by summarizing recent progress and encouraging future research in this area. The book is structured into five main sections providing background material, reviews, and applications of detection strategies, forecast and nowcast methods and their verification, observational and modeling studies, and finally discussions of future opportunities and research needs. Each major section contains several chapters for a total of 25 chapters. The authors of each chapter were chosen because of their expertise in their area, and every chapter has been peer reviewed by at least two other experts.

"DESCRIPTION AND DERIVED CLIMATOLOGIES OF AUTOMATED IN SITU EDDY-DISSIPATION-RATE REPORTS OF ATMOSPHERIC TURBULENCE"

Journal of Applied Meteorology and Climatology, Vol. 53, 2014, pp. 1416-1432.

The statistical properties of turbulence at upper levels in the atmosphere [upper troposphere and lower stratosphere (UTLS)] are still not well known, partly because of the lack of adequate routine observations. This is despite the obvious benefit that such observations would have for alerting aircraft of potentially hazardous conditions, either in real time or for route planning. To address this deficiency, a research project sponsored by the Federal Aviation Administration has developed a software package

that automatically estimates and reports atmospheric turbulence intensity levels (as EDR defined as epsilon to the 1/3 power, where epsilon is the energy or eddy dissipation rate). The package has been tested and evaluated on commercial aircraft. The amount of turbulence data gathered from these in situ reports is unprecedented. As of January 2014, there are approximately 200 aircraft outfitted with this system, contributing to over 137 million archived records of EDR values through 2013, most of which were taken at cruise levels of commercial aircraft, that is, in the UTLS. In this paper, techniques used for estimating EDR are outlined and comparisons with pilot reports from the same or nearby aircraft are presented. These reports allow calibration of EDR in terms of traditionally reported intensity categories ('light', 'moderate,' or 'severe'). The results of some statistical analyses of EDR values are also presented. These analyses are restricted to the United States for now, but, as this program is expanded to international carriers, such data will begin to become available over other areas of the globe.

"RESEARCH NEEDS"

In *Aviation Turbulence*, edited by R. Sharman and T. Lane, Chapter 25, 2016, Springer International Publishing Switzerland, pp. 501-518.

The current state of our understanding of aviation-scale turbulence processes and overviews of current detection and forecasting methods were provided in previous chapters of this book. Future progress will require a multipronged multidisciplinary approach from the academic, engineering, and user communities underpinned by advances in our fundamental understanding of turbulence process. The chapter outlines the required research and development, as well as operational needs, required to better understand, observe, and predict turbulence regions.

Sharpe, P. and Agarwal, R. K.

"CONCEPTUAL AND NUMERICAL ANALYSIS OF ACTIVE WINGTIP VORTEX CANCELLATION IN PROPELLER-DRIVEN ELECTRIC AIRCRAFT"

AIAA Paper 2019-1091, January 2019, San Diego, CA.

As battery and electric motor technology continues to advance rapidly, propeller-driven electric aircraft are likely to become a significant part of the aviation market in the near future. One proposed design configuration for electric aircraft involves using large, wingtip-mounted propellers to actively cancel wingtip vortices, a method called active wingtip vortex cancellation (AWVC). By reclaiming part of the kinetic energy that would otherwise be lost to tip vortex formation, drag is decreased. In addition, the induced spanwise flow and upwash from the propeller causes the spanwise lift distribution to remain more uniform at the wingtips, increasing lift.

Shaw, J. and Cole R.

"POTENTIAL BENEFITS OF REDUCING WAKE-RELATED AIRCRAFT SPACING AT THE DALLAS/FORT WORTH INTERNATIONAL AIRPORT"

ATC-304, June 2002, MIT Lincoln Lab., Lexington, MA

Measurements and modeling of wake vortices reveal that the Federal Aviation Administration's (FAA) minimum separation requirements for departing aircraft are often overly conservative. If the separation times following heavy aircraft can be safely reduced, considerable savings will be realized. The Dallas/Fort Worth International Airport (DFW) experiences departure delays daily. Banks of departing aircraft often create a significant queue at the end of the runway, with aircraft waiting between 10-20 minutes to depart. Additional delays occur during weather recovery operations after the terminal airspace has been impacted by thunderstorms. This report produces projected delay and cost benefits of implementing reduced wake spacing for departing aircraft at DFW. The benefits are calculated by simulating aircraft departures during both clear weather and weather recovery operations, using current and possible reduced spacings. The difference in delay values using different separation standards is used to calculate a cost savings to the airlines. The benefits for a single day are extended to a yearly approximation based on the estimated number of days that the separation criteria could be safely reduced.

Shaw, S. T., Hill, J. L. and Villamarin, C. E. M.

"A PRIORI GRID ADAPTATION FOR HELICOPTER ROTOR WAKES USING UNSTRUCTURED AND STRUCTURED-UNSTRUCTURED HYBRID GRIDS"

AIAA Paper No. 2005-0463, Reno, NV, January 2005

A numerical method for the calculation of the flow around isolated helicopter rotors in hovering flight is described. The method is based on the solution of a finite volume formulation of the governing equations on arbitrary cells using a high-resolution Godunov scheme. This capability is exploited to perform calculations on structured-unstructured hybrid grids that have been adapted to the expected location of significant wake structures. The results suggest that if sufficient care is taken in the design of the grid then both the tip vortex and wake sheet can be resolved to significant wake ages. Results are presented that show that the wake of a single bladed rotor could be captured to 3 turns of the tip vortex and two turns of the wake sheet on grids containing less than 3 million cell volumes. It is shown that the use of local adaptation provides improved resolution at a fraction of the cost of calculations based upon structured grid systems. Furthermore, the use of locally structured grids that are aligned with the main flow features provides improved resolution for modest additional computational expense.

"THE VORTEX TRAJECTORIES INVOKED BY AN ARRESTING CYLINDER"

Fifth International Conference on CFD in the Process Industries, CSIRO, December 2006, Melbourne, Australia.

The vortex dynamics of a translating circular cylinder which is rapidly arrested is investigated. Simulated particle tracking is employed to identify the trajectory of both the wake vortex pair, and the secondary vortices which are induced as the wake convects over the cylinder. In a similar fashion to the flow past an arresting sphere, each wake vortex induces a counter-rotating vortex, which subsequently self-propel over a range of sometimes surprising trajectories, as the Reynolds number and cylinder translation distance are varied. The results of these simulations have an application in small-scale mixing technologies. At low Reynolds numbers and short translation distances, the wake vortices propel past the cylinder, continuing in the direction of the original cylinder motion. At higher Reynolds numbers, the vortices deviate outwards in circular arcs of increasing curvature, to the point where the vortex pairs collide behind the cylinder. At longer translation distances, Hopf instability destroys the relative symmetry about the wake centerline.

Shebalin, J. V.

"THE THERMAL-VORTEX EQUATIONS"

NASA-CR-178242, Feb. 1987, Old Dominion University, Norfolk, VA.

The Boussinesq approximation is extended to explicitly account for the transfer of fluid energy through viscous action into thermal energy. Ideal and dissipative integral invariants are discussed, in addition to the general equations for thermal-fluid motion.

Sheehan, W. E.

"EVALUATION OF WAKE VORTEX CHARACTERISTICS OF A WIDE-BODY, TRI-JET, COMMERCIAL AIRCRAFT"

Report LR 29620, September 1980, Lockheed California Co, Palmdale, CA.

Under contract to the National Aeronautics and Space Administration, Hugh L. Dryden Flight Research Center, an L-1011 TriStar was used to investigate wake vortex attenuation under various conditions of wing lift distribution, both steady state and oscillatory. This was accomplished by use of various combinations of wing spoiler and aileron operation. The TriStar in all cases was used as the generating aircraft for a probe aircraft as well as low altitude and in-flight photographic evaluation. Wake vortex visualization was obtained through use of smoke generators mounted on the TriStar. Specific wake vortex attenuation data analysis and conclusions are not within the scope of the accomplished contract and are therefore not presented.

Sheftel, D. J.

"OVERVIEW OF POTENTIAL ATC DEVELOPMENTS"

Proceedings 22nd Annual Meeting, Air Traffic Control Assoc., Las Vegas, NV, October 1977, pp. 252-257

The paper presents a broad overview of developments in air traffic control. Projects related to improved aircraft safety are noted including the beacon collision avoidance system, the minimum safe

altitude warning concept, and studies of wind shear. Improvements in controller productivity have been suggested in terms of the electronic tabular display subsystem, the discrete address beacon system, and the automation of flight service stations. Increases in capacity are discussed with reference to the wake vortex avoidance system, the microwave landing system, and airport surface traffic control. Energy conservation is considered and developments in fuel conservation are proposed including flow control. Future air traffic control procedures are identified such as automated en route traffic control, automated terminal service, advanced computer systems, and the incorporation of satellite technology.

Shekarriz, A., Fu, T. C., Katz, J. and Huang, T. T.

"NEAR-FIELD BEHAVIOR OF A TIP VORTEX"

AIAA Journal, Vol. 31, No. 1, January 1993, pp. 112-118

The near-field behavior of a tip vortex trailing behind a low aspect ratio wing, attached to an axisymmetric body, is investigated in this paper. This study was performed in a tow tank and involved the use of particle displacement velocimetry. Evolution of the tip vortex was studied by mapping its instantaneous lateral velocity at several consecutive axial locations. The axial velocity distribution was also measured. Experiments were repeated at various Reynolds numbers and incidence angles. Repeatability was also examined at the same conditions. The results indicate that roll-up is almost complete at the trailing edge and that less than 66% of the root circulation is entrained into the vortex. At chord $Re = 220,000$, the results are steady, and the spatially averaged tangential velocity agrees well with the existing models. At chord $Re < 100,000$ the entire flow structure, including the overall circulation, fluctuates from one experiment to the next. The tangential velocity profiles seem to be dominated by secondary vortices located primarily outside of the vortex core. Axial variations in the flow structure along the parallel middle body, during the same run, are limited to the location of these secondary vortices. The vortex is observed to expand in the afterbody region, without a change in its total strength. For all but one case (chord $Re = 220,000$ and $\alpha = 10$ deg), there is a substantial axial velocity deficit within the vortex core near the trailing edge of the wing. At chord $Re < 100,000$, the axial velocity deficit increases with incidence angle and decreasing chord Re .

"SIMULATION OF DOPPLER RANDOM ERROR IN WIND PROFILES IN ATMOSPHERIC BOUNDARY LAYER"

1957

15th Coherent Laser Radar Conference Proceedings, June 2009, Toulouse, France, pp. 141-144.

The general equations are proposed for the numerical simulation of Doppler random error in wind profiles in atmospheric boundary layer in the paper. The wind velocity retrievals are calculated by minimizing the least-squares fit cost function, which is the difference between the modeled and observed radial wind velocity. Numerical simulation is based on 'e-l' model of atmospheric turbulence and one-dimensional model of the homogeneous atmospheric boundary layer, which consider diurnal variations of meteorological parameters and the turbulent structure of the atmospheric boundary layer.

Shen, S., Ding, F., Han, J., Lin, Y.-L., Arya, S. P. and Proctor, F. H.

"NUMERICAL MODELING STUDIES OF WAKE VORTICES: REAL CASE SIMULATIONS"

AIAA Paper No. 1999-0755, Reno, NV, January 1999

A three-dimensional large-eddy simulation model, TASS, is used to simulate the behavior of aircraft wake vortices in a real atmosphere. The purpose for this study is to validate the use of TASS for simulating the decay and transport of wake vortices. Three simulations are performed and the results are compared with the observed data from the 1994-1995 Memphis field experiments. The selected cases have an atmospheric environment of weak turbulence and stable stratification. The model simulations are initialized with appropriate meteorological conditions and a post roll-up vortex system. The behavior of wake vortices as they descend within the atmospheric boundary layer and interact with the ground is discussed.

Sheng, C.

"ROLE OF TRANSITION MODELING IN ROTOR HOVER PREDICTIONS"

Journal of Aircraft, Vol. 55, No. 1, January-February 2018, pp. 23-37.

The Langtry-Menter transition model is used to predict the aerodynamic performance of three realistic helicopter and tiltrotor blades in hover: the XV-15 proprotor, the joint-service vertical takeoff/landing experimental rotor, and the S-76 conventional scaled rotor. The role of transition modeling in rotor hover predictions is investigated based on comparative studies using the full turbulence model and the transition model. The subsequent predicted transition phenomena are then validated with the experimental data. The focus of this study is to explore three major issues pertinent to rotor hover predictions: 1) the effect of transition modeling on the rotor aerodynamic prediction, 2) rotor prediction at high thrusts or collective angles, and 3) rotor flow characteristics and their influence on aerodynamic performance. Numerical computations indicate different impacts of the transition modeling on predicting the aerodynamic performance for conventional rotors and proprotors.

Sheng, C. and Zhang, F.

"THE EXPERIMENTAL INVESTIGATION ON THE FORMATION AND DECAY OF VORTEX UNDER INTERACTION OF A JET WITH A CROSSFLOW"

Acta Aerodynamica Sinica, Vol. 6, March 1988, pp. 104-109

Three different vortex systems exist in the flow field for the interaction of a jet with a crossflow: bound vortex, wake vortex, and shear vortex. In this paper, the mechanism of vortex formation is suggested, and interference among vortices is investigated based on observation and measurement by the fluorescent-filament method and seven-hole probes. Finally, the major factors which influence the development and decay of streamwise vortices are also analyzed and discussed.

Shephard, D. J., Kyte, A. P. and Segura, C. A.

"RADAR WAKE VORTEX MEASUREMENTS AT F AND I BAND, "

IEE Colloquium on Radar and Microwave Imaging, London, UK, November 199.

All aircraft generate vortices in their wakes, which are created by the wings as the aircraft produces lift. The wakes consist of two counter-rotating masses of air that are cylindrical in shape and are a potential hazard to a following aircraft. When encountering a vortex, a severe roll that may not be possible to control, can be induced, with the possible catastrophic results. The most hazardous situation is when a small aircraft is following a larger one on landing approach. Aviation regulations specify minimum separations between different types of aircraft when they are receiving an Air Traffic Control service, to ensure that a vortex does not present a hazard to following aircraft. There are two weather conditions that particularly concern ATC authorities. First, those where the vortices persist, and second those which lead to a rapid dispersion of the vortices which could enable the minimum separation between aircraft to be significantly reduced. The successful reduction in separations could improve runway capacity and contribute to the growth in air transport. As of yet there is no reliable all weather method in operation that can determine whether the vortices generated by an aircraft have dispersed, and so, there is an important requirement for a technique or techniques to be developed that can be reliably employed to detect the presence of vortices in the vicinity of airports. This paper describes work undertaken at the GEC-Marconi Research Center to investigate the feasibility of detecting aircraft wake vortices using a microwave radar.

"A REDUCED AIRCRAFT SEPARATION RISK ASSESSMENT MODEL"

AIAA Paper No. 1997-3735, New Orleans, LA, August 1997

A risk assessment methodology has been developed for three scenarios: runway occupancy, wake vortex encounter, and blunder. The operational focus of these scenarios is separation between aircraft on final approach and landing, when flight risks are greater than during any other phase of flight. The result for each scenario is a consolidated risk of incident and accident from all sources applicable to the scenario. In the lateral blunder scenario, there is a well-established target level of safety for the risk of

near misses. For the other scenarios as defined here there is yet no consensus on target measures of safety nor on the target levels of safety for the target measures. The approach used in the model quantifies the connection between several risk measures.

"AERODYNAMICS OF HELICOPTER FLIGHT NEAR THE GROUND"

33rd Annual Forum, American Helicopter Society, Washington, DC, May 1977

Nap-of-the-earth (NOE) tactical doctrine will require sustained flight close to the ground at low speeds. All helicopters in the battle zone frequently will be forced to seek cover and fly for long periods of time at very low heights which were formerly encountered only in the takeoff run and during the landing flare or avoided entirely. Such transitory operations within the low-slow flight regime until recently have placed a low priority on aerodynamic research on ground-proximity effects. There is now a compelling need, however, to understand the unsteady and complex flow environment resulting from the interactions of rotor downwash, the ground boundary, and the velocity of translation. Recent studies have begun to provide the required insights for this regime of flight, especially the role of the ground vortex. This anomaly is the dominant feature of the aerodynamic flow field from approximately 10 to 30 knots. The flow associated with the vortex and the loads it produces on the helicopter can be a key factor in many problem areas of flying qualities, component design, performance, and operations.

"STUDY OF THE AERODYNAMIC INTERACTIONS OF THE TAIL ROTOR AND FIN"

ARO-15710.2-EG, Boeing Vertol, Philadelphia, PA, June 1983

The results of a wind tunnel investigation of the aerodynamic interaction of the tail rotor and fin are presented. Model loads data were measured for a 1/4.85 scale model of the YUH-61A. Tests were conducted deep in ground effect at wind speeds ranging from 0 to 45 knots; representative of Nap-of-the-Earth. Flow visualization studies provided additional insight into the flow mechanisms at work such as the ground vortex. Distributional flow characteristics, particularly the location and structure of the main rotor tip vortex, were measured by a hot film probe. A variable fin incidence mechanism was incorporated in the model to measure the integrated flow at the empennage. Adverse fin force and tail rotor power variations are measured as functions of airspeed, wind azimuth, tail rotor thrust and main rotor thrust.

Sherratt, S. R.

"RE-CLASSIFICATION OF WAKE VORTEX WAKE GROUPS: A CONTROLLER'S VIEW"

Proceedings of the Aircraft Wake Vortices Conf., DOT/FAA/SD-92/1.1, DOT Volpe National Transportation Systems Center, Cambridge, June 1992, pp. 25-1 - 25-7

There are two main sections to this paper, a consideration of the human factors of implementing an enlarged classification system and a brief look at how enhanced vortex advisory systems and aircraft weight data may be integrated into ATC systems. One of the prime aims of the FAA vortex wake program is the development of revised classifications, followed by the issuing of recommendations for new standards. As an air traffic controller, however, a plea is made for usability. When the groups have been redefined, controllers are the people who must execute the separations with real airplanes. It seems likely that more than the present three ICAO groups will be defined to improve/maintain safety margins and minimize impacts on airport capacity. The past procedure for implementing the classification seems to have been a case of working out the inter and intra group separations first and worrying about how the controller should implement them later. It is suggested that in any future classification scheme the usability of the system could (and should) be tackled first. If controllers find the system difficult to remember or execute, then safety could be compromised, or any theoretical capacity gains negated.

"RAPID UPDATE CYCLE (RUC) WINDS ALOFT FORECAST ACCURACY AS A FUNCTION OF OUTPUT RESOLUTION"

8th AMS Conference on Aviation, Range, and Aerospace Meteorology, January 1999, Dallas, TX, pp. 391-395.

Resolution based requirements for gridded forecast weather data (i.e., 'highest available resolution') do not necessarily provide the highest available accuracy. Forecast data 50 percent coarser than the model's computational resolution can reduce random noise in the winds aloft forecast to the extent that any loss of information due to decreased resolution is offset and forecast accuracy is therefore not degraded. An 80 km, 50 mb (25 mb above 29,000 feet), and 2-hour RUC II resolution with hourly updates provides on average about a tenth of a knot better winds aloft forecast accuracy than 40 km, 25 mb, and 1 hour. Although analysis data below 29,000 feet can slightly increase winds aloft forecast accuracy when used for forecast interpolation between hours one and three, above 29,000 feet it does not perform any better than forecast hour one and performs slightly worse in jet stream winds.

"CHARACTERISATION OF A HORIZONTAL AXIS WIND TURBINE'S TIP AND ROOT VORTICES"

Experiments in Fluids, Vol. 54, 2011, pp. 1417-1 to 1417-19.

The vertical near wake of a model horizontal axis wind turbine has been investigated experimentally in a water channel. The objective of this work is to study vortex interaction and stability of the helical vortex filaments within a horizontal axis wind turbine wake. The experimental model is a geometrically scaled version of the Tjaereborg wind turbine, which existed in western Denmark in the late 1980s. Here, the turbine was tested in both the upwind and downwind configurations. Qualitative flow visualizations using hydrogen bubble, particle streak line and planer laser-induced fluorescence

techniques were combined with quantitative data measurements taken using planar particle image velocimetry. Vortices were identified using velocity gradient tensor invariants. Parameters that describe the helical vortex wake, such as the helicoidal pitch, and vortex circulation, were determined for three tip speed ratios. Particular attention is given here to the root vortex, which has been investigated minimally to date. Signatures of the coherent tip vortices are seen throughout the measurement domain; however, the signature of the root vortex is only evident much closer to the rotor plane, irrespective of the turbine configuration. It is postulated that the root vortex diffuses rapidly because of the turbine support geometries.

Sherwin, L. K., Baggaley, A. W. and Barenghi, C. F.

"ENERGY AND GEOMETRY OF A TANGLE OF VORTEX FILAMENTS"

14th European Turbulence Conference, September 2013, Lyon, France.

By performing a numerical experiment, we show that the energy of a superfluid turbulent vortex tangle is not proportional to its length, as usually assumed in the literature. We discuss the consequence in the interpretation of turbulence decay experiments.

Shevchenko, A. M., Kavun, I. N., Pavlov, A. A. and Zapryagay, V. I.

"REVIEW OF ITAM EXPERIMENTS ON SHOCK WAVE / VORTEX INTERACTION"

Proceedings 21st ICTAM, August 2004, Warsaw, Poland.

The interaction of concentrated streamwise wing-tip vortices and shock waves is investigated at Mach numbers of 3, 4 and 6. Research program included observations of the flowfield in the core of supersonic wing tip vortices, a study of bow shock / vortex interaction and a hypersonic interaction of the streamwise vortex with a Pitot-type inlet.

Shevchenko, A. M., Shmakov, A.S. and Zapryagaev, V. I.

"EXPERIMENTAL STUDY OF AN UNSTEADY FLOWFIELD IN WING WAKE/SHOCK INTERACTIONS"

West-East High Speed Flow Field Conference, November 2007, Moscow, Russia.

A review of a comprehensive experimental study of an unsteady flowfield at different types of interactions of a wing wake with a shock wave is presented. The complex of experimental techniques included a shadowgraph visualization, and pressure fluctuations measurements. Following main topics are discussed: the interaction of a vortex wake with the bow shock generated by the cylinder obstacle; the hypersonic interaction of the vortex wake with a Pitot-type inlet.

Shevchenko, A. M. and Shmakov, A. S.

"EXPERIMENTAL TECHNIQUES AND RESULTS OF INVESTIGATIONS OF AN UNSTEADY FLOWFIELD IN WING WAKES / BOW SHOCK WAVE INTERACTIONS"

International Conference on Methods of Aerophysical Research (ICMAR) 2006, July 2008, Novosibirsk, Russia.

One specific feature of interaction of a vortex wake with a shock wave is the unsteadiness of this process. It is manifested in experimentally observed fluctuations of gas-dynamic parameters of the flow and the changes in the flow structure and interaction region size with time. Recent numerical results showed that the unsteady process may possibly be periodic. A hypersonic interaction of a wing-tip vortex with a Pitot type inlet has been examined at Mach number of 6. It was obtained that the wing-tip vortex is the initiator of self-oscillatory process with salient fundamental. Therefore, two sets of experiments were performed to investigate the unsteady nature of a wing wake / bow shock wave interaction in a wide Mach number range of 3-6. The present paper describes the experimental techniques and results of these studies.

Shevehenko, A. M., Kharitonov, A. and Shmakov, A. S.

"HYPERSONIC VORTEX WAKE BEHIND THE WING AND ITS INTERACTION WITH SHOCK WAVES"

5th European Conference for Aerospace Sciences (EUCASS), July 2013, Munich, Germany

Shock/Vortex interaction is one of the fundamental problems of aerogasdynamics. The absence of numerical and experimental data for hypersonic velocities should be specially noted. Obtaining results for this range of velocities is extremely important for the development of promising flying vehicles (avoiding of catastrophic operation regimes of a hypersonic inlet and improvement of mixing in the combustor). Earlier studies found principal differences in unsteady regimes during the interaction at Mach numbers of 2-4 and at $M = 6$. Therefore, three sets of experiments were performed to study a free vortex wake behind a wing and an unsteady nature of a wing wake / shock wave interaction at Mach number of 6.

"SYMMETRIC AND ASYMMETRIC JETS IN A UNIFORM CROSSFLOW"

AIAA Paper No. 1991-0722, Reno, NV, January 1991

This paper presents both physical analysis and numerical study on a jet with different cross-section shape and orientation issuing normally to a uniform crossflow. The production and evolution of the vorticity in this type of flowfield are discussed analytically based on the vorticity and enstrophy transport equation, as well as the boundary vorticity flux formula. It is concluded that although there is no vorticity source within the fluid, a large amount of vorticity generated from solid surfaces will be brought into the fluid by diffusion due to the tangential pressure gradient near the jet-orifice, the wall curvature of the jet-pipe and its edge, and the curl of the wall shear stress vector. It is also described that how the jet wake-vortices are formed from the existing vorticity field by vortex-line bending and

stretching. The unsteady, three-dimensional, incompressible Navier-Stokes equations were solved numerically by using the SOLA algorithm in the present work and the numerical results fully supported the above physical analyses.

Shieh, C. M. and Morris, P. J.

"A NUMERICAL SOLUTION OF ACOUSTIC SCATTERING BY AN AIRCRAFT WAKE VORTEX"

ASA Paper No. 5aEA9, Penn State, University Park, PA, June 1997

Monostatic and bistatic acoustic scattering has been used in studies of the characteristics and motions of the atmosphere. This technique has been successfully implemented in the Monostatic Acoustic Vortex Sensing System (MAVSS) for the measurement of the characteristics of aircraft wake vortices during landing and take-off. In the present study, calculations are performed to simulate the MAVSS. The results of this study are giving information about the acoustic scattering by the vortex, as well as providing a controlled test bed for the instrument's operation. Since the Doppler shifts, characteristic of the vortex velocity, are dependent on the incoherent scattering of the acoustic waves by turbulence advected by the vortex, a statistical model is proposed that describes the turbulence imbedded in the vortex. The simulations are performed using high-order accuracy finite-difference algorithms that have been developed for computational aero-acoustic (CAA) and wave propagation problems.

"ROLL STALL FOR LOW-ASPECT-RATIO WING"

Journal of Aircraft, Vol. 50, No. 4, July-August 2013, pp. 1060-1069.

The longitudinal aerodynamics of micro aerial vehicles, although not fully understood, have been the subject of several studies in recent years; however, little work has been done to investigate the lateral loading. In this experiment, flat=plate wings with rectangular planforms of aspect ratios $AR = 0.75, 1, 1.5,$ and 3 and tapered planforms of taper ratio $= 0.75, 0.5,$ and 0.25 were placed in the wind tunnel at a Reynolds number of 75000 . Angle-of-attack sweeps were performed at sideslip angles of $0, -5, -10, -15, -20$ and -35 deg, and the side force, yaw moment, and roll moment were measured. Although the side force and yaw moment coefficients were typically negligible, the roll moment coefficient $C_{l_{roll}}$ was found to increase linearly with angle of attack before stalling in a manner reminiscent of a lift curve. This 'roll stall', which has not previously been observed for micro-aerial-vehicle-type wings, is attributed to the upstream tip vortex creating an additional lift component due to its impact on the spanwise variation of effective angle of attack in addition to the force generated by its own low-pressure core. As the downstream tip vortex is convected away from the wing, a net moment is created. Computations of the roll-stability derivative indicate that a micro aerial vehicle in equilibrium flight conditions may experience magnitudes of the roll-stability derivative at the upper limit of, or even above, the range of -0.10 to 0 considered to represent good handling qualities in aircraft.

"AIRCRAFT WAKES: A NEW LOOK AT A CLASSICAL PROBLEM"

Aircraft Wake Turbulence and Its Detection, 1st ed., Plenum Press, New York, 1971, pp. 1-8

The paper presents a frame of reference for the Wake Turbulence Symposium, first by elucidating some historical aspects of the aircraft wake problem, then by recounting the genesis of the AFOSR wake turbulence research program and finally by commenting on some of the challenging research opportunities contained within the wake problem.

Shirgaonkar, A. A. and Lele, S. K.

"SIMULATIONS OF AIRCRAFT WAKE-EXHAUST MIXING USING LES: CONTRAIL FORMATION IN THE NEAR FIELD"

AIAA Paper No. 2005-4909, Toronto, Canada, June 2005

Aircraft flying at cruise conditions produce contrails if conditions are favorable. Persistent contrails and contrail-induced cirrus clouds are thought to contribute to climate change on global scales. The dynamics of jet exhaust plays an important role in determining properties and persistence of contrails. The present study focuses on three-dimensional Large Eddy Simulations (LES) of aircraft wake and exhaust jets at cruise conditions in the extended near-field (1-2 minutes or 15-35 km behind the airplane). An attempt is made to reproduce realistic conditions by including jet turbulence, stratification, and jet buoyancy. We describe a mixed Eulerian-Lagrangian approach to computational modeling of contrail evolution. We present results from small domain calculations for the water vapor content and ice growth in the aircraft wake. Effects of stratification and atmospheric temperature are studied.

Shirgaonkar, A. A. and Lele, S. K.

"LARGE EDDY SIMULATION OF EARLY STAGE CONTRAILS: EFFECT OF ATMOSPHERIC PROPERTIES"

AIAA Paper No. 2006-1414, Reno, NV, January 2006

Prediction of growth and persistence of aircraft condensation trails involves uncertainties arising from numerous factors. It is sensitive to the atmospheric thermodynamic variables. Ambient relative humidity (RH) and temperature are themselves difficult to predict accurately, and they also affect the contrail growth. This study carries out Large Eddy Simulations (LES) of aircraft wake-contrail system to find the sensitivity of contrails to atmospheric conditions. A mixed Eulerian-Lagrangian approach is used to simulate the wake-jet flow and ice particle evolution. The microphysics model used is described. Unsaturated, saturated, and supersaturated atmospheric conditions are studied. Quantitative comparison for total ice amount and particle statistics is presented for various values of ambient temperature, RH, and jet exhaust temperature. The focus is on early stage (up to 15 sec) ice particle growth of a typical subsonic transport aircraft.

Shirgaonkar, A. A. and Lele, S. K.

"INTERACTION OF VORTEX WAKES AND BOUYANT JETS: A STUDY OF TWO-DIMENSIONAL DYNAMICS"

Physics of Fluids, Vol. 19, 2007, pp. 086601-1 - 086601-11.

The dynamics of aircraft wakes are affected by buoyancy forces resulting from stratification and exhaust jets. In this study the influence of jet buoyancy on the descent and spacing of a trailing vortex pair is characterized using a two-dimensional model problem. Results from laminar wake-jet simulations with and without stratification are presented. In addition to the vorticity dynamics of wakes in a stratified medium reported in the existing literature, the presence of the jets causes additional mechanisms which affect the wake behavior. The two opposite-signed components of baroclinic vorticity induced by the jets result in strengthening of the primary trailing vortices and produce an induced velocity on the primary vortices. Both components cause an overall reduction in the primary vortex spacing and a faster vortex wake descent. The entrainment of jet fluid into the vortex cores and detrainment into the atmosphere is illustrated. The influence of buoyancy on jet exhaust fluid transport and total circulation is investigated.

Shirgaonkar, A. A. and Lele, S. K.

"LARGE EDDY SIMULATION OF EARLY STAGE AIRCRAFT CONTRAILS"

Report TF-100, April 2007, Stanford University, Dept. of Mechanical Engineering, Stanford, CA.

Aircraft contrails at cruise present a unique problem in atmospheric sciences due to their location where other anthropogenic sources of particulate emissions are absent, and due to their potential impact on the Earth's radiative balance. We investigate the behavior of two-dimensional aircraft wakes containing exhaust jets. A mechanism is identified by which the jet-induced baroclinic vorticity influences the wake dynamics. The jets strengthen the primary vorticity and reduce the primary vortex pair spacing, causing accelerated wake descent. Three-dimensional LES of contrails are carried out for the first 20 second duration of contrail life, starting at 1 second behind the aircraft. The initial conditions at 1 s correspond to a typical large subsonic aircraft. Three different regimes of early contrail growth are found, which are controlled by jet humidity, jet turbulence and ice particle-induced perturbations, and ambient relative humidity with respect to ice, respectively.

"SURFACE PRESSURE MEASUREMENTS AT THE TIP OF A MODEL HELICOPTER ROTOR IN HOVER"

Journal of Aircraft, Vol. 15, No. 8, August 1978, pp. 460-467.

Detailed blade-tip surface pressure distribution data for a single-bladed model helicopter rotor in hover are presented. The pressure measurements were made along the chordwise direction at six spanwise stations outboard of the 94 percent radial location on the rotor blade. Data were taken at blade collective pitch angles of 0, 6.2 and 11.4 degrees at Reynolds numbers (based upon rotor tip speed and chord) of 544000 and 736000. The points of inception of the primary vortex inferred from the pressure data agree with those noted by other investigators using surface flow visualization techniques. The presence of both a primary and a secondary vortex near the rotor tip at a pitch angle of 11.4 degrees is observed. Normal and chordwise force coefficients obtained by integrating the pressure data are also presented.

Shizawa, T. and Endo, S.

"PRODUCTION AND DIFFUSION MECHANISM OF LONGITUDINAL VORTICES DOWNSTREAM OF ACTIVE VORTEX-GENERATORS PAIR"

AIAA Paper No. 2007-1422, Reno, NV, January 2007

This paper focuses on the time-dependent convection, production, and diffusion mechanism of longitudinal vortices downstream of a pair of active vortex generators controlling angle of pitch with common flow up configuration. Controlling turbulent shear flow skillfully is one of the most challenging topics. The most effective control device is to employ longitudinal vortices for the boundary layer manipulation and local heat transfer modification. Therefore, it is important to understand the transient interacting processes between turbulent boundary layer and longitudinal vortices. The interests of this paper are to make clear the time dependent characteristics of the interacting region and to make clear the dominant time scales. Time-dependent mechanism of longitudinal vortices is clarified by evaluating each term in streamwise vorticity transport equation by the use of newly developed rotating X-array hot-wire anemometer which can measure full components of turbulent Reynolds stresses.

Shkarayev, S., Su, E. and Zhao, L.

"AERODYNAMICS OF WING WITH OSCILLATING WINGTIP FLAPPER"

AIAA Paper 2016-3119, June 2016, Washington, DC.

1967

In the present study, a membrane oscillating flapper was pivotally attached to the wingtip of a conventional rigid wing. Stroke-average aerodynamic forces were measured for the range of the flapping frequency, showing significant increase in the lift coefficient and lift-to-drag ratio for the wing with a flapper. Wake structures were visualized using smoke-wire techniques and 2D phase-locked PIV. Major vortex patterns were deduced from the observations: primary and secondary undulating vortices and a vortex ring. The primary vortex oscillates in both vertical and horizontal planes. At the beginning of the downstroke, the secondary vortex sheds from the flapper then merges with the primary one at the beginning of the upstroke. The vortex ring sheds from the flapper during the second half of the upstroke and on pronation. The circulation of undulating vortices and of the ring decreases significantly with increasing distance from the wing downstream, while the decrease of the vortex core size is minimal.

Shmakov, A. S. and Shevchenko, A. M.

"AN EXPERIMENTAL STUDY OF THE VORTEX WAKE AT MACH NUMBER OF 3"

Proceedings of the XXV Conference on High-Energy Processes in Condensed Matter (HEPPCM 2017), AIP Conference Proceedings, Vol. 1893, 2017, pp. 030089-1 to 030089-5.

The results of experimental study of the flow in the wing wake at Mach number of 3 are presented. These experiments extend the data obtained in the same experimental setup at Mach numbers 2.5 and 4. Experiments were carried out in supersonic wind tunnel T-325 of ITAM SB RAS. Rectangular half-wing with sharp edges with a chord length of 30 mm and semispan of 95 mm was used to generate vortex wake. Experimental data were obtained in two cross sections located 1.5 and 6 chord length downstream of the trailing edge at wing angle of attack of 10 degrees. Constant temperature hot-wire anemometer was used to measure disturbances in supersonic flow. Hot-wire anemometer was made of a tungsten wire with a diameter of 10 microns and length of 1.5 mm. Schlieren flow visualization were performed. As a result, the position and size of the vortex core in the wake of a rectangular wing were determined. For the first time mass flow distribution and its pulsations in the supersonic longitudinal vortex was measured at Mach number of 3.

Shmakov, A. S., Shevchenko, A. M. and Kharitonov, A. M.

"VISUALIZATION AND SIMULTANEOUS PULSATION CHARACTERISTIC MEASUREMENT IN PROBLEMS OF VORTEX WAKE/SHOCK INTERACTION"

VIIth International Conference on the Methods of Aerophysical Research (ICMAR 2014), July 2014, Novosibirsk, Russia.

The paper presents methods and examples of data processing visualization and pressure fluctuations in the experimental study of the fast unsteady interaction of vortex wake behind the wing with the bow shock wave in front of a cylinder with a flat end.

Shmakov, A. S., Shevchenko, A. M., Yatskikh, A. A. and Yermolaev, Yu. G.

"MASS FLOW AND ITS PULSATION MEASUREMENTS IN SUPERSONIC WING WAKE"

International Conference on the Methods of Aerophysical Research (ICMAR 2016), AIP Conference Proceedings, Vol. 1770, 2016, pp. 030019-1 to 030019-6.

The results of experimental study of the flow in the wing wake are presented. Experiments were carried out in supersonic wind tunnel T-325 of ITAM SB RAS. Rectangle half-wing with sharp edges with a chord length of 30 mm and semispan 95 mm was used to generate vortex wake. Experimental data were obtained in the cross section located 6 chord length downstream of the trailing edge at Mach numbers of 2.5 and 4 and at wing angles of attack of 4 and 10 degrees. Constant temperature hot-wire anemometer was used to measure disturbances in supersonic flow. Hot-wire was made of a tungsten wire with a diameter of 10 microns and length of 1.5 mm. Schlieren flow visualization was performed. As a result, the position and size of the vortex core in the wake of a rectangular wing were determined. For the first time experimental data on the mass flow distribution and its pulsations in the supersonic longitudinal vortex were obtained.

"APPARATUS AND METHOD FOR THE CONTROL OF TRAILING WAKE FLOWS"

US Patent 7,100,875 B2, September 2006.

A system and method for dissipating vortices that form at the wingtips on aircraft and from other airfoils. A jet air stream is discharged in a location at or proximate to the outer end portion of the airfoil into the vortex flow, and the jet air stream is moved cyclically back and forth. The cyclic movement can be at lower or higher frequencies to alleviate at least in part intensity of the vortex or accelerate instability of the vortex which leads to vortex dissipation.

Shmilovich, A., Yadlin, Y., Clark, R. and Leopold, D.

"APPARATUS AND METHOD FOR THE CONTROL OF TRAILING WAKE FLOWS"

US Patent 7,597,289 B2, October 2009.

A system and method for dissipating vortices that form at the wingtips on aircraft and from other airfoils. A jet air stream is discharged in a location at or proximate to the outer end portion of the airfoil into the vortex flow, and the jet air stream is moved cyclically back and forth. Shmilovich, A., Yadlin, Y., Clark, R. and Leopold, D.

"SYSTEMS AND METHODS FOR DESTABILIZING AN AIRFOIL VORTEX"

US Patent 7,661,629 B2, February 2010.

Apparatuses and methods for the controlled trailing wake flows. An apparatus in accordance with one embodiment is directed to an aircraft system that includes an airfoil having first and second oppositely facing flow surfaces and a tip. The system can further include a vortex dissipation device including a fluid flow nozzle, a valve device, and a controller. The fluid flow nozzle can be coupled to a source of pressurized fluid and can include an orifice positioned to direct a flow of fluid outwardly from the tip. The valve device can be coupled in fluid communication with the fluid flow nozzle to selectively control the flow passing through the orifice. The controller can be coupled to the valve device to direct the operation of the valve device. Accordingly, the vortex dissipation device can be activated to accelerate the rate at which vortices (e.g., wing tip vortices) dissipate after they are generated.

Short, B. J. and Jacobsen, R. A.

"EVALUATION OF A WAKE VORTEX UPSET MODEL BASED ON SIMULTANEOUS MEASUREMENTS OF WAKE VELOCITIES AND PROBE-AIRCRAFT ACCELERATIONS"

NASA-TM-78561, March 1979, NASA Ames Research Center, Moffett Field, CA

Simultaneous measurements were made of the upset responses experienced and the wake velocities encountered by an instrumented Learjet probe aircraft behind a Boeing 747 vortex-generating aircraft. The vortex-induced angular accelerations experienced could be predicted within 30% by a mathematical upset response model when the characteristics of the wake were well represented by the vortex model. The vortex model used in the present study adequately represented the wake flow field when the vortices dissipated symmetrically and only one vortex pair existed in the wake.

"APPLYING QUALITATIVE HAZARD ANALYSIS TO SUPPORT QUANTITATIVE SAFETY ANALYSIS FOR PROPOSED REDUCED WAKE SEPARATION CONOPS"

6th USA/Europe ATM R&D Seminar, April 2005, Paper 82, Baltimore, MD

This paper describes a scenario-driven hazard analysis process to identify, eliminate, and control safety-related risks. Within this process, we develop selective criteria to determine the applicability of applying engineering modeling to hypothesized hazard scenarios. This provides a basis for evaluating and prioritizing the scenarios as candidates for further quantitative analysis. We have applied this methodology to proposed concepts of operations for reduced wake separation for closely spaced parallel runways. For arrivals, the process identified 43 core hazard scenarios. Of these, we classified 12 as appropriate for further quantitative modeling, 24 that should be mitigated through controls, recommendations, and / or procedures (that is, scenarios not appropriate for quantitative modeling), and 7 that have the lowest priority for further analysis.

Shortle, J. F.

"A COMPARISON OF WAKE-VORTEX MODELS FOR USE IN PROBABILISTIC AVIATION SAFETY ANALYSIS"

Proceedings of the 25th International System Safety Conf., System Safety Society, 2007, Baltimore, MD, pp. 581-589.

The goal of this paper is to address part of a larger safety issue in aviation. What is the probability that a landing aircraft flies through a wake vortex generated by the aircraft in front of it and subsequently crashes? An important element needed to address this overall research question is a model to predict the evolution of wake vortices in time. Several such models have been developed and published in the literature. However, accurate prediction of wakes is inherently difficult. The objective of this paper is to assess the performance of different wake models when imbedded within a larger probabilistic safety analysis. This paper does not attempt to assess the accuracy of wake models by comparison to actual data. The purpose here is to compare the models with each other, and evaluate differences in performance when used within a safety assessment.

Shortle, J. F. and Jeddi, B. G.

"PROBABILISTIC ANALYSIS OF WAKE VORTEX HAZARDS FOR LANDING AIRCRAFT USING MULTILATERATION DATA"

TRB Annual Meeting, Washington, DC, 2007

Wake vortices are a safety hazard to landing aircraft. A landing aircraft that encounters a wake may roll, resulting in a fatal crash if the roll is severe enough and/or if the aircraft is low enough to the ground. Therefore, aircraft are separated by a sufficient distance to ensure that wakes have time to decay in strength. However, because of the inherent variability in wake behavior and aircraft separation and position, there is still a possibility for a wake encounter. The objective of this paper is to estimate the probability of such encounters. This paper presents a hybrid simulation methodology. The approach is hybrid in the sense that part of the simulation is conducted using a direct data feed of flight-track data, while the other part is obtained by simulation of wake-evolution models. We demonstrate the approach on a one-week sample of flight tracks to predict the frequency of potential wake alerts. In this paper a wake alert is defined to be an event where the trailing aircraft is in a region of space where the wake is likely to be. We show how the results depend on atmospheric conditions and other model parameters.

Shortle, J. F., Zhang, Y. and Wang, J.

"STATISTICAL CHARACTERISTICS OF AIRCRAFT ARRIVAL TRACKS"

Journal of the Transportation Research Board, No. 2177, 2010, pp. 98-104.

The statistical characteristics of flight tracks is a critical component of safety analysis models. This paper presents an analysis of multilateration data that uses an extension of an algorithm. Key results are as follows: the separation distribution does not appear to change much at different points along the approach path. The left tail of separation (corresponding to the smallest separation values) decays

faster than a normal distribution. This is positive from a safety perspective. If this behavior is extrapolated beyond the observed data, one can conjecture that smaller separations have probabilities that rapidly decay to effectively zero. Lateral positions near the threshold do not appear to be heavy tailed, either. Finally, estimates of the final approach separation variability are consistent with previously published results.

Shrager, J. J.

"A SUMMARY OF HELICOPTER VORTICITY AND WAKE TURBULENCE PUBLICATIONS WITH AN ANNOTATED BIBLIOGRAPHY"

FAA-RD-74-48, May 1974, Federal Aviation Administration, Atlantic City, NJ

A review of all literature published since 1964 relating to helicopter vortex systems and wake turbulence was made. The results of this review are evaluated and summarized and conclusions are drawn relative to that review. The documents are grouped in general categories, and this is further supplemented by an annotated bibliography and author's index. Also incorporated in the review is a comparative analysis of rotary-wing versus fixed-wing circulation intensity time history.

Shrestha, B. and Joseph, E.

"RETRIEVAL OF PM SUB 2.5 PROFILE USING THE DOPPLER LIDAR ACROSS NEW YORK STATE MESONET"

19th Coherent Laser Radar Conference (CLRC), Paper P22, June 2018, Okinawa, Japan.

The University of Albany has developed a Mesonet, a network of 17 enhanced sites across the NY state, comprised of Doppler Lidar, Microwave Radiometer and Sun Photometer. The goal of the network is to enhance information content by combining all sensors for Numerical Weather Prediction and air quality forecasting. The vertical profile of PM sub 2.5 is very important for the study of air quality and its forecasting. The commonly used method only estimates surface PM sub-2.5, which is based on its relationship with Aerosol Optical Depth (AOD) from satellite and Sun Photometer. In this study, the relationship of aerosol extinction coefficient retrieved from the Doppler Lidar inversion, with surface PM sub 2.5 is presented. Then, the PM sub 2.5 profile is retrieved using the extinction coefficient profile. Three cases of high, low and medium PM sub 2.5 are presented and compared with surface PM sub 2.5 measurements. The experiment results show that Doppler Lidar can be used to continuously monitor PM sub 2.5 profile and hence, the retrieval technique when applied throughout the network is a good sign for real time 3D monitoring of PM sub-2.5.

"VORTEX BREAKDOWN AS A CATASTROPHE"

Proceedings IUTAM Symposium on Dynamics of Slender Vortices, September 1997, Aachen, Germany, pp. 297-306.

By studying swirling viscous jets, we develop a new explanation of vortex breakdown, show how solution non-uniqueness appears through cusp and fold catastrophes as the Reynolds number Re increases, and obtain analytical solutions for Re approaching infinity. Although inviscid theories also involve fold catastrophe, they have a strong limitation: the dependence of the head H and circulation G on stream function S is undetermined inside a recirculatory zone. Analytical continuation and stagnation zone models used to resolve this indeterminacy appear inadequate for swirling jets: $H(S)$ and $G(S)$, which we obtain here by the inviscid limit, differ from those based on the inviscid theories. We therefore suggest a new model consistent with the limiting transition. Also, we analyze turbulent vortex breakdown with a conical wake which has been recently observed at large Re .

Shtern, V. and Hussain, F.

"COLLAPSE, SYMMETRY BREAKING, AND HYSTERESIS IN SWIRLING FLOWS"

Annual Review of Fluid Mechanics, Vol. 31, 1999, pp. 537-56.

The paper reviews striking features of swirling flows, collapse, swirl generation, vortex breakdown, hysteresis, and axisymmetry breaking, and the mechanisms involved with the help of conical similarity solutions of the Navier-Stokes equations. The strong accumulation of axial and angular momenta, observed in tornadoes and flows over delta wings, corresponds to collapse, i.e., the singularity development in these solutions. Bifurcation of swirl explains the threshold character of swirl development in capillary and electro vortex flows. Analytical solutions for fold catastrophes and hysteresis reveal why there are so few stable states and why the jump transitions between the states occur, features typical of tornadoes, of flows over delta wings, and in vortex devices. Finally, the divergent instability explains such effects as the splitting of a tornado and the development of spiral branches in tree and near-wall swirling flows.

"VORTEX SINKS WITH AXIAL FLOW: SOLUTION AND APPLICATIONS"

Physics of Fluids, Vol. 9, No. 10, October 1997, pp. 2941-2959.

In this paper we develop a new class of analytical solutions of the Navier-Stokes equations and suggest ways to predict and control complex swirling flows. We consider vortex sinks on curved axisymmetric surfaces with an axial flow and obtain a five-parameter solution family that describes a large variety of flow patterns and models fluid motion in a cylindrical can, whirlpools, tornadoes, and cosmic swirling jets. The singularity of these solutions on the flow axis is removed by matching them with swirling jets. The resulting composite solutions describe flows, consisting of up to seven separation regions (recirculatory 'bubbles' and vortex rings), and model flows in the Ranque-Hilsch tube, in the meniscus of electrosprays, in vortex breakdown, and in an industrial vortex burner. The analytical solutions allow a clear understanding of how different control parameters affect the flow and guide selection of optimal parameter values for desired flow features. The approach permits extension to swirling flows with heat transfer and chemical reaction, and have the potential of being significantly

useful for further detailed investigation by direct or large-eddy numerical simulations as well as laboratory experimentation.

Shugaev, F. V., Cherkasov, D. Y. and Solenaya, O. A.

"ACOUSTIC RADIATION BY 3D VORTEX RINGS IN AIR"

Aerospace, Vol. 2, November 2015, pp. 627-636.

Acoustic radiation emitted by three-dimensional (3D) vortex rings in air has been investigated based on the unsteady Navier-Stokes equations. Power series expansions of the unknown functions with respect to the initial vorticity which is supposed to be small are used. In such a manner the system of the Navier-Stokes equations is reduced to a parabolic system with constant coefficients at high derivatives. The initial value problem is as follows. The vorticity is defined inside a toroid at $t = 0$. Other gas parameters are assumed to be constant throughout the whole space at $t = 0$. The solution is expressed by multiple integrals which are evaluated with the aid of the Korobov grids. Density oscillations are analyzed. The results show that the frequency band depends on the initial size of the vortex ring and its helicity. The presented data may be applied to the study of a flow in a wake region behind an aerodynamic body.

"TWO NUMERICAL STUDIES OF TRAILING VORTICES"

AIAA Paper No. 1998-0595, Reno, NV, January 1998

Two types of trailing-vortex flows are calculated based on the Reynolds Averaged Navier-Stokes equations coupled with three turbulence models: the one-equation Spalart-Allmaras model, the SA model with a rotation/curvature correction, and the two-equation k- ω model of Menter. The first flow type contains one or more vortex pairs in ground effect with side wind. The second type is the trailing-vortex system behind a generic civil aircraft model at high lift, for which we have experimental data of de Bruin et al. The major conclusion of the study performed is that the rotation/curvature correction proposed for the SA model actually provides much better predictions of both flows, by drastically reducing the diffusion of the vorticity.

Shustov, A. V.

"MODELING OF AEROSOL PARTICLES DISTRIBUTION IN AIRCRAFT WAKE"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 324-328

The work adduces results obtained from development of space-time relationships for distribution of the aircraft wake aerosols. The relationships are further employed to model signals supplied to the mobile laser system. The model is based on a partial differential equation, which is being solved by the

1974

characteristic method. A numerical test calculation of aerosol particles concentration time-dependence, where the particle size is specified, serves to illustrate effectiveness of the proposed model (the MATLAB program has been employed for the calculations).

Silverman, P.

"VORTEX CASES - AT A TURBULENT CROSSROADS"

J. Air Law and Commerce, Vol. 39, Summer 1973, pp. 325-342

Discussion of some of the legal aspects of the problem of wake turbulence, a phenomenon to which a substantial number of air crashes has been attributed in recent years. The duty of air traffic controllers to warn of possible wake turbulence and the nature of this warning are examined. Several court cases are reviewed to show how the courts look at wake turbulence, and some controversial cases are analyzed. During 1968-1970, more than \$3,000,000 have been paid by the United States Government in indemnities where air traffic controllers were judged to have been negligent in helping prevent air crashes that had been caused by wake turbulence. It is felt that wake turbulence accidents cannot be expected to cease to happen, but the trend against the Government may ease sufficiently to permit a greater sharing of responsibility by pilots, the flying schools, and air taxi operators that employ them.

Silverstein, A. and Katzoff, S.

"DESIGN CHARTS FOR PREDICTING DOWNWASH ANGLES AND WAKE CHARACTERISTICS BEHIND PLAIN AND FLAPPED WINGS"

NACA TR-648, January 1939, NACA Langley Memorial Aeronautical Lab., Langley Field, VA

Equations and design charts are given for predicting the downwash angles and the wake characteristics for power-off conditions behind plain and flapped wings of the types used in modern design practice. The downwash charts cover the cases of elliptical wings and wings of taper ratios 1, 2, 3, and 5, with aspect ratios of 6, 9, and 12, having flaps covering 0, 40, 70, and 100 percent of the span. Curves of the span load distributions for all these cases are included. The wake width and the distribution of dynamic pressure across the wake are given in terms of the profile-drag coefficient and the distance behind the wing. A method of estimating the wake position is also given.

Silverstein, A., Katzoff, S. and Bullivant, W. K.

"DOWNWASH AND WAKE BEHIND PLAIN AND FLAPPED AIRFOILS"

NACA TR-651, January 1939, NACA Langley Aero. Lab., Langley Field, VA

Extensive experimental measurements have been made of the downwash angles and the wake characteristics behind airfoils with and without flaps and the data have been analyzed and correlated with the theory. A detailed study was made of the errors involved in applying lifting-line theory, such as the effects of a finite wing chord, the rolling-up of the trailing vortex sheet, and the wake. The

1975

downwash angles, as computed from the theoretical span load distribution by means of the Biot-Savart equation, were found to be in satisfactory agreement with the experimental results. The rolling-up of the trailing vortex sheet may be neglected, but the vertical displacement of the vortex sheet requires consideration. Using a theoretical treatment indicated by Prandtl, it has been possible to generalize the available experimental results so the predictions can be made of the important wake parameters in terms of the distance behind the airfoil trailing edge and the profile-drag coefficient. The method of application of the theory to design and the satisfactory agreement between predicted and experimental results when applied to an airplane are demonstrated.

Simand, C., Chilla, F. and Pinton, J.-F.

"INHOMOGENEOUS TURBULENCE IN THE VICINITY OF A LARGE-SCALE COHERENT VORTEX"

Europhysics Letters, Vol. 49, No. 3, 2000, pp. 336-342.

We study the statistics of turbulent velocity fluctuations in the neighborhood of a strong large-scale vortex at large Reynolds number. At integral scale, the vortex dynamics can be either stable or unstable. We observe that at each distance from the vortex core, the velocity spectrum has a power law 'inertial range' of scales and that intermittency is also present. The texture of turbulence is also influenced by the large-scale dynamics of the vortex: as measurements are made closer to the core the spectrum scaling exponents, the energy transfer rate (estimated via the third-order structure function) and the intermittency characteristics follow different evolutions in each regime.

Simand, C., Chilla, F. and Pinton, J.-F.

"STRUCTURE, DYNAMICS AND TURBULENCE FEATURES OF A CONFINED VORTEX"

Lecture Notes in Physics, Vol. 555, 2000, pp. 291-29.

We study inhomogeneous turbulence in the presence of a strong large-scale vortex. To understand its influence on the observed properties of the turbulence, we determine the large-scale structure and dynamics of the flow, using LDV and visualizations of the motion of solid particles. We then describe the small scales fluctuations of velocity. We show that the features of turbulence vary with the distance to the vortex, and are also influenced by its dynamics.

"MODELLING THE MEAN FLOW THROUGH A ROTOR IN AXIAL FLIGHT INCLUDING VORTEX RING CONDITIONS"

The 2nd International Basic Research Conference on Rotorcraft Technology, Nanjing, China, November 2005.

An engineering model for the mean flow through a rotor in descending flight, based on a vortex tube element representation of the wake, proposed by Wang is re-examined and related to other theoretical

approaches. The assumptions, on which the model is based and the properties of its vortex tube formulation are described and examined in the light of recent detailed theoretical calculations. This information is used to expose important underlying physical issues.

Simons, I. A., Pacifico, R. E. and Jones, J. P.

"THE MOVEMENT, STRUCTURE, AND BREAKDOWN OF TRAILING VORTICES FROM A ROTOR BLADE"

ARC-28993, April 1967, Aeronautical Research Council, London, England.

The results of some flow visualization experiments on the trailing vortices from a model rotor blade are presented. It is found that, at low tip-speed ratios, trailing vortices close to the leading edge of the disc first pass up through the disc before entering the main flow field. At the rear of the disc, the vortices maintain a regular pattern relative to each other. The vortices are fully rolled-up in about 60 degrees of azimuth movement of the blade. Measurements with a hot-wire anemometer show that the vortex core is about one-tenth of a blade chord in diameter, which is consistent with a laminar core state. Outside the core, the velocity field is irrotational.

Simpson, R. G, Ahmed, N. A. and Archer, R. D.

"NEAR FIELD STUDY OF VORTEX ATTENUATION USING WING-TIP BLOWING"

Aeronautical Journal, March 2002, pp. 117-120

Tip blowing was investigated in a wind tunnel as an active flow control scheme to attenuate the trailing vortex generated by a rectangular wing. Tip blowing was introduced at the quarter chord, at a constant blowing coefficient of 0.065, and in the forms of both straight Coanda jets. Hot-wire measurements were made at one semi-wing span downstream for both flapped and non-flapped wing configurations. The straight and Coanda jets provided similar results. Relative to the no-blowing baseline case, a reduction in the peak tangential velocity up to 55 percent was achieved. The associated enlargement of the core was by a factor as large as 2.5, with an attenuation of streamwise vorticity around 20 percent. With blowing, the axial velocity in the vortex core also transits from a jet-like to a wake-like profile, suggesting a modification of the spanwise loading on the wing. Blowing was also seen to have caused the vortex core migrate upward and outboard, which suggested a decrease in the induced drag. It is recommended that future studies should include an overall aerodynamic performance of the wing with and without blowing.

Simpson, R. J. S., Palacios, R. and Murua, J.

"INDUCED-DRAG CALCULATIONS IN THE UNSTEADY VORTEX LATTICE METHOD"

AIAA Journal, Vol. 51, No. 7, July 2013, pp. 1775-1779.

Unsteady aerodynamics methods that use lifting-surface approximations require the solution of the leading-edge suction in their induced-drag calculations. Results of two force-calculation methods used

in the unsteady vortex lattice method (the Joukowski method and the Katz and Plotkin method) have been presented with a focus on the calculation of unsteady induced drag. Comparisons of both methods have been made with analytical solutions for the induced drag of plunging and pitching flat-plate airfoils. It was shown that the methods converge equally well to the analytical solutions as finer discretizations are used.

Simpson, T. R.

"PRELIMINARY ANALYSIS OF CIVIL AVIATION ACCIDENTS, JANUARY 1964 -DECEMBER 1972"

FAA-AVP-75-2, April 1975, Mitre Corp., McLean, V.

This document presents a preliminary analysis of all civil aviation accidents which occurred within the United States and its territories and possessions during the nine-year period from January 1964 to December 1972. An overview is first presented which identifies the distribution of these accidents by user class, by aircraft type, and by phase of flight. Due to earlier detailed studies of midair collisions and the small number of fatalities that occurred in accidents when the aircraft were on the ground, the category of single aircraft airborne accidents was selected for further examination. Accidents that occurred during landing and accidents involving encounters with wake vortices were given special emphasis.

Sinclair, P. C.

"THE LOWER STRUCTURE OF DUST DEVILS"

Journal of the Atmospheric Sciences, Vol. 30, November 1973, pp. 1599-1619.

Measurements from an extensive field program in the desert near Tucson, Ariz., are used to formulate a quantitative dust devil model. The model is based on measurements of temperature, pressure and wind velocity taken from a mobile instrumental tower near and within dust devils at levels of 6, 17 and 30 ft. Three dust devil penetrations are analyzed with respect to the temperature, pressure and wind velocity profiles contained in a plane defined by the dust devil axis (or local vertical) and the direction of motion. These profiles corroborate earlier preliminary measurements by Sinclair and thus firmly establish the existence of the warm, low-pressure core of the dust devil. Maximum temperature and pressure variations within the dust devil varied from 4 to 8 C and 2.5 to 4.5 mb. The most significant result of the measurement program was the discovery of a down current or a region of markedly reduced vertical motion along and surrounding the sloping dust devil axis. Immediately outside the down current, the vertical velocity reaches positive peak values and then diminishes rapidly with respect to increasing radius. Superimposed on this motion is a strong rotary and radial motion which results in a combined flow pattern similar to that of a helical vortex. The measurements are synthesized into a dust devil model. The observational model represents a two-cell structure which also appears to exist in other atmospheric vortices, such as the tornado and hurricane and some laboratory and theoretical vortex models.

Singer, B. A. and Banks, D. C.

"A PREDICTOR-CORRECTOR SCHEME FOR VORTEX IDENTIFICATION"

NASA CR-194882, ICASE Report No. 94-11, May 1994, Institute for Computer Applications in Science and Engineering, NASA Langley Research Center, Hampton, VA

A new algorithm for identifying and characterizing vortices in complex flows is presented. The scheme uses both the vorticity and pressure fields. A skeleton line along the center of a vortex is produced by a two-step predictor-corrector scheme. The technique uses the vector field to move in the direction of the skeleton line and the scalar field to correct the location in the plane perpendicular to the skeleton line. A general vortex cross section can be concisely defined with five parameters at each point along the skeleton line. The details of the method and examples of its use are discussed.

Singh, J.

"AN ENHANCED SIMPLIFIED ZONAL APPROACH FOR UNSTEADY AERODYNAMICS OF NONRIGID BODIES"

AIAA Paper No. 1995-1557, Clearwater Beach, FL, May 1995

Unsteady aerodynamics of bodies undergoing time-dependent deformations is of interest to the aerodynamicist. To address this, a simplified zonal approach was developed in a previous effort to evaluate unsteady aerodynamic forces for nonrigid bodies undergoing time-dependent deformations. In the present study, this approach is enhanced to better handle arbitrary two-dimensional bodies using a robust numerical conformal transformation. The enhanced simplified zonal approach gives explicit expressions for the surface vortex sheet strength signifying vorticity content of boundary layer. Using a viscous theory of aerodynamic forces, contributions from various flow subsystems to unsteady aerodynamic force are identified. Thus, this method offers much needed physical insights into generation of and major contributions to unsteady aerodynamic forces for airfoils undergoing prescribed time-dependent deformations.

Singh, P. I. and Uberoi, M. S.

"EXPERIMENTS ON VORTEX STABILITY"

Physics of Fluids, Vol. 19, No. 12, December 1976, pp. 1858-1863

The tip vortex of a laminar flow wing was studied at a sectional lift-to-drag ratio of 60. The vortex Reynolds number was $7.8 \times 10,000$. At and near the wing the vortex core was turbulent with an axial jet. Downstream of the wing the jet rapidly dissipated and a wake developed in the core and intensity of turbulent velocities decreased. From 13 to 40 chord length periodic oscillations dominated the velocity fluctuations with little background turbulence. These instabilities had a symmetric and a helical mode with wavelength of the same order as the core diameter. In this range of distances along the vortex core the maximum axial, swirl, and fluctuating velocities vary slowly. At 40 chord lengths behind the wing there is a rapid change in these velocities. This change of state of the vortex core is

accompanied by change of velocity fluctuations from periodic to turbulent. The core showed spatial excursions. Measurements up to 80 chord lengths downstream showed no self-similar decay.

Singh, S. P., Singh, J., Stallings, J., Burgess, G. and Saha, K.

"MEASUREMENT AND ANALYSIS OF TEMPERATURE AND PRESSURE IN HIGH ALTITUDE AIR SHIPMENTS"

Packaging Technology and Science, Vol. 23, 2010, pp. 35-46.

This study was performed (at the request of the FAA) to measure temperature and pressure conditions observed by standard packages in the FedEx 'Next Day Air' network and the environmental conditions of passenger aircraft. To measure the single parcel environment, two destinations known to be served by non-pressurized feeder and pressurized aircrafts in the USA, San Luis Obispo, California, and Twin Falls, Idaho, were used to represent higher altitude paths. Test packages (0.30 x 0.30 x 0.30 m) containing one Madge Tech PRTempl 10 recorder were shipped Priority Overnight by FedEx from East Lansing, Michigan. For 6 weeks, two test packages were shipped to each destination. To measure the passenger aircraft environment, test packages (0.14 x 0.11 x 0.06 m) were both carried in the passenger cabin and checked with luggage. Results show temperature ranges, pressure drop rates, and maximum altitudes observed from 52 flights (17 feeder aircrafts) in the FedEx environment and from eight commercial passenger flights. This study compares these results with the ASTM D6653-01 test procedure with respect to suggested test pressure, pressure change, temperature, and test duration.

Sinha, A. N.

"USE OF MULTIPLE GLIDE SLOPE ANGLES"

WP-79W00278, May 1979, Mitre Corp., McLean, VA

There has been renewed interest in the use of multiple glide slopes for vortex avoidance with the development of microwave landing systems. Three concepts of multiple glide slope use are proposed and analyzed from navigation error, vortex safety and capacity benefit aspects. The results of this analysis are to be considered as preliminary findings. The primary purpose of this report is to consolidate some of the recent work in this area and present a unified talking paper as a base for further discussion and research. As a result, the paper draws heavily on the work of others - the major ones being reproduced as appendices for ready reference.

Sinha, N. K. and Ananthkrishnan, N.

"MAXIMUM STEADY ROLL RATE IN ZERO-SIDESLIP ROLL MANEUVERS OF AIRCRAFT"

Journal of Aircraft, Vol. 39, No. 5, 2002, pp. 897-899.

The maximum steady roll rate in a zero-sideslip roll maneuver has been computed using the newly developed EBA (extended bifurcation analysis) procedure. It is shown that the maximum value of the

roll rate is limited by roll coupling instabilities and is marked by a trans critical bifurcation point where the zero-sideslip states lose stability.

Sipp, D. and Jacquin, L.

"WIDNALL INSTABILITIES IN VORTEX PAIRS"

Physics of Fluids, Vol. 15, No. 7, July 2003, pp. 1861-1874

In this article we analyze the cooperative three-dimensional short-wave instabilities developing on concentrated vortex dipoles that have been obtained by means of two-dimensional direct numerical simulations. These dipoles are characterized by their aspect ratio a/b where a is the radius of the vortices based on the polar moments of vorticity and b is the separation between the vortex centroids. In the inviscid case, we show that the selection of the antisymmetric eigenmode smoothly increases with a/b : for $a/b = 0.208$, the amplification rate of the antisymmetric eigenmode is only 1.4% larger than the amplification rate of the symmetric eigenmode. When $a/b = 0.288$, this difference increases up to 7%. The results of the normal mode analysis may be compared to those of an asymptotic stability analysis of a Lamb-Oseen vortex subjected to a weak straining field, following Moore and Saffman [Proc. R. Soc. London, Ser. A 346, 413 (1975)]. This theory shows that the instability may occur whenever two Kelvin waves exist with the same frequency ω , the same axial wavenumber k and with azimuthal wavenumbers m and $m + 2$. Contrary to the case of a Rankine vortex [Tsai and Widnall, J. Fluid Mech. 73, 721 (1976)], the presence of critical layers in a Lamb-Oseen vortex prevents many possible resonances. For example, resonances between $m = -2$ and $m = 0$ modes lead to damped modes. The only resonances that occur are related to the stationary ($\omega = 0$) bending waves ($m = \pm 1$) obtained for specific values of the axial wavenumber. All these predictions are found to be in good agreement with the results obtained by the stability analysis of the considered vortex pairs. At last, we present a nonautonomous amplitude equation which considers all effects of viscosity, i.e., the viscous damping of the amplification rate of the perturbation but also the increase of the dipole aspect ratio a/b due to the viscous diffusion of the basic flowfield. The low-Reynolds number experiment of Leweke and Williamson [J. Fluid Mech. 360, 85 (1998)] is revisited under the light of these theoretical results. We show that these theoretical results yield predictions for the amplification rate and for the wavenumber that agree with the experimental observations.

Sipp, D. and Jacquin, L.

"A CRITERION OF CENTRIFUGAL INSTABILITIES IN ROTATING SYSTEMS"

Lectures in Physics, Vol. 555, 2000, pp. 299-308

This article deals with the stability of incompressible inviscid 2D planar flows in a rotating frame. We give a sufficient condition for such flows to undergo 3D short-wave centrifugal-type instabilities. If this condition is satisfied then the flow is unstable to short-wavelength perturbations. When the streamlines are closed, it is further shown that a localized unstable normal mode can be constructed in the vicinity of a streamline.

Sipp, D., Coppens, F. and Jacquin, L.

"THEORETICAL AND NUMERICAL ANALYSIS OF WAKE VORTICES"

Proceedings of 3rd International Workshop on Vortex Flows and Related Numerical Methods, ESAIM, Vol. 7, 1999, pp. 397-407

The first part of the paper analyses the linear dynamics of a vortex pair thanks to a normal mode analysis. The basic flow is a superposition of two Lamb-Oseen vortices of radius a and distance b . The long-wave Crow instability and the short-wave Widnall instabilities are fully characterized for different aspect ratios a/b of the vortex pair. In particular, as a/b increases, it is shown that the antisymmetric Widnall instabilities are favored for short-wave perturbations. This constitutes an explanation for the results obtained by Leweke & Williamson (1998). The second part of the paper deals with turbulence in the Batchelor vortex. A 3D Large Eddy Simulation (LES) shows that, starting from a linearly unstable wake-type vortex, high levels of turbulence can be obtained. But, the mean-flow then rapidly evolves towards a stable state.

Sipp, D., Coppens, F. and Jacquin, L.

"THEORETICAL AND NUMERICAL ANALYSIS OF VORTEX WAKE VORTICES"

Third International Workshop on Vortex Flows and Related Numerical Methods, ONERA, TP No. 1998-160, Toulouse, France, August 1998

This paper analyzes some linear and nonlinear properties of the dynamics of vortices. Two problems are discussed. The first concerns the linear dynamics of two Lamb-Oseen vortices. The second deals with the turbulence effects on a Batchelor-type vortex. These constitute two different aspects of the general airplane vortex wake hazard problem. The linear stability of two counter-rotating vortices, including the (long-wave) Crow instability (Crow, 1970) and the (short-wave) Widnall instability (Tsai and Widnall, 1976, and Moore and Saffman, 1975), may contribute to an aircraft vortex wake dispersion. In the present paper, these two instabilities are fully characterized in a unified frame by means of a normal mode analysis. The development of turbulence and its impact on aircraft vortices is still a matter of question. A temporal numerical simulation of an unstable Batchelor vortex is performed in order to get an insight into this problem. The first part of this paper is devoted to the linear dynamics. We first obtain the bending wave oscillation frequencies of a single Lamb-Oseen vortex by means of a shooting method. It is shown that a single Lamb-Oseen vortex is stable. Then, a spectral collocation and matrix eigenvalue method is used to analyze the dynamics of a vortex pair. In particular, the Crow instability in the long-wave limit and the Widnall instabilities are recovered by this general method. We also prove that increasing the core radius makes the interaction between the two vortices stronger. It is shown, for example, that the antisymmetric mode of the Widnall instability is promoted as the core radius increases. The second part deals with turbulence in the Batchelor vortex. It is shown that high levels of turbulence can be obtained in the vortex. Starting from a linearly unstable wake-type vortex, the mean flow evolves towards a stable state through an increase of its axial momentum. This is in accordance with the results of Ragab and Sreedhar (1995).

Sipp, D., Fabre, D., Michelin, S. and Jacquin, L.

"STABILITY OF A VORTEX WITH A HEAVY CORE"

J. Fluid Mech., Vol. 526, 2005, pp. 67-76

This paper examines the stability of swirling flows in a non-homogeneous fluid. Density gradients are shown to produce two distinct kinds of instability. The first is the centrifugal instability (CTI) which mainly affects axisymmetric, short-axial wavelength eigenmodes. The second is the Rayleigh-Taylor instability (RTI) which mainly affects non-axisymmetric, two dimensional eigenmodes. These instabilities are described for a family of model flows for which the velocity law corresponds to a Gaussian vortex with radius 1, and the density law corresponds to a Gaussian distribution characterized by a density contrast C and a characteristic radius b . A full map in the (C, b) -plane is given for the amplification rate and the structure of the most amplified eigenmode. For small density contrasts, the CTI occurs only for $b > 1$ and the RTI for b less than or equal to 0.8. On the other hand, for high density contrasts, a competition between the two kinds of instabilities is observed. From a fundamental point of view, the nature of the instability depends on the local values. This asymptotic analysis confirms that shear has a stabilizing effect on RTI and that this instability is strictly analogous to the standard RTI obtained in the case where light fluid is situated below heavier fluid in the presence of gravity.

Sipp, D., Jacquin, L. and Sagaut, P.

"A DIRECT NUMERICAL SIMULATION OF A SINUSOIDAL INSTABILITY"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 19-1 to 19-9

We present the results of a direct temporal simulation of a sinusoidal instability which developed in an eddy path that was composed of two, counter-rotating eddies. The results compare to the theory of linear instability developed by Crow. In particular, we studied the effect of grid density, limiting conditions, and the form of the initial perturbation with regards to the quality of the solution. [In French.]

"COMPUTATIONAL-FLUID-DYNAMICS-BASED ENHANCED INDICIAL AERODYNAMIC MODELS"

Journal of Aircraft, Vol. 41, No. 4, July-August 2004, pp. 798-810

Direct Euler calculations were performed to verify the accuracy of linearized airload models and to generate a numerical database for the determination of generalized sharp-edged vertical gust response functions. The field velocity approach was used in the computational fluid dynamics (CFD) code to incorporate the impulsive boundary conditions that were characteristic of the problems studied. Linearized airload models were constructed in three dimensions by coupling the indicial models

obtained in two dimensions with a Weissinger-L vortex panel method. The vortex panel method was suitably modified to include the shed near wake effects and impulsive boundary conditions. Studies conducted on step change in angle of attack and step change in pitch rate for a finite wing showed that the linearized models are sufficiently accurate in predicting the section wise air loads. Generalized gust functions were determined with a constrained minimization of least-square error with a CFD-generated database. Studies on airfoil vortex interaction and parallel blade vortex interaction showed excellent correlation of results from linearized aerodynamic model with the corresponding CFD calculations for both lift and pitching moment response. Overall, the linearized methods were found to produce sufficiently accurate results compared to CFD calculations, taking about four orders of magnitude less computational time.

"ROTOR LOADS PREDICTION USING HELIOS: A MULTISOLVER FRAMEWORK FOR ROTORCRAFT AEROMECHANICS ANALYSIS"

Journal of Aircraft, Vol. 50, No. 2, March-April 2013, pp. 478-492.

This paper documents the prediction of UH-60A Black Hawk aerodynamic loading using the multisolver Computational Fluid Dynamics/Computational Structural Dynamics analysis framework for rotorcraft Helios for a range of critical steady forward flight conditions. Comparisons with available flight test data are provided for all the predictions. The Helios framework combines multiple solvers and multiple grid paradigms (unstructured and adaptive Cartesian) such that the advantages of each paradigm is preserved. Further, the software is highly automated for execution and designed in a modular fashion to minimize the burden on both the users and developers. The technical approach presented herein provides details of all the participant modules and the interfaces used for their integration into the software framework. The results composed of sectional aerodynamic loading and wake visualizations are presented. Solution-based adaptive mesh refinement, a salient feature of the Helios framework, is explored for all flight conditions and comparisons are provided for both aerodynamic loading and vortex wake structure with and without adaptive mesh refinement.

"HELICOPTER DOWNWASH MEASURED BY CONTINUOUS-WAVE DOPPLER LIDARS WITH AGILE BEAM STEERING"

16th International Symposium for the Advancement of Boundary-Layer Remote Sensing, June 2012, Boulder, CO, Poster Session 2, pp. 267-270.

A ground-based remote sensing short-range WindScanner with agile beam steering based on a modified ZephIR continuous-wave wind lidar (Light Detection And Ranging) and a double prism arrangement has recently been developed at the Department of Wind Energy at the DTU Riso campus. The WindScanner measures the line-of-sight component of the wind and by rapid steering of the line-

of-sight and the focus position, all locations within a cone with a full top angle of 120 degrees can be reached from about 8 meters out to some hundred meters depending on the range resolution needed. By using three such WindScanners, all three components of the wind can be retrieved. Here, the first mean 2D turbulent wind fields measured in a horizontal and a vertical plane below a hovering search and rescue helicopter are presented. The line-of-sights of two synchronized WindScanners were scanned within the plane of interest. Since both line-of-sights always were inside the plane scanned, the influence of the wind component perpendicular to the plane was avoided. The results indicate that the flow field below a helicopter can be characterized remotely, which can support helicopter optimization regarding, for example, minimizing the risk to aircraft and personnel when operating in a search and rescue role. The results from the application of the short-range WindScanner technology to the complex and turbulent helicopter downwash demonstrates the possibilities also within less demanding flows encountered within complex terrain and wind energy related research for which the WindScanner technology primarily has been developed.

"TWO-DIMENSIONAL ROTORCRAFT DOWNWASH FLOW FIELD MEASUREMENTS BY LIDAR-BASED WIND SCANNERS WITH AGILE BEAM STEERING"

Journal of Atmospheric and Oceanic Technology, Vol. 31, April 2014, pp. 930-937.

A major risk to helicopters is the unexpected encounter of degraded visual environments in close-to-ground operations, where a loss of visibility often is caused by clouds of dust (brownout) stirred up by intense downwash. The understanding of the phenomenon is limited, and there is a need for instruments that can measure flow fields on scales larger than a few meters with good resolution. This paper reports on the use of synchronized continuous-wave Doppler lidars for rotorcraft downwash flow field studies. Built from a modified ZephIR wind lidar and a double-prism arrangement for agile beam steering, a wind scanner -- WindScanner -- has been developed at the Department of Wind Energy at the Technical University of Denmark Riso campus. The WindScanner measures the line-of-sight component of the airflow remotely and by rapid steering, the line-of-sight direction, and the focus position; all points in space within a cone with a full opening angle of 120 degrees can be reached from about 8 m out to some hundred meters depending on the range resolution required. The first two-dimensional mean wind fields measured in a horizontal plane and in a vertical plane below a hovering search and rescue helicopter are presented. Since the line-of-sight directions of the two synchronized WindScanners were scanned within the plane of interest, the influence of the wind component perpendicular to the plane was avoided. The results also demonstrate the possibilities within less demanding flows encountered within complex terrain and wind-energy-related research for which the WindScanner technology primarily has been developed.

Skoog, R. B.

"A COMPARISON OF TWO FLIGHT-TEST PROCEDURES FOR THE DETERMINATION OF AILERON CONTROL CAPABILITIES OF AN AIRPLANE"

NACA Report 5E22, July 1945, Ames Aeronautical Laboratory, Moffett Field, CA.

A comparison, based on actual flight tests of several airplanes, has been made between two flight-test procedures for the determination of the aileron control capabilities of an airplane. The procedures consist of performing rudder-fixed aileron rolls from straight unbanked flight and from steady turning flight. For the airplanes considered in this report, no significant difference was found to exist in the index of aileron power $p_b/2V$ as determined from data taken with either of the testing methods. This agreement was confirmed as being correct in a comparison of sideslip angle occurring at the time of maximum rate of roll. Extension of the close agreement shown in the report to cover all other present-day airplanes is believed to be reasonable.

Skully, M. P.

"A METHOD OF COMPUTING HELICOPTER VORTEX WAKE DISTORTION"

Report ASRL 138-1, June 1967, Massachusetts Institute of Technology, Cambridge MA.

A method of computing the geometry of the tip vortex of a helicopter rotor in steady, forward flight, including the distortion due to the velocities induced by the vortex wake, has been developed. The relative importance of various parameters and approximations used by this method has been evaluated for one test case., including comparison with experimental results obtained from a flow visualization study.

Slaboch, P. E.

"AN OPERATIONAL MODEL FOR THE PREDICTION OF JET BLAST"

AIAA Paper No. 2012-1229, January 2012, Nashville, Tennessee.

This paper presents an operational model for the prediction of jet blast. The model was developed based upon three modules including a jet exhaust model, jet centerline decay model and aircraft motion model. The final analysis was compared with data acquired during a jet blast study conducted by the Volpe Center in 1999. The current analysis closely matched the data from the 1999 test. The analysis was then used to predict the jet blast evolution from aircraft that have been introduced since 1999, including the Boeing 777-300ER. The result of this analysis is a tool that can be used to help provide insight to operating procedure designs where jet blast concerns may arise.

"SENSITIVITY OF EN-ROUTE SCHEDULING TO VARIABLE SEPARATION IN THE TERMINAL AREA"

AIAA Paper No. 1997-3736, Reston, VA, August 1997

NASA is developing a system that can provide dynamic wake vortex separation criteria by predicting the decay and transport of the vortices in various atmospheric conditions. Varying separation affects aircraft throughout the airspace, and the wake vortex system should be designed not to cause the controllers to continuously replan. Stability is defined as producing delays that can be absorbed solely by aircraft close to landing, instead affecting aircraft in a larger airspace. This paper examines the stability of the wake vortex system by way of parametric study. The parameters are the frequency and size of the separation changes, and their probability distributions. The transient behavior of the system delay under changing separation is examined; it is shown that for the same time, reductions in separation have a larger effect than increases. A linear relationship between the parameters producing a stable delay profile is calculated for the assumed probability distributions.

"AERODYNAMIC AND AERO-ACOUSTIC EFFECTS OF FLAP TIP FENCES, "

AIAA Paper No. 2002-0848, Reno, NV, January 200.

The application of winglet or end-plate type devices to the tips of the trailing-edge flap of a wing has, for some time, been suggested as a (potential) means for improving the aerodynamic efficiency during take-off/climb and for decreasing the airframe noise of transport aircraft in the approach/landing configuration. A third aspect of the application of such devices is their possible effect on the wake vortex characteristics. In this paper the main results and conclusions are presented of exploratory CFD simulations and low-speed wind tunnel tests on a half model of a civil transport type of aircraft configuration with trailing-edge flaps extended and with (and without) winglet type 'fences' attached to the main wing at the position of the outboard tip of the trailing-edge flap. Both take-off/climb and approach/landing flap settings were tested. The main results of the investigation are that the application of flap tip fences may lead to: a substantial (up to 7 dB) reduction of the noise source level of the flap tip in the approaching/landing configuration (about equal for the lower and the upper + lower fence configurations), a (small) improvement of L/D and C_{lmax} in take-off/climb of up to 1% (lower fence only), and possibly a small reduction of a few percent of the strength of the wake vortex from the flap tip region.

Slooff, J. W., de Wolf, W. B., van der Wal, H. M. M. and Maseland, J. E. J.

"AERODYNAMIC AND AERO-ACOUSTIC EFFECTS OF FLAP TIP FENCES"

AIAA Paper No. 2002-0848, Reno, NV, Jan. 2002

The application of winglet or end-plate type devices to the tips of the trailing-edge flap of a wing has, for some time, been suggested as a (potential) means for improving the aerodynamic efficiency during take-off/climb and for decreasing the airframe noise of transport aircraft in the approach/landing configuration. A third aspect of the application of such devices is their possible effect on the wake vortex characteristics. In this paper the main results and conclusions are presented of exploratory CFD simulations and low-speed wind tunnel tests on a half model of a civil transport type of aircraft

configuration with trailing-edge flaps extended and with (and without) winglet type 'fences' attached to the main wing at the position of the outboard tip of the trailing-edge flap. Application of flap tip fences may lead to a small reduction of a few percent of the strength of the wake vortex from the flap tip region.

"NAVIER-STOKES ANALYSIS OF A HIGH WING TRANSPORT HIGH-LIFT CONFIGURATION WITH EXTERNALLY BLOWN FLAPS"

AIAA Paper No. 2000-4219, Denver, CO, August 2000

This paper gives an overview of the numerical simulation of the complete 3D High Wing Transport landing configuration using Reynolds-Averaged Navier-Stokes methods. Rather than concentrating on the numerical details of the CFD simulations themselves, an assessment of the predictive capability of the computational method relative to test data is emphasized. Several technical issues, including test facility wall interference effects and jet modeling effects, are presented in detail. The application of the computational method to study nacelle strake effectiveness and wake vortex prediction is also highlighted.

"INVESTIGATION OF FEASIBILITY OF WIND TURBULENCE MEASUREMENT BY A PULSED COHERENT DOPPLER LIDAR IN THE ATMOSPHERIC BOUNDARY LAYER"

28th International Laser Radar Conference, June 2017, Bucharest, Romania, published in EPJ Web of Conferences, Vol. 176, 2018, pp. 06016-1 to 06016-4.

Feasibilities of determination of the wind turbulence parameters from data measured by the Stream Line coherent Doppler lidar under different atmospheric conditions have been studied experimentally. It has been found that the spatial structure of the turbulence is described well by the von Karman model in the layer of intensive mixing. From the lidar measurements at night under stable conditions the estimation of the outer scale of turbulence with the use of the von Karman model is not possible.

Smalikho, I. N.

"ACCURACY OF THE TURBULENT ENERGY DISSIPATION RATE ESTIMATION FROM THE TEMPORAL SPECTRUM OF WIND VELOCITY FLUCTUATIONS"

Atmospheric and Oceanic Optics, Vol. 10, No. 8, August 1997, pp. 559-563.

This paper describes the errors in the estimates of the turbulent energy dissipation rate based on the likelihood maximum from time spectra of wind velocity measured with an acoustic anemometer and a Doppler lidar.

Smalikho, I. N.

"ON MEASUREMENT OF THE DISSIPATION RATE OF THE TURBULENT ENERGY WITH A CW DOPPLER LIDAR"

Atmospheric and Oceanic Optics, Vol. 8, No. 10, October 1995, pp. 788-793.

Various methods of measurement of the dissipation rate of the turbulent energy by means of a cw Doppler lidar are analyzed in the paper. It is shown that information on the dissipation rate can be derived from the structure function or the spectrum of wind velocity measured with Doppler lidar having arbitrary length of a sounded volume.

"ESTIMATION OF AIRCRAFT WAKE VORTEX PARAMETERS FROM DATA MEASURED WITH A 1.5-MICRON COHERENT DOPPLER LIDAR"

Optics Letters, Vol. 40, No. 14, July 2015, pp. 3408-3411.

A strategy of measurement by a 1.5-micron pulsed coherent Doppler lidar 'Stream Line' has been developed, and a method for estimation of aircraft wake vortices from the lidar data has been proposed. The principal possibility of obtaining the information about the vortex situation over an airport airfield with the Stream-Line lidar has been demonstrated.

Smalikho, I. N. and Banakh, V. A.

"ESTIMATION OF AIRCRAFT WAKE VORTEX PARAMETERS FROM DATA MEASURED BY A STREAM LINE LIDAR"

XXI International Symposium on Atmospheric and Ocean Optics: Atmospheric Physics, November 2015, Tomsk, Russian Federation, Proceedings of SPIE, Vol. 9680, pp. 968037-1 to 968037-7.

A method for estimation of aircraft wake vortex parameters (coordinates of axis and circulation of vortices) from raw data measured by a pulsed coherent Doppler lidar 'Stream Line' has been offered. By numerical simulation we found optimal measurement parameters, with which it is possible to obtain information about the wake vortices, despite the low level of echo signal inherent to this lidar. The method was tested in an experiment at the airfield of Tomsk airport. The results of the experimental data processing are consistent with theoretical calculations for the type of aircrafts involved in this experiment.

"LIDAR INVESTIGATIONS OF THE EFFECTS OF WIND AND ATMOSPHERIC TURBULENCE ON AN AIRCRAFT WAKE VORTEX"

Atmospheric and Oceanic Optics, Vol. 23, No. 2, 2010, pp. 137-146.

The effects of wind and atmospheric turbulence on an aircraft wake vortex are studied experimentally. A 2-micron coherent Doppler lidar is used for measuring the parameters of the aircraft vortices, wind, and turbulence. The results are presented of lidar measurements of aircraft vortex parameters at different wind velocities and turbulence levels. An empirical dependence of the aircraft vortex lifespan on the dissipation rate of atmospheric turbulence energy has been obtained from the experimental data for the first time.

Smalikho, I. N., Banakh, V. A. and Falits, A. V.

"INVESTIGATION OF FEASIBILITIES OF AIRCRAFT WAKE VORTEX MEASUREMENT BY A LOW-ENERGY 1.5-MICRON PULSED COHERENT DOPPLER LIDAR"

18th Coherent Laser Radar Conference, June 2016, Boulder, CO.

In this work the feasibilities of the extraction of information about aircraft wake vortices from data measured by a low-energy 1.5-micron pulsed coherent Doppler lidar (PCDL) are investigated. A strategy of measurement by such lidar at airfield of an airport has been developed and the conditions of applicability of the lidar for wake vortex measurement have been determined. The applicability of the 1.5-micron Stream Line PCDL for measurements of the wake vortices generated by a landing aircraft has been demonstrated in the experiments carried out at the airfield of the Tolmachevo Airport. We estimated parameters of the wake vortices for aircrafts of various types, including Boeing-747 cargo aircraft.

Smalikho, I. N., Banakh, V. A. and Falits, A. V.

"MEASUREMENTS OF AIRCRAFT WAKE VORTEX PARAMETERS BY A STREAM LINE DOPPLER LIDAR"

Atmospheric and Oceanic Optics, Vol. 30, No. 6, 2017, pp. 588-595.

Results of measurements of the parameters of aircraft wake vortices by a Stream Line coherent Doppler lidar during the three-day experiment on the airfield of Tolmachevo Airport are presented. The spatial dynamics and evolution of the wake vortices generated by landing aircraft of different types, from Airbus A319 passenger aircraft to heavy Boeing 747-8 cargo aircraft, are analyzed. It is shown that Stream Line lidars may be used to receive reliable information about the presence and intensity of aircraft wake vortices in the vicinity of a runway.

Smalikho, I. N., Banakh, V. A., Holzaepfel, F. and Rahm, S.

"METHOD OF RADIAL VELOCITIES FOR THE ESTIMATION OF AIRCRAFT WAKE VORTEX PARAMETERS FROM DATA MEASURED BY COHERENT DOPPLER LIDAR"

1990

Optics Express, Vol. 23, No. 19, September 2015, pp. A1194-A1207.

The method of radial velocities (RV) is applied to estimate aircraft wake vortex parameters from measurements conducted with pulsed coherent Doppler lidar (PCDL). Operations of the Stream Line lidar and the 2-micron PCDL are simulated numerically to analyze the accuracy of the estimated wake vortex parameters with the RV method. The RV method is also used to estimate wake vortex trajectories and circulation from lidar measurements at Tomsk and Munich airports. The method of velocity envelopes and the RV method are compared employing data gathered with the 2-micron PCDL. The domain of applicability of the RV method is determined.

"LIDAR INVESTIGATION OF ATMOSPHERE EFFECT ON A WIND TURBINE WAKE"

Journal of Atmospheric and Oceanic Technology, Vol. 30, November 2013, pp. 2554-2570.

An experimental study of the spatial wind structure in the vicinity of a wind turbine by a NOAA coherent Doppler lidar has been conducted. It was found that a working wind turbine generates a wake with the maximum velocity deficit varying from 27 to 74 percent and with the longitudinal dimension varying from 120 up to 1180m, depending on the wind strength and atmospheric turbulence. It is shown that, at high wind speeds, the twofold increase of the turbulent energy dissipation rate (from 0.0066 to 0.013 (meter squared)/(second cubed)) leads, on average, to halving of the longitudinal dimension of the wind turbine wake (from 680 to 340m).

Smalikho, I., Kopp, F. and Rahm, S.

"MEASUREMENT OF ATMOSPHERIC TURBULENCE BY 2-MICRON DOPPLER LIDAR"

Journal of Atmospheric and Oceanic Technology, Vol. 22, No. 5, November 2005, pp. 1733-1747.

Two methods for the estimation of the turbulence energy dissipation rate (TEDR) from data measured by a 2-micron coherent Doppler lidar are described in this paper. Based on data measured at the Tarbes-Lourdes-Pyrenees International Airport in summer 2003, height profiles of TEDR have been retrieved. The results of TEDR estimation both from the Doppler spectrum width and from the velocity structure function are compared. Moreover, the experiment has been treated by numerical simulation and the theoretical results have been used for verification of the described methods.

Smart, M. K. and Kalkhoran, I. M.

"EFFECT OF SHOCK STRENGTH ON OBLIQUE SHOCK-WAVE/VORTEX INTERACTION"

AIAA Journal, Vol. 33, No. 11, November 1995, pp. 2137-2143

An experimental study of the interaction between streamwise vortices and two-dimensional oblique shock waves has been conducted at Mach 2.5. The experiments involved positioning an instrumented two-dimensional wedge downstream of a semispan wing so that the trailing tip vortex from the wing interacted with the oblique shock wave formed over the wedge surface. The experiments were designed to simulate interaction of streamwise vortices with shock waves formed over aerodynamic surfaces or in supersonic inlets. The influence of oblique shock wave intensity on this inherently three-dimensional interaction was examined for vortices of variable strength. Results indicate that the interaction of a moderate strength vortex with an oblique shock wave can lead to the formation of a steady separated shock structure upstream of the oblique shock front. A significant expansion of the vortex core is observed in these cases, and the scale of the structure increases with shock wave intensity. In some instances, the separated shock structure continues through the oblique shock front to strike the shock-generating wedge forming a three-dimensional shock-wave/boundary-layer interaction. The experiments indicate that significant distortion of streamwise vortices can be precipitated by oblique shock fronts with supersonic downstream conditions.

Smart, M. K. and Kalkhoran, I. M.

"FLOW MODEL FOR PREDICTING NORMAL SHOCK WAVE INDUCED VORTEX BREAKDOWN"

AIAA Journal, Vol. 35, No. 10, October 1997, pp. 1589-1596

An analytical study of normal shock wave induced vortex breakdown has been undertaken. In this inviscid axisymmetric analysis, the response of supersonic streamwise vortices to imposed normal shocks has been determined by modeling the rotational core of the vortex as a slender, swirling layer. For vortex/shock combinations of increasing strength, the analysis predicts an ever-increasing axial velocity deficit in the vortex core. Vortex breakdown is presumed to occur if a vortex/shock combination leads to flow stagnation at the vortex axis. The results of this study indicate that an inverse relationship exists between vortex swirl and freestream Mach number at breakdown. The breakdown limit curve generated using this analysis shows good correlation with established experimental results, indicating that the onset of normal shock wave induced vortex breakdown can be predicted with a relatively simple flow model and without recourse to numerical simulation. Interpretation of some normal shock wave/vortex interaction experiments in light of the predictions suggests that the phenomenon previously known as supersonic vortex distortion is a form of vortex breakdown.

Smart, M. K. and Kalkhoran, I. M.

"A SCENARIO FOR OBLIQUE SHOCK WAVE INDUCED VORTEX BREAKDOWN"

AIAA Paper No. 1997-0069, January 1997, Reno, NV.

Thus far the 3D nature of oblique shock wave/vortex interaction has made its measurement and analysis difficult in both experimental and numerical simulation frameworks. As an alternative, the problem has been examined here from a physically intuitive standpoint to better understand its

dominant features. This approach has enabled a fluid dynamic scenario involving supersonic vortex breakdown to be developed as an explanation for the observed flow reorganization. An approximate analysis for predicting oblique shock wave induced vortex breakdown was developed using this scenario. Results of the analysis for some experimentally investigated vortex/shock combinations indicate that the prediction of vortex breakdown corresponds closely with the appearance of a fully developed separated shock structure upstream of the original oblique shock plane. This correlation is seen as strong circumstantial evidence that vortex breakdown is responsible for the dramatic changes observed in the interaction flow fields.

Smart, M. K. and Kalkhoran, I. M.

"THE EFFECT OF SHOCK STRENGTH ON OBLIQUE SHOCK WAVE-VORTEX INTERACTION"

AIAA Paper No. 1995-0098, January 1995, Reno, NV.

An experimental study of the interaction between streamwise vortices and two-dimensional oblique shock waves has been conducted at Mach 2.5. The experiments involved positioning an instrumented two-dimensional wedge downstream of a semi-span wing so that the trailing tip vortex from the wing interacted with the oblique shock wave formed over the wedge surface. The experiments were designed to simulate interaction of streamwise vortices with shock waves formed over aerodynamic surfaces or in supersonic inlets. The influence of oblique shock wave intensity on this inherently three-dimensional interaction was examined for vortices of variable strength. Results indicate that the interaction of a moderate strength vortex with an oblique shock wave can lead to the formation of a steady separated shock structure upstream of the oblique shock front. The scale of the structure increased with shock wave intensity and showed a close resemblance to the unsteady vortex distortion observed during the head-on interaction of streamwise vortices with a wedge leading edge reported in previous studies. In some instances, the separated shock structure was observed to continue through the oblique shock front to strike the shock generating wedge forming a three-dimensional shock wave/boundary layer interaction.

Smart, M. K., Kalkhoran, I. M. and Bentson, J.

"MEASUREMENTS OF SUPERSONIC WING TIP VORTICES"

AIAA Paper No. 1994-2576, Colorado Springs, CO, June 1994

Small-scale 4- 5-hole cone probes have been used to experimentally survey supersonic wingtip vortices at Mach 2.5, for wing angles of attack in the 5-10 deg range. The vortex core region's Mach number, flow angularity, and total pressure distribution are obtained, and the feasibility of using cone probes calibrated with a numerical flow solver is demonstrated.

Smart, M. K., Kalkhoran, I. M. and Bentson, J.

"MEASUREMENTS OF SUPERSONIC WING TIP VORTICES"

1993

AIAA Journal, Vol. 33, No. 10, October 1995, pp. 1761-1768.

An experimental study of supersonic wing tip vortices has been conducted at Mach 2.49 using small-scale four-hole and five-hole conical probes. The study was performed 2.25 chords downstream of a semispan rectangular wing at angles of attack of 5.7 and 10.4 deg. The main objective of the experiments was to determine the Mach number, flow angularity, and total pressure distribution in the core region of supersonic wing tip vortices. A secondary aim was to demonstrate the feasibility of calibrating a conical probe using a computational solution to predict the flow characteristics. Results of the present investigation showed that the numerically generated calibration data can be used for pointed nose four-hole conical probes but were not sufficiently accurate for conventional five-hole probes due to nose bluntness effects. A combination of four-hole conical probe measurements with independent pitot pressure measurements indicated a significant Mach number and total pressure deficit in the core regions of supersonic wing tip vortices, combined with an asymmetric 'Burger-like' swirl distribution.

Smart, M. K., Kalkhoran, I. M. and Popovic, S.

"SOME ASPECTS OF STREAMWISE VORTEX BEHAVIOR DURING OBLIQUE SHOCK WAVE/VORTEX INTERACTION"

Shock Waves, Vol. 8, 1998, pp. 243-255

An experimental study of the flowfield generated by the interaction of a streamwise vortex having a strong wake-type axial Mach number profile and a two-dimensional oblique shock wave was conducted in a Mach 2.49 flow. The experiments were aimed at investigating the dynamics of supersonic vortex distortion and to study downstream behavior of a streamwise vortex during a strong shock wave/vortex encounter. The experiments involved positioning an oblique shock generator in the form of a two-dimensional wedge downstream of a semi-span, vortex generator wing section so that the wing-tip vortex interacted with the otherwise planar oblique shock wave. Planar laser sheet visualizations of the flowfield indicated an expansion of the vortex core in crossing a spherically blunt-nose shock front. The maximum vortex core diameter occurred at a distance of 12.7 mm downstream of the wedge leading edge where the vortex had a core diameter of more than double its undisturbed value. At distances further downstream the vortex core diameter remained nearly constant, while it appeared to become more diffused at distances far from the wedge leading edge. Measurements of vortex trajectory revealed that the vortex convected in the freestream direction immediately downstream of the bulged-forward shock structure, while it traveled parallel to the wedge surface at distances further downstream. The turbulent distorted vortex structure which formed because of the interaction, was found to be sensitive to downstream disturbances in a manner consistent with incompressible vortex breakdown. Physical arguments are presented to relate behavior of streamwise vortices during oblique and normal shock wave interactions.

Smith, A. P.

"USING REAL-TIME AIRCRAFT REPORTS OF WIND AND ENVIRONMENTAL PARAMETERS TO ENABLE DYNAMIC COCKPIT-BASED WAKE TOOLS"

ICNS 2011 Renovating the Global Air Transportation System, May 2011, Herndon, VA.

The FAA is implementing the NextGen in the US NAS. The MITRE Corp. is supporting the FAA in this mission, and conducts research activities that assist the FAA in leveraging emerging aircraft capabilities. A key area is evaluating the feasibility of delegating longitudinal aircraft spacing to pilots even during low visibility conditions. As longitudinal spacing is delegated to the flight crew, flight-deck based tools are needed to support the task. To make a realistic assessment of the location and strength of a wake vortex, real-time weather information needs to be known in the vicinity of the aircraft producing the wake. This paper addresses the quality of that information and how any uncertainty in this information will affect the estimate of the location and strength of wake using current wake dynamics estimating programs that could be used on an aircraft. Using MDCRS data, we have found that there is uncertainty in wind and other atmospheric parameters, even in the approach phase of flight, over a short span of time. Using these results, we show the uncertainty in the wake positions and discuss the implications for using this information for cockpit visualization tools.

Smith, A., Lott, N. and Vose, R.

"THE INTEGRATED SURFACE DATABASE: RECENT DEVELOPMENTS AND PARTNERSHIPS"

Bulletin of the American Meteorological Society, vol. 92, issue 6, June 2011, pp. 704-708

This paper describes a dataset containing data from more than 100 original data sources that collectively archived hundreds of meteorological variables. The primary data sources include the Automated Surface Observing System (ASOS), Automated Weather Observing System (AWOS), Synoptic, Airways, METAR, Coastal Marine (CMAN), Buoy, and various others, from both military and civilian stations including both automated and manual observations. Summary of daily parameters such as maximum/minimum temperature, 24-h precipitation, and snow depth are also included in ISD, to the extent that they are reported in the hourly data sources. Furthermore, this paper describes Quality Control, Examples Research and Industry, Recent Plans, and Data Access and Products.

Smith, B. E. and Ross, J. C.

"APPLICATION OF PANEL METHOD TO WAKE VORTEX/WING INTERACTION AND COMPARISON WITH EXPERIMENTAL DATA"

NASA TM-88337, September 1987, NASA Ames Research Center, Moffett Field, CA

The ability of the Vortex Separation AEROdynamics (VSAERO) program to calculate aerodynamic loads on wings due to interaction with free vortices was studied. The loads were calculated for various positions of a downstream following wing relative to an upstream vortex-generating wing. Calculated vortex-induced span loads, rolling-moment coefficients, and lift coefficients on the following wing were

compared with experimental results of McMillan et al. and El-Ramly et al. Comparisons of calculated and experimental vortex tangential velocities were also made.

Smith, B. E. and Ross, J. C.

"APPLICATION OF PANEL METHOD TO WAKE VORTEX/WING INTERACTION AND COMPARISON WITH EXPERIMENT"

AIAA Paper No. 1984-2182, Seattle, WA, August 1984

The ability of a low-order panel method to calculate the aerodynamic loads on wings caused by interaction with wake vortices was studied. The loads were calculated for various positions of a downstream following wing relative to an upstream vortex-generating wing. Calculated vortex-induced span loads and rolling-moment coefficients on the following wing were compared with experimental data. A good agreement with experiment was obtained when the following wing was located more than one following-wing chord length from the tip vortex. The predictions deteriorated as the following wing was placed closer to the vortex. At large downstream distances (approximately 10 generating-wing chord lengths), induced rolling-moment coefficients on the following wing were consistently overestimated. Despite the strong interaction between the wake-vortex filaments and surface doublet panels, the accuracy of the calculations was in most cases independent of the panel distribution and density. A good agreement between theoretical and experimental loads was obtained with a minimum of experimentation with panel arrangements.

Smith, H. C.

"METHOD FOR REDUCING THE TANGENTIAL VELOCITIES IN AIRCRAFT TRAILING VORTICES"

J. Aircraft, Vol. 17, No. 12, December 1980, pp. 861-866

A method is presented to reduce the tangential velocities in the trailing vortex system shed from an airplane wing. The device employed is a porous section of the wing at the tip which essentially tends to equalize the pressure on the upper and lower surfaces. Experiments were conducted on a full-scale aircraft in flight and vorticity measured by probes devised specifically for this purpose. Results showed significant reduction in tangential velocities close behind the wing and to a lesser degree far downstream. Controllable porosity is suggested as a means of reducing the vortex tangential velocities and subsequent potential induced rolling moment imposed on a following aircraft.

Smith, H. J.

"A FLIGHT TEST INVESTIGATION OF THE ROLLING MOMENTS INDUCED ON A T-37B AIRPLANE IN THE WAKE OF A B-747 AIRPLANE"

NASA TM X-56031, April 1975, NASA Flight Research Center, Edwards, CA

A flight test investigation of the B-747 vortex wake characteristics was conducted using a T-37B as a probe aircraft. The primary purpose of the program was the validation of the results of B-747 model test which predicted significant alleviation of the vortex strength when only the inboard flaps were deflected. Measurements of the vortex-induced rolling moments of the probe aircraft showed that the predicted alleviation did occur. Unfortunately, this alleviation could not be fully realized for realistic operations: the effects of landing gear extension, increased lift coefficient, idle thrust, and side-slip were investigated, and all had an adverse effect on the alleviated condition as evidenced by increased induced rolling moments of the T-37B probe aircraft. Idle thrust also increased the strength of the B-747 wake vortices with both inboard and outboard flaps extended.

Smith, J. C.

"ANALYSIS OF WAKE VAS BENEFITS USING ACES BUILD 3.2.1"

NASA/CR-2005-213939, January 2005, Swales Aerospace, Hampton, VA

The FAA and NASA are currently engaged in a Wake Turbulence Research Program to revise wake turbulence separation standards, procedures, and criteria to increase airport capacity while maintaining or increasing safety. The research program is divided into three phases: Phase I - near term procedural enhancements; Phase II - wind dependent Wake Vortex Advisory System (WakeVAS) Concepts of Operations (ConOps); and Phase III - farther term ConOps based on wake prediction and sensing. This report contains an analysis that evaluates the benefits of a closely spaced parallel runway (CSPR) Phase I ConOps, a single runway and CSPR Phase II ConOps and a single runway Phase III ConOps. A series of simulation runs were performed using the Airspace Concepts Evaluation System (ACES) Build 3.2.1 air traffic simulator to provide an initial assessment of the reduction in delay and cost savings obtained using a WakeVAS at selected U.S. airports. The ACES simulator is being developed by NASA Ames Research Center as part of the Virtual Airspace Modelling and Simulation (VAMS) program.

Smith, J. C.

"ANALYSIS OF WAKE VAS BENEFITS USING ACES BUILD 3.2.1 - VAMS TYPE 1 ASSESSMENT"

NASA/CR-2005-213940, December 2005, Swales Aerospace, Hampton, VA

The FAA and NASA are currently engaged in a Wake Turbulence Research Program to revise wake turbulence separation standards, procedures, and criteria to increase airport capacity while maintaining or increasing safety. The research program is divided into three phases: Phase I - near term procedural enhancements; Phase II - wind dependant Wake Vortex Advisory System (WakeVAS) Concepts of Operations (ConOps); and Phase III - farther term ConOps based on wake prediction and sensing. The Phase III Wake VAS ConOps is one element of the Virtual Airspace Modelling and Simulation (VAMS) program blended concepts for enhancing the total system wide capacity of the National Airspace System (NAS). This report contains a VAMS Program Type 1 (stand-alone) assessment of the expected capacity benefits of Wake VAS at the 35 FAA Benchmark Airports and determines the

consequent reduction in delay using the Airspace Concepts Evaluation System (ACES) Build 3.2.1 simulator.

"WAKE VORTEX ADVISORY SYSTEM (WakeVAS) EVALUATION OF IMPACTS ON THE NATIONAL AIRSPACE SYSTEM"

NASA CR-2005-213523, January 2005, Swales Aerospace, Hampton, VA

This report is one of a series that describes an ongoing effort in high-fidelity modeling/simulation, evaluation and analysis of the benefits and performance metrics of the Wake Vortex Advisory System (WakeVAS) Concept of Operations being developed as part of the Virtual Airspace Modeling and Simulation (VAMS) project. A previous study, determined the overall increases in runway arrival rates that could be achieved at 12 selected airports due to WakeVAS reduced aircraft spacing under Instrument Meteorological Conditions. This study builds on the previous work to evaluate the NAS wide impacts of equipping various numbers of airports with WakeVAS. A queuing network model of the National Airspace System, build by the Logistics Management Institute, McLean, VA, for NASA (LMINET) was used to estimate the reduction in delay that could be achieved by using WakeVAS under non-visual meteorological conditions for the projected air traffic demand in 2010. The results from LMINET were used to estimate the total annual delay reduction that could be achieved and from this, an estimate of the air carrier variable operating cost saving was made.

Smith, J. H. B.

"VORTEX FLOWS IN AERODYNAMICS"

Annual Review Fluid Mechanics, 1986, Vol. 18, pp. 221-242

Many different vortex flows arise in the external aerodynamics of aircraft. This review has concentrated on two types of vortex flow, distinguished by their relative simplicity and their susceptibility to inviscid modeling. The relevance of Prandtl-Batchelor flows in any practical context has yet to be demonstrated, but indications of their potential usefulness justify the continuing investigation of their behavior, of the means to compute them, and of the circumstances in which they exist. The relevance of vortex flows arising from highly swept separation lines, on the other hand, is not in doubt. However, despite the many treatments developed and the numerous configurations studied, some fundamental problems remain. On the fringes of the subject lie the two principal needs: a model of secondary separation, and (relatedly) a convincing treatment of turbulent separation from a smooth surface to parallel the triple-deck treatment of laminar separation. These are needed to supplement the inviscid models. All the models suffer from weaknesses when the vortices lie close to solid surfaces: particularly the surfaces generating them, but also surfaces downstream. Yet these are often the circumstances of greatest interest when gains in aerodynamic efficiency become possible and when the most serious stability and control difficulties arise. The unsought appearance of vortices in time-marching solutions of the Euler equations is an exciting and unexpected development, which offers

great promise of unified prediction methods for wing-dominated flows, including the prediction of vortex breakdown.

Smith, J. M.

"DOES FAA NEED A NEW SYSTEM TO TRACK WAKE INCIDENTS?"

Government Computer News, October 1994, Vol. 13, No. 23, p. 16

An internal report from the Federal Aviation Administration (FAA) calls for a tracking system that will collect and analyze data on wake vortices so that air traffic controllers can give pilots better flight advice. The system should be able to allow air traffic controllers to determine airplane separation distances more accurately and foresee conditions that are likely to lead to wake vortex encounters. The proposal is prompted by recent air disasters that were traced to wake vortices. Vortex accidents occur when aircrafts are behind or below another. The FAA report is aware that there are no sufficient funds to develop such a system but suggests that instead of building a new one, the agency should just test a prototype vortex tracking system.

"FLOW VISUALIZATION STUDIES OF BLOWING FROM THE TIP OF A SWEPT WING"

NASA TM-4217, November 1990, NASA Langley Research Center, Hampton, VA.

Flow visualization studies of blowing from the tip of a swept wing were conducted in the Langley 16-by 24-Inch Water Tunnel. Four wing tips, each with two independent blowing slots, were tested. The two slots were located one behind the other in the chordwise direction. The wing tips were designed to systematically vary the jet length, the jet in-plane exhaust direction (sweep), and the jet out-of-plane exhaust direction (anhedral). Each blowing slot was tested separately at two angles of attack and at four ratios of jet to free-stream velocity. Limited tests were conducted with blowing from both slots simultaneously. Blowing from the tip inhibited inboard spanwise flow on the upper wing surface near the tip. The jet path moved farther away from the tip as the ratio of jet velocity to free-stream velocity increased, and moved closer to the tip as angle of attack increased.

Smith, Jr., W. J. and King, C. J.

"EFFECT ON WING TIP VORTICES AND SONIC SHOCK ON ARMY AIRCRAFT IN FLIGHT"

Evaluation Report, January 1957, Beech Aircraft Corp., Wichita, KS

The report is a preliminary study of the oscillograph records obtained during the United States Army Aviation Board tests conducted in conjunction with the Air Force at Eglin AFB, Florida. In a limited number of flights involving QL-17, F-100, B-47, and L-19 aircraft, the following items were tentatively established: negative load factors higher than the minimum ultimate design requirements for normal category personal aircraft can reasonably be expected at higher cruise speed; every change in attitude

of the QL-17 resulting from vortex penetrations would have been more severe for a piloted Navion than for the QL-17 controlled by the autopilot; and separations greater than 30 seconds would be required by light aircraft following a B-47.

"LASER VELOCIMETRY MEASUREMENTS OF VORTEX FLOWS ON A DELTA WING AT MACH 1.9"

WL-TR-93-3059, January 1993, Flight Dynamics Directorate, WPAFB, OH.

Off-body flow visualizations and fluid velocity measurements are conducted in a supersonic vortex flow. Three-dimensional laser velocimetry measurements are made in the leeward flowfield over a simple sharp-edged delta wing with 75-degree sweep angle. Tests are conducted at Mach 1.9 and Reynolds number of 2,400,000 based on model root chord. Measurements are made at 40 percent and 80 percent chord positions for 20- and 30-degree angles of attack and at 40 percent chord for 35 degrees. Mean velocities and turbulence intensities are measured on the five planes. Measurement accuracy is discussed in detail. The measurements define the location of the vortex core and provide the flowfield velocities surrounding the vortex. The difficulties inherent with seeding high velocity vortex flows are discussed.

"PERFORMANCE ANALYSIS OF A WING WITH MULTIPLE WINGLETS"

AIAA Paper 2001-2407, June 2001, Anaheim, CA.

This effort examined the potential of multi-winglets for the reduction of induced drag without increasing the span of aircraft wings. Wind tunnel models were constructed using a NACA 0012 airfoil section for the untwisted, rectangular wing and flat plates for the winglets. Testing of the configurations occurred over a range of Reynolds numbers from 161,000 to 300,000. Wind tunnel balances provided lift and drag measurements, and laser flow visualization obtained wingtip vortex information. The Cobalt60 unstructured solver generated flow simulations of the experimental configuration via solution of the Euler equations of motion. The results show that certain multi-winglet configurations reduced the wing induced drag and improved L/D by 15-30 percent compared with the baseline 0012 wing. A substantial increase in lift curve slope occurs with dihedral spread of winglets set at zero incidence relative to the wing. Dihedral spread also distributes the tip vortex. These observations supplemented previous results on drag reduction due to lift reorientation with twisted winglets set at negative incidence.

Smith, N. F.

"NUMERICAL EVALUATION OF MASS-FLOW COEFFICIENT AND ASSOCIATED PARAMETERS FROM WAKE-SURVEY EQUATIONS"

NACA TN-1381, August 1947, Langley Aeronautical Lab., Langley Field, VA

A method is presented for the determination by use of charts of mass-flow coefficient and associated flow parameters from pressure surveys in internal-flow systems. For isoenergetic flows the point mass-flow coefficient is shown to be an explicit function of the free-stream Mach number and of the static-pressure and total-pressure-loss coefficients at the measurement station. These parameters are easily determined from the test data; hence, their use provides a convenient method of evaluation of the point mass-flow coefficient. The charts presented cover a wide range of these parameters through the complete range of subsonic Mach numbers. The equations have also been evaluated for flows wherein mechanical or thermal energy is added, such as flows behind radiators or propellers. The fundamental principles may be applied to the measurement of flow from jet-propulsion units; however, under these conditions the mass of the fuel and the change in the value of the ratio of specific heats must be considered.

Smith, R.

"AN INVESTIGATION OF SUPERSONIC SWIRLING JETS"

Aeronautical Journal, Vol. 24, August 1973, pp. 167-178.

A theoretical and experimental investigation has been made into the effect of swirl on a supersonic jet. In certain circumstances a core of reversed flow can occur along the axis of symmetry and the jet mixes much more quickly with the ambient air than does the corresponding non-rotating jet. A characteristic calculation has been performed for the first cell in the case where the axial flow is not reversed. This indicates a shortening of the cell length and the formation of shocks nearer the nozzle.

Smith, R.

"HYPERSONIC SWIRLING FLOW PAST BLUNT BODIES"

Aeronautical Quarterly, Vol. 24, 1973, pp. 241-251.

The effect of swirl on the high-speed flow past blunt bodies is analyzed by assuming constant density in the region between the shock wave and the body. For small swirl the stand-off distance is only slightly affected, but it is shown that there is a critical value of the swirl parameter which, if exceeded, will cause a jump in the position of the shock. This is demonstrated by solving the full constant-density equations for the flow past a sphere and by a perturbation expansion in powers of the density ratio across the shock for a more general body shape. The perturbation solution shows that the pressure coefficient on the body is constant at the critical swirl number.

Smith, R. K.

"ACCURATE DETERMINATION OF A BALANCED AXISYMMETRIC VORTEX IN A COMPRESSIBLE ATMOSPHERE"

Tellus, Vol. 58A, 2006, pp. 98-103.

We give a simple method to calculate without approximation the balanced density field of an axisymmetric vortex in a compressible atmosphere in various coordinate systems given the tangential wind speed as a function of radius and height and the vertical density profile at large radius. The method is generally applicable, but the example considered is relevant to tropical cyclones. The exact solution is used to investigate the accuracy of making the anelastic approximation in a tropical cyclone, i.e. the neglect of the radial variation of density when calculating the gradient wind. We show that the core of a baroclinic vortex with tangential wind speed decreasing with height is positively buoyant in terms of density differences compared at constant height, but at some levels may be interpreted as cold-cored or warm-cored depending on the surfaces along which the temperature deviation is measured. However, it is everywhere warm-cored if the potential temperature deviation is considered. In contrast, a barotropic vortex in a stably-stratified atmosphere is cold-cored at all levels when viewed in terms of the temperature deviation at constant height or constant vertical component, but warm-cored when viewed in terms of the potential temperature deviation along these surfaces. The calculations provide a possible explanation for the observed reduction in surface air temperature in the inner core of tropical cyclones.

"COMPUTATION OF INDUCED DRAG FOR ELLIPTICAL AND CRESCENT-SHAPED WINGS"

J. Aircraft, Vol. 30, No. 4, July-August 1993, pp. 446-452

Recent interest in the induced drag characteristics of crescent-shaped wings has led to a closer look at the methods used for determination of induced drag from computational aerodynamic methods. Induced drag may be computed by integration of surface pressure or by evaluation of a contour integral in the Trefftz plane. A high-order panel method was used to study the induced drag of elliptical and crescent-shaped wings using both techniques. Induced drag computations using surface pressure integration were strongly affected by panel density and angle of attack. Drag computations for the crescent wing were especially sensitive to spanwise panel density because of the complex flowfield near the tip. Trefftz-plane results for the two wing planforms were not sensitive to panel density or angle of attack. The effect of correctly modeling the force-free, rolled-up wake geometry on the predicted span efficiency was demonstrated for both wing planforms. The span efficiency predicted from Trefftz-plane integration was about 0.97 for the elliptical wing and 0.99 for the crescent wing, both somewhat less than the classical theoretical maximum for planar wings. Most of the apparent drag reduction of the crescent wing claimed in previous studies was probably an artifact of the surface-pressure integration. The slightly higher span efficiency for the crescent wing was attributed to a more nearly elliptical spanwise lift distribution.

Smith, S. C. and Kroo, I. M.

"INDUCED DRAG COMPUTATIONS ON WINGS WITH ACCURATELY MODELED WAKES"

A technique has been developed for numerically computing the force-free wake shape downstream of finite wings, based on the need for very accurate integration of induced drag in the Trefftz-plane. An $AR = 7$ elliptical wing with straight trailing edge was used to study the influence of the computed wake shape on induced drag. A traditional vortex-lattice relaxation method produced a wake that led to a 9% error in Trefftz-plane drag. The new method presented here obtains more accurate wing-induced velocities from a high-order panel method, while relying on the well-behaved nature of the discrete-vortex wake model for the wake-induced velocities. The induced drag with the wake produced by this hybrid scheme agreed with the drag predicted with a straight wake within 0.1%, consistent with high-resolution pressure integration. These and other cited results indicate that the hybrid scheme produces wakes of sufficient accuracy to enable Trefftz-plane integration of drag on the force-free wake.

Smith, S. T.

"MODELING OF WAKE-VORTEX AIRCRAFT ENCOUNTERS"

MS Thesis, April 1999, Howard University, Washington, DC

There are more people passing through the world's airports today than at any other time in history. With this increase in civil transport, airports are becoming capacity limited. To increase capacity and thus meet the demands of the flying public, the number of runways and number of flights per runway must be increased. In response to the demand, the National Aeronautics and Space Administration (NASA), in conjunction with the Federal Aviation Administration (FAA), airport operators, and the airline industry are taking steps to increase airport capacity without jeopardizing safety. Increasing the production per runway increases the likelihood that an aircraft will encounter the trailing wake vortex of another aircraft. The hazard of a wake vortex encounter is that heavy load aircraft can produce high intensity wake turbulence, through the development of its wing-tip vortices. A smaller aircraft following in the wake of the heavy load aircraft will experience redistribution of its aerodynamic load. This creates a safety hazard for the smaller aircraft. Understanding this load redistribution is of great importance, particularly during landing and take-off. In this research wake vortex effects on an encountering 10% scale model of the B737-100 aircraft are modeled using both strip theory and vortex lattice modeling methods. The models are then compared to data taken in the 30 ft x 60 ft wind tunnel at NASA Langley Research Center (LaRC). The accuracy of the models for a reduced geometry, such with the horizontal stabilizer and the vertical tail removed, is also investigated. Using a 10% error in the circulation strength and comparing the model's results with the experiment illustrates the sensitivity of the models to the vortex circulation strength. It was determined that both strip theory and the vortex lattice method give accurate results when all the geometrical information is used. When the horizontal stabilizer and vertical tail were removed there were difficulties modeling the side force coefficient and pitching moment. With the removal of only the vertical tail unacceptable errors occurred when modeling the side force coefficient and yawing moment. Lift could not be accurately modeled with either the full geometry or the reduced geometry.

Smith, S. T.

"INVESTIGATION OF WAKE VORTEX AIRCRAFT ENCOUNTERS; FINAL REPORT"

USGRDR0122, March 1999, Howard University, Washington, DC

The National Aeronautics and Space Administration is addressing airport capacity enhancements during instrument meteorological conditions through the Terminal Area Productivity (TAP) program. The major goal of the TAP program is to develop the technology that will allow air traffic levels during instrument meteorological condition to approach those achieved during visual operations. The Reduced Spacing Operations (RSO) subelement of TAP at the NASA Langley Research Center (LaRC) will develop the Aircraft Vortex Spacing System (AVOSS). The purpose of the AVOSS is to integrate current and predicted weather conditions, wake vortex transport and decay knowledge, wake vortex sensor data, and operational definitions of acceptable strengths for vortex encounters to produce dynamic wake vortex separation criteria. The proposed research is in support of the wake vortex hazard definition component of the LaRC AVOSS development research. The research program described in the next section provided an analysis of the static test data and uses this data to evaluate the accuracy vortex/wake-encounter models. The accuracy of these models has not before been evaluated using experimental data. The research results also presented the first analysis of the forces and moments imparted on an airplane during a wake vortex encounter using actual flight test data.

Smith, T. B. and MacCready, Jr., P. B.

"AIRCRAFT WAKES AND DIFFUSION ENHANCEMENT"

MRI63-FR-71, May 1963, Meteorology Research Inc., Altadena, CA

Studies have been made of the effect of an aircraft wake on the size and growth characteristics of a cloud of material disseminated from the aircraft. Smoke released from a Cessna 180 has been measured on several occasions to determine the dimensions of the wake at various distances behind the aircraft. Results indicate that the wake descends for a short time at a rate which approximates the calculated downwash velocity but soon slows appreciably to a much smaller descent rate. This effect limits the usefulness of the aircraft wake in downward propagation of material under light turbulence conditions.

Smith, W. G. and Lazzeroni, F. A.

"EXPERIMENTAL AND THEORETICAL STUDY OF A RECTANGULAR WING IN A VORTICAL WAKE AT LOW SPEED"

NASA TN-339, October 1960, NASA Ames Research Center, Moffett Field, CA

A systematic study has been made, experimentally and theoretically, of the effects of a vortical wake on the aerodynamic characteristics of a rectangular wing at subsonic speed. The vortex-induced lift was calculated by several theoretical methods including strip theory, reverse-flow theory, and reverse-

flow theory including a finite vortex core. In addition, the Prandtl-lifting-line theory and the Weissinger theory were used to calculate the spanwise distribution of vortex-induced loads.

Smits, A. J. and Kummer, R. P.

"THE INTERACTION AND MERGING OF TWO TURBULENT LINE VORTICES"

AIAA Paper No. 1985-0046, Reno, NV, January 1985

An experimental investigation of the interaction and merging of two turbulent line vortices is described. The vortices were generated by two airfoils set at opposite angles of attack, and they were of opposite sign and equal strength. As the vortices proceed downstream, they rotate around each other, and eventually they merge to produce a dominant, central vortex, with vestigial traces of the original vortices. Mean flow and turbulence measurements were made throughout the merging zone. The circulation profiles varied logarithmically with radius, for a considerable radial extent, at all stations. The turbulent shear stresses appeared to be simply related to the mean velocity gradients, and it seems that first-order turbulence models may be adequate to describe the merging process.

Snedeker, R. S.

"EFFECT OF AIR INJECTION ON THE TORQUE PRODUCED BY A TRAILING VORTEX"

J. Aircraft, Vol. 9, No. 9, September 1972, pp. 682-684

An experiment was performed to determine the effect of air injection on the torque produced by a trailing vortex. The results of this experiment was limited to measurement at a single axial station. It was shown that the torque induced by the vortex on a typical wing changes very little in the near field.

Snedeker, R. S.

"A COMPARISON OF THE TRAILING VORTEX MEASUREMENTS OF POPPLETON WITH INVARIANT MODELING COMPUTATIONS"

ARAP Tech. Memo 72-5, November 1972, Aeronautical Research Assoc. of Princeton, Princeton, NJ

The trailing vortex measurements made in a wind tunnel by Poppleton were used as a basis for comparison with computations made by application of the invariant modeling method. The measured profiles of mean and turbulent velocity at a point downstream of the vortex generator were used as initial conditions for the computation. A comparison was then made between the measured and computed profiles at a point further downstream. The comparison revealed that the computation, which was based on a two-dimensional form of the theory, gave poor agreement with the measured data, except in the case of the mean tangential velocity. It was concluded that the lack of agreement was primarily a result of the strong axial or three-dimensional effects which were evident throughout most of the range of the measurements. It was suggested that a form of the theory in which axial

effects are included, and which is now under development at A.R.A.P., would be more appropriate for application to flows of the type studied by Poppleton.

Snedeker, R. S. and Bilanin, A. J.

"ANALYSIS OF THE VORTEX WAKES OF THE BOEING 727, LOCKHEED L1011, MCDONNELL DOUGLAS DC-10, AND BOEING 747 AIRCRAFT"

ARAP Report 245, July 1975, Aeronautical Research Assoc. of Princeton, Princeton, N.

A study has been made of the vortex wakes behind B-727, L1011, DC-10, and B-747 aircraft in several flight conditions. An analytical method is developed for the computation of the wake vortex patterns and their velocity profiles for these aircraft. The method, which is based on an extension of the Betz method for an inviscid wake, is further modified to include the effects of distributed wing drag and the computation of axial velocity profiles. Comparisons are made between wake vortex swirl velocity profiles computed for these aircraft and corresponding measurements made by the FAA in full-scale flyby tests. The results indicate that the inviscid calculation works well for simple wakes containing one predominant pair of vortices, such as those shed with the aircraft in its cruise or holding configuration. With flaps deployed for takeoff or landing, these aircraft, because of the segmented design of their flaps, produce complex wakes, which may contain as many as five pairs of vortices. It is concluded that the effects of drag on the inviscid structure of the vortices are small.

Snel, H. and van Holten, Th.

"REVIEW OF RECENT AERODYNAMIC RESEARCH ON WIND TURBINES WITH RELEVANCE TO ROTORCRAFT; DATA (AND RIDDLES) ON DYNAMIC INFLOW, FLOW FIELD OF YAWED ROTORS, AND ROTATING 3-D STALL"

Aerodynamics and Aeroacoustics of Rotorcraft, AGARD-CP-552, August 1995, pp. 7-1 to 7-11.

A review is given of recent research on the aerodynamics of wind turbine rotors. The following subjects are covered in extenso: The induced velocity field of rotors, including dynamic inflow and yawed flow effects. Stall delay on rotating blades, a new boundary layer formulation is outlined applicable to this phenomenon. Without any further discussion, also some references have been given concerning recent wind turbine research on: simulation methods of atmospheric turbulence, dynamic stall effects and comparisons between theory and experiments, and effect of several types of blade tips on radiated noise.

"PHOTOGRAMMETRIC TECHNIQUE USING ENTRAINED BALLOONS FOR IN-FLIGHT RANGING OF TRAILING VORTICES"

NASA TM-4129, October 1989, NASA Langley Research Center, Hampton, VA

A novel method for experimentally determining the radial distance of a probe aircraft from a trailing vortex is described. The method relies on photogrammetric triangulation of targets entrained in the vortex core. The report describes the theory and preliminary testing using laboratory mock-ups.

Snyder, D. and Memory, C.

"A MODIFIED VORTEX ALGORITHM FOR LOW REYNOLDS NUMBER, LOW ASPECT-RATIO WINGS"

AIAA Paper 2005-4608, June 2005, Toronto, Canada.

A numerical algorithm based on Prandtl's lifting line theory is developed and applied to low Reynolds number aerodynamic force prediction for wings with low aspect ratio. The algorithm accounts for Reynolds number through viscous effects on the two-dimensional section lift and drag forces. Improved low aspect-ratio behavior is achieved by allowing the trailing vortex sheet to roll up with the wing tip vortices. The results of the algorithm are compared with experimental measurements.

Snyder, Jr., M. H.

"EFFECTS OF A WINGTIP-MOUNTED PROPELLER ON WING LIFT, INDUCED DRAG, AND SHED VORTEX PATTERN"

Ph.D. Thesis, May 1967, Oklahoma State University, Stillwater, OK

Experimental investigations of the use of end-plates to control and to vary the wing lift distribution and induced drag are reviewed. An experimental investigation of a reflection-plane wing with a nacelle and propeller mounted at the wingtip is reported. Use of a rotor turning in the direction opposite to that of the wing's trailing vortex shifts the core of the trailing vortex outboard and downward. Use of a pro-vortex rotating rotor moves the core inboard. A counter-vortex turning propeller decreased drag; a vortex-turning propeller increases drag.

Snyder, T. and Povitsky, A.

"FAR-FIELD INDUCED DRAG PREDICTION USING VORTICITY CONFINEMENT TECHNIQUE"

Journal of Aircraft, Vol. 51, No. 6, November-December 2014, pp. 1953-1958.

The goal of this study is to show the efficiency of the wake-integral technique coupled with vorticity confinement method for the prediction of induced drag by inviscid numerical modeling. While the vorticity confinement method has previously been used to capture trailing vortices, its quantitative effect on improving wake-integral drag prediction has not been investigated. In the present study, parameters of vorticity confinement are tuned and the advantages of using a variable confinement parameter are demonstrated. A combination of vorticity confinement with the wake-integral technique indicates that the computational fluid dynamics-predicted induced drag for wing with and without winglet becomes insensitive to wake-integration plane location, the computed drag approaches its theoretical lifting-line value, and the spurious drag is suppressed.

So, J., Ryan, K. and Sheard, G. J.

"SHORT-WAVE INSTABILITIES ON A VORTEX PAIR OF UNEQUAL STRENGTH CIRCULATION RATIO"

Seventh International Conference on CFD in the Minerals and Process Industries, CSIRO, December 2009, Melbourne, Australia.

The creation of vortex pairs occurs in a range of industries, including mixing, transport, and plastic molding. In particular, vortex pairs are observed in the wake of aircraft, and are the cause of a significant hazard in the aviation industry. Instabilities, which grow on vortex pairs, have been shown to lead to rapid diffusion, thus limiting this safety concern. To date research has only considered instabilities growing on a vortex pair where each vortex has the same magnitude of circulation. However, in practice it is unusual to have an equal strength vortex pair. This investigation is the first to consider the instability modes that may develop on a Lamb-Oseen vortex pair of arbitrary circulation ratio. We find a significant change in the growth rates of all instability modes reported previously for an equal strength vortex pair. All simulations employ an accurate spectral-element method to discretize the domain coupled with a three-step time splitting scheme. A wide range of instability wavelengths is considered to ensure that all instability modes are captured. By identifying and enhancing the leading instability modes, we can enhance the dissipation of the vortex pair.

So, J., Ryan, K. and Sheard, G. J.

"LINEAR STABILITY ANALYSIS OF A COUNTER ROTATING VORTEX PAIR OF UNEQUAL STRENGTH"

Australian and New Zealand Industrial and Applied Mathematics Journal, Vol. 50, October 2008, pp. C137-C151.

An elliptic type instability of a counter rotating vortex pair of unequal strength was numerically investigated with a linear stability analysis method. The peak growth rates of the unstable modes were predicted. The instability characteristics were found to differ from an equal strength vortex pair, of either co-rotating or counter rotating vortices. This investigation serves as a fundamental model to the flow of two unequal strength vortices, which can be generated from the ends of aerodynamic surfaces of an aircraft, such as wing tips and ailerons. These results provide predictions of the vortex arrangements likely to develop three dimensional instabilities, which is known to promote the dissipation of the underlying vortex structure.

Sohn, M. H. and Chang, J. W.

"VISUALIZATION AND PIV STUDY OF WING-TIP VORTICES FOR THREE DIFFERENT TIP CONFIGURATIONS"

Aerospace Science and Technology, April 2011, pp. 1-7.

The planform, profile, and cross-sectional views of the wing-tip region of a half-wing model with an aspect ratio of 3.2 and three different wing configurations, namely, square-cut, simple fairing, and

Whitcomb's full winglet wing-tip, were visualized at various angles of attack using smoke-wire visualization technique. Visualization pictures clearly show that the wing-tip vortices at different angles of attack and wing-tip configurations had distinct formation and structure characteristics. A comparison of simple fairing and Whitcomb's winglet configurations shows that the wing-tip vortices of the Whitcomb's winglet configuration were reduced in strength and displaced outboard and upward, at least in the near-wake region. This resulted in an increased lift-to-drag ratio for the Whitcomb's winglet configuration. The changes in the wing-tip vortex characteristics and the improved aerodynamic performance of the winglet were confirmed by Particle Image Velocimetry measurements of the cross-flow velocity of the wing-tip trailing regions and the force measurement of the model.

"EFFECTS OF STRAKE PLANFORM CHANGE ON VORTEX FLOW OF A DOUBLE-DELTA WING"

Journal of Aircraft, Vol. 44, No. 6, November-December 2007, pp. 1842-1848.

This study examines the effects of a strake planform change on the vortex characteristics of double-delta wings through wing-surface pressure measurements and the off-surface flow visualization of the wing-leeward flow region. Three different shapes of strakes (65/90 deg sweep cropped-delta, 79 deg sweep single-delta, and 72/84 deg sweep cropped-delta) were tested. The double-delta wing configuration with the 79 deg sweep single-delta shape strake produced a more concentrated vortex system at upstream locations and showed advanced coiling and downward movement of the strake and wing vortices compared with the other two configurations. However, the concentrated vortex system for the double-delta wing configuration with the 79 deg sweep single-delta shape strake tended to diffuse and break down much faster than the other two configurations as the flow proceeded downstream. The test results reveal that strake modification can greatly alter flow pattern around a double-delta wing.

"VORTEX FLOW VISUALIZATION OF A YAWED DELTA WING WITH LEADING-EDGE EXTENSION"

Journal of Aircraft, Vol. 41, No. 2, March-April 2004, pp. 231-237.

The development and interaction of vortices over a yawed delta wing with leading-edge extension (LEX) was investigated through off-surface flow visualization using micro water droplets and a laser beam sheet. Angles of attack of 12, 16, 20 and 24 deg were tested at sideslip angles of 0, -5 and -10 deg. The flow Reynolds number based on the main-wing chord was 182,000. The wing vortex and the LEX vortex coiled around each other while maintaining comparable strength and identity at a zero sideslip. The increase of angle of attack intensified the coiling and shifted the cores of the wing and LEX vortices inboard and upward. By sideslip, the coiling, the merging and the diffusion of the wing and LEX vortices increased on the windward side, whereas they became delayed significantly on the leeward side. Also, the migration behavior of vortices on the windward and leeward sides of the wing changed considerably. The present study confirms that the sideslip angle has a profound effect on the vortex

structure and interaction of a delta wing with LEX, which characterized the vortex-induced aerodynamic load.

"NUMERICAL SIMULATIONS OF VORTEX SHEET EVOLUTION IN STRATIFIED SHEAR FLOW"

J. Physical Society of Japan, Vol. 74, 2005, pp. 1472-1478.

The nonlinear evolution of an interface subject to a parallel shear flow is studied based on the vortex sheet model. We perform numerical simulations of the vortex sheet in density stratified fluids by using the point vortex method. The numerical algorithm based on two types of regularization method improves the stability of the vortex method and provides solutions with much higher resolutions than previous results. The numerical results show that, for a smaller density ratio, the interface has a larger growth rate and a more singular vortex sheet strength and curvature at late times. It is also found that, for an infinite density ratio, the interface has a solution of a traveling wave with no deformations.

"INTERACTION OF TIP VORTICES GENERATED BY TWO BLADED ROTOR COMPOSED OF DIFFERENT PITCH ANGLES IN A HOVER"

AIAA Paper No. 2011-0678, January 2011, Orlando, FL.

Interaction between tip vortices generated by two bladed rotors with slightly different pitch angles was investigated with the use of laser Doppler velocimetry. The velocity field was measured at 20 different wake ages within one revolution of rotor blade. The swirl velocity of the tip vortex generated by the first blade was found to have a self-similar behavior while that of the second blade was distorted in radial direction by the effect of vortex trail induced by the first blade. The axial velocity components of both tip vortices showed the merging process of both vortex filaments near the 236 degrees of wake age. The vortex core was substantially reduced in merging region making the vortex strength increase temporarily. Core growth, empirical model correlation for both swirl and axial velocity components were observed, and stretched filament of tip vortices was also found.

"PERFORMANCE OF ONBOARD WAKE-VORTEX PREDICTION SYSTEMS EMPLOYING VARIOUS METEOROLOGICAL DATA SOURCES"

Journal of Aircraft, Vol. 53, No. 5, September-October 2016, pp. 1505-1516.

In this work the accuracy of wake-vortex prediction of DLR's wake encounter avoidance and advisory system (WEAA) is analyzed by means of data gathered from a flight test campaign in April 2014. The system is based on airborne data exchange between aircraft and allows pilots to avoid potentially dangerous wake-vortex encounters. As the vortex evolution is strongly controlled by atmospheric

parameters, the acquisition of meteorological data is crucial for WEAA. The accuracy of the wake-vortex prediction is investigated, employing first the current automatic dependent surveillance (ADS-B) standard, which is then extended by additional meteorological data transmitted via telemetry, or data from numerical weather predictions.

"HUMAN-IN-THE-LOOP INVESTIGATION OF VARIABLE SEPARATION STANDARDS IN THE EN ROUTE AIR TRAFFIC CONTROL ENVIRONMENT"

Proceedings of the Human Factors and Ergonomics Society, 55th Annual Meeting, 2011, pp. 66-70.

Human factors researchers from the FAA William J. Hughes Technical Center conducted a human-in-the-loop simulation to investigate variable lateral separation standards in the enroute air traffic control environment. Twelve Certified Professional Controllers participated in the study. In addition to the typical 5-mile separation standard for the en route environment, we used reduced and increased separation requirements in the study. We simulated reduced separation requirements (i.e., 3 miles) using a Single Sensor Radar Site Adaptation as well as for aircraft with either Automatic Dependent Surveillance-Broadcast or Performance-Based Navigation equipment. We simulated increased separation (i.e., 10 miles) for Unmanned Aircraft Systems. In addition, we simulated variable wake turbulence separation requirements for Airbus 380s and Very Light Jets. We also developed a set of support tools to assist the controllers in using the variable separation procedures. We identified several human factors issues that may affect air traffic controllers when using variable separation standards in the en route environment.

"EXPERIMENTAL INVESTIGATION OF THE EFFECT OF VARIOUS WINGLET SHAPES ON THE TOTAL PRESSURE DISTRIBUTION BEHIND A WING"

ICAS 2004, Paper 2004-2.11.3, Aug.-Sept. 2004, Yokohama, Japan.

A series of low-speed wind tunnel tests to investigate the effect of different winglet shapes and orientations on the flowfield of a swept wing were conducted. Both surface pressure and wake data at various angles of attack, -10 to 15 degrees were measured. Further, the flowfield around the wing is visualized using tufts. Four types of winglet shapes, spiroid (forward and aft), blended and wing grid are used in this investigation. The wake profile behind the wing at various angles of attack with different winglets is measured, too. Furthermore, the effect of Turbulator strip on the wing upper surface is examined. Results are compared with conditions of no winglets. The results indicate that the presence of winglets change the flowfield over and around the wing significantly. The total pressure in the wake of the model varies drastically when the wing is equipped with winglets.

"ICE ACCRETION ON HELICOPTER FUSELAGE CONSIDERING ROTOR-WAKE EFFECTS"

Journal of Aircraft, Vol. 54, No. 2, March-April 2017, pp. 500-518.

To accurately predict the ice shape on the fuselage under rotor-wake effects, discrete modeling of individual tip vortices is essential to determine the local aerodynamic interactions between the vortex and the fuselage. To this end, the actuator surface model is developed and applied to the present study. Then, water-droplet-trajectory prediction, thermal analysis, and ice growth module are seamlessly integrated. This study aims to perform detailed analysis of the rotor downwash effects on ice that accretes on a helicopter fuselage and to determine the variation with respect to the forward flight speed. As a result of comprehensive numerical computations, the following conclusions are reached. First, the rotor inflow transforms the droplet trajectories, the location of ice accretion and the amount of ice are changed. 16.5 percent less ice is accumulated on the overall fuselage in the rotor-fuselage interaction case compared to the isolated fuselage case. Second, a clear-cut distinction of the icing locations on the fuselage is observed with various advance ratios. In hovering conditions, massive ice is accumulated on the tail-boom and fuselage nose region, where the tip vortices collide with fuselage. Due to the large collision area with high speed of droplets, 15.2 and 9.1 percent more ice is accumulated in hovering case than that of forward flight case with the advance ratio 0.075 and 0.15, respectively. However, as the forward speed grows from 0.15 to 0.2, the total mass of ice exponentially increases. In case of the advance ratio 0.2, 36 percent more ice is accumulated than that of the hovering case.

"DATA ANALYSIS STUDY AND PERFORMANCE EVALUATION OF THE SCANNING LASER DOPPLER SYSTEM"

Interim Report NAS-8-30795, December 1974, Raytheon Company, Sudbury, MA

This report describes the data analysis performed on the laser Doppler system data to evaluate system performance, develop vortex location algorithms, and obtain vortex transport data during testing at Marshall Space Flight Center and early operations at JFK International Airport.

Sonnenschein, C. M., DiMarzio, C. A., Clippinger, D. H. and Toomey, D. W.

"AVIATION SAFETY RESEARCH AND TECHNOLOGY/HAZARD AVOIDANCE AND ELIMINATION"

Interim Report NAS-8-30795, October 1975, Raytheon Company, Sudbury, MA

This report describes the data analysis performed on the data from the Scanning Laser Doppler System during tests at Marshall Space Flight Center and at JFK International Airport through May 1975. Vortex tracks and flow fields are considered with several hundred tracks analyzed to determine data quality and average parameters of vortex tracks from different aircraft in different wind conditions.

Sonnenschein, C. M., DiMarzio, C. A., Clippinger, D. H. and Toomey, D. W.

"AVIATION SAFETY RESEARCH AND TRANSPORTATION/HAZARD AVOIDANCE AND ELIMINATION"

ER 76-4220, August 1976, Raytheon Company, Sudbury, MA

Data collected by the Scanning Laser Doppler Velocimeter System (SLDVS) was analyzed to determine the feasibility of the SLDVS for monitoring aircraft wake vortices in an airport environment. Data were collected on atmospheric vortices and analyzed. Over 1600 landings were monitored at Kennedy International Airport and by the end of the test period 95 percent of the runs with large aircraft were producing usable results in real time. The transport was determined in real time and post analysis using algorithms which performed centroids on the highest amplitude in the thresholded spectrum. Making use of other parameters of the spectrum, vortex flow fields were studied along with the time histories of peak velocities and amplitudes. The post analysis of the data was accomplished with a CDC-6700 computer using several programs developed for LDV data analysis.

"REMOTE DETECTION OF TRAILING VORTICES"

NAS-8-30512, February 1970, Raytheon Company, Sudbury, MA

This report summarizes the results of the first successful remote detection of vortices with a CO₂ laser system. Sample signal spectra of vortices were obtained and results were compared with visualizations of the vortex made possible by introducing smoke into the flow field.

Sorbjan, Z.

"SIMILARITY OF STABLY STRATIFIED GEOPHYSICAL FLOWS"

In Aviation Turbulence, edited by R. Sharman and T. Lane, Chapter 21, 2016, Springer International Publishing Switzerland, pp. 425-440.

The article reviews the gradient-based similarity theory of shear-dominated, stably-stratified turbulent flows. The gradient-based similarity scales are classified as explicit or implicit. The explicit

scaling employs the length scale as a specified function of height. Within the implicit type, the mixing length is locally related to various moments of turbulence. The analytical form of the explicit similarity functions of the Richardson number Ri is obtained based on experimental data collected in the atmospheric surface layer. The implicit similarity functions can be derived by renormalization of the explicit-type expressions. Since the implicit scales and similarity functions are not directly dependent on height, they are expected to be universally valid in shear-driven, stably-stratified turbulent flows, in the atmospheric boundary layer and in the upper atmosphere.

"REQUIREMENTS FOR INTEGRATED FLIGHT AND TRAFFIC MANAGEMENT DURING FINAL APPROACH"

IEEE Plans '92 - Position Location and Navigation Symposium, Monterey, CA, March 1992, pp. 248-255

It is pointed out that significant runway throughput is lost due to ineffective control of aircraft spacing during final approach. The solution is to integrate the terminal air traffic management (ATM) automation process with cockpit avionics via data link. Components of the ultimate integrated ATM-cockpit design might include (a) an ATM spacing algorithm that accounts for wake vortex and runway occupancy spacing constraints; (b) downlink of desired final approach speed profile; (c) uplink of desired spacing and threshold crossing times; (d) a heads-up traffic display to provide pilot spacing guidance; (e) a flight management system to drive the aircraft to meet timing requirements; and (f) an ATM display to allow close monitoring of the landing process. The research required to develop this integrated ATM-cockpit concept is presented.

Sorensen, J. N.

"INSTABILITY OF HELICAL TIP VORTICES IN ROTOR WAKES"

Journal of Fluid Mechanics, Vol. 682, 2011, pp. 1-4.

The conditions for the appearance of instabilities in systems of helical vortices constitute an intriguing problem that still remains partly unsolved. The experimental study of Felli, Camussi and Di Felice has shed new light on some of the basic mechanisms governing the instability mechanisms.

Sorensen, J. N., Naumov, I. V. and Okulov, V. L.

"MULTIPLE HELICAL MODES OF VORTEX BREAKDOWN"

Journal of Fluid Mechanics, Vol. 683, 2011, pp. 430-441.

Experimental observations of vortex breakdown in a rotating lid-driven cavity are presented. The results show that vortex breakdown for cavities with high aspect ratios is associated with the appearance of stable helical vortex multiplets. By using results from stability theory generalizing Kelvin's problem on vortex polygon stability, and systematically exploring the cavity flow, we succeeded

in identifying two new stable vortex breakdown states consisting of triple and quadruple helical multiplets.

"ADAPTING AND CALIBRATION OF EXISTING WAKE MODELS TO MEET THE CONDITIONS INSIDE OFFSHORE WIND FARMS"

Report 5899, February 2008, EMD International A/S, Aalborg, Denmark.

The project has as purpose to improve the existing PARK models for calculating the wake loss within wind farms with a special emphasis on large offshore wind farms. The existing models are based on wind farms consisting of few onshore turbines and while there is no work underway to produce better models, developers and planners must use the existing models. These existing models are suspected of being inadequate at handling large offshore wind farms, but as this project shows, an intelligent use of model parameters can reduce the error and uncertainty when using them. Sensitivity studies are made and the models are tested and demonstrated through three case examples.

Sorokin, A. M. and Vladimirova, N. A.

"ALGORITHMS FOR GENERATION OF THE GRIDS FOR SOLVING EULER EQUATIONS AND COMPUTING FLOW FIELDS ABOUT AIRCRAFT CONFIGURATIONS (WING+FUSELAGE+TAIL, WING+SLOTTED FLAP) UNDER UNIFORM AND VORTEX FREESTREAM CONDITIONS"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 66-7.

Reasonably simple and effective algorithms are developed for generating computational grids around such complex configurations as wing + fuselage + tail and wing + slotted high-lift device (flap) to study multi-core vortex structures and determining aircraft aerodynamic characteristics under uniform and disturbed vortical freestream conditions. Advantages and disadvantages are analyzed to evaluate various approaches to constructing surface and off-surface (3D - spatial) grids around complex geometry bodies: composite overlapping 'chimera'-type grids, multi-block and single-block structured grids, etc. A technology is proposed of 'fitting' the horizontal and vertical tails and wing high-lift slotted device into the grid topology around simpler configurations (wing, wing + fuselage). New gridding algorithms are combined with the code EULERCON that solves the 3-D Euler equations and modified solver versions are developed that incorporate additional aircraft surfaces (tail unit and flaps).

Sotiropoulos, F., Webster, D. R. and Lackey, T. C.

"EXPERIMENTS ON LAGRANGIAN TRANSPORT IN STEADY VORTEX-BREAKDOWN BUBBLES IN A CONFINED SWIRLING FLOW"

J. Fluid Mech., Vol. 466, 2002, pp. 215-248

In a recent study, Sotiropoulos et al. (2001) studied numerically the chaotic particle paths in the interior of stationary vortex-breakdown bubbles that form in a closed cylindrical container with a rotating lid. Here we report the first experimental verification of these numerical findings along with new insights into the dynamics of vortex-breakdown bubbles. We visualize the Lagrangian transport within the bubbles using planar laser-induced fluorescence (LIF) and show that even though the flow fields are steady - from the Eulerian standpoint - the spatial distribution of the dye tracer varies continuously, and in a seemingly random manner, over very long observation intervals. Sequences of instantaneous LIF images also show that the steady bubbles exchange fluid with the outer flow via random bursting events during which blobs of dye exit the bubble through the spiral-in saddle. The experimental Poincare maps are in good agreement with the numerical computations. We apply this method to visualize the dynamics in the interior of the vortex-breakdown bubble that forms in the wake of the first bubble for governing parameters in the steady, two-bubble regime. In striking contrast with the asymmetric image obtained for the first bubble, the time-averaged light intensity field for the second bubble is remarkably axisymmetric. Numerical computations confirm this finding and further reveal that the apparent axisymmetry of this bubble is because orbits in its interior exhibit quasi-periodic dynamics. We argue that this stark contrast in dynamics should be attributed to differences in the swirl-to-axial velocity ratio in the vicinity of each bubble. By studying the bifurcation of a simple dynamical system, with manifold topology resembling that of a vortex-breakdown bubble, we show that sufficiently high swirl intensities can stabilize the chaotic orbits, leading to quasi-periodic dynamics.

Soudakov, G. G.

"NONLINEAR ASYMPTOTIC MODEL OF THE FAR VORTEX WAKE BEHIND AN AIRCRAFT FLYING THROUGH THE TURBULENT AIR"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 162-175

The paper considers evolution of several endless vortex filaments having a specified internal structure with accounting for the ground proximity and air turbulence effects. The vortex filaments are divided into rectilinear segments and the velocities induced by them are calculated using the Biot-Savart formula. To evaluate a singularity appearing in determining the velocity at the point of the segment itself, asymptotic methods are used. The velocity at the point of a vortex filament is a sum of the velocities induced by vortex filaments and by a stochastic function that models the atmospheric turbulence. The atmospheric turbulence was modeled using the von Karman model. The problem on the evolution of vortex filaments was solved in the nonlinear formulation, that is, without an assumption that disturbance amplitudes are small as compared to the distance between the vortices. The vortex system lifetime was studied, depending on various parameters, as well as the physical effects associated with the presence of a multi-core structure. Both the case of symmetrical vortex filament motion and the general case are considered.

Soudakov, G. G.

"ENGINEERING MODEL OF THE WAKE BEHIND AN AIRCRAFT"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 95-110

This paper is devoted to the study of the aircraft vortex wake using an engineering approach based on similarity laws. The landing regime of an aircraft is considered where a multi-vortex wake system forms. Vortex parameters behind an aircraft are obtained both in the near field and in the far field with considering the circulation loss effect.

Soudakov, G. G. and Zamyatin, A. N.

"THEORETICAL AND EXPERIMENTAL INVESTIGATIONS OF EXTERNAL TURBULENCE EFFECT ON AIRCRAFT VORTEX WAKE"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

The problem under investigation was to obtain the real flight data about spatial kinematical and geometrical parameters of aircraft wake at various meteorological conditions. The flight conditions were close to the landing ones. Hot-wire measurements were made to obtain the flow fields of the mean velocity vector in the vortex area. Furthermore, as a result of measuring the mean velocity distribution in the vortex area the evaluation of the geometrical parameters of the vortex can be made. This information was supplemented by the geometrical parameter measurements using the visualization and stereophotogrammetric technique. In these investigations smoke visualization was used for the qualitative evaluation of the process of vortex forming and evolution and for measuring the geometrical vortex parameters as a function of time. CFD method of calculation of the near and far wake parameters is presented based on 2D RANS. A new non-linear two-scale eddy viscosity model is proposed which considers the presence of two greatly different turbulence scales (vortex turbulence scale is about 10 m, ambient atmosphere turbulence scale is about 200 m).

Soudakov, G. G., Voyevodin, A. V. and Zubtsov, A. V.

"ALLEVIATION OF THE VORTEX WAKE BEHIND AN AIRCRAFT"

In: Flight Safety, Aircraft Vortex Wake and Airport Operation Capacity - Collection of Papers, Trudy TsAGI, Vol. 2641, Publishing Dept. of TsAGI, Moscow, Russia, 1999, pp. 183-190

This work dwells upon the vortex wake behind a heavy aircraft. Vortex wake parameters characterizing the aircraft wake vortex hazards to an encountering aircraft are determined. Cases are considered where the most important among the parameters is the lifetime of the vortex wake. Using the model of a four-core vortex wake, it is shown that a redistribution of circulation over the wing could lead to a significant decrease in the wake lifetime. An assessment is made for a minimum possible landing value of the wake lifetime. Computation of flow about the B747-400 aircraft during landing has showed that variation of flap deviation angles could result in decreasing the vortex wake lifetime by a factor of 1.5 and 2 compared to a standard case.

"EVOLUTION OF A VORTEX IN GLOW DISCHARGE PLASMA"

Physics of Fluids, Vol. 17, May 2005, pp. 058102-1 to 058102-4

The evolution of a vortex in glow discharge plasma is studied analytically. Specifically, the mechanism of local energy deposition into the flow by the plasma is considered and its effect on the structure of an inviscid vortex is analyzed. The vortex is modeled by a set of Euler's equations while the energy transferred by the plasma into the gas is represented by Rayleigh mechanism. In this mechanism, the amount of heat addition is a function of local gas density. The analysis indicates that the plasma can have a considerable effect on the structure of a vortex. The inviscid calculations show that in a uniform discharge, a 1 cm vortex dies out in a fraction of a second.

"THE EXPERIMENTAL DETERMINATION OF THE MOMENTS OF INERTIA OF AIRPLANES"

NACA TR-467, January 1934, Langley Aeronautical Lab., Langley Field, VA

The application of the pendulum method to the experimental determination of the moments of inertia of airplanes is discussed in this report. Reference is made to the effects of the air, in which the airplane is immersed, on the swinging tests and to the procedure by which these effects are considered. This procedure has been used for some time, and the data on several airplanes for which the moments of inertia have been found are included.

Sousa, J. M. M. and Pereira, J. C. F.

"ROLLUP REGION OF A TURBULENT TRAILING VORTEX ISSUED FROM A BLADE WITH FLOW SEPARATION"

Experimental Thermal and Fluid Science, Vol. 20, 2000, pp. 150-161.

This paper presents the results of an experimental investigation on the near field of a tip vortex generated by a blade at moderate incidence. The experiments were conducted at $Re = 15000$ and the boundary layer over the blade separated around midchord on the upper surface. Laser-Doppler measurements of the turbulent flow ($Tu = 1.5$ percent) were performed at various stations downstream of the blade. The three components of the mean velocity field and turbulent attributes were quantified at cross-planes, characterizing both the blade wake and the tip vortex structure. This allowed the analysis of the rollup and initial stages of decay of the tip vortex in the light of known theories and models. The axial velocity defect at the center of the vortex core evolved as $(1/x)\log x$, without displaying any significant outgrowth imposed by the separated flow upstream. Momentum balances were also carried out at a station downstream to the conclusion of vortex rollup. The approximate axisymmetry of the flow field in the trailing vortex was used to formulate the balances in a cylindrical

coordinate system. Among other observations, it was seen that an adverse axial pressure gradient developed in the vortex core, which reinforced the tenacity of the axial velocity defect. In contrast, an area influenced by a favorable pressure gradient was found outside the core.

South, P.

"A SIMPLE THEORY OF VORTEX BURSTING"

Report LR-414, November 1964, National Research Laboratories, Ottawa, Canada.

This report proposes a simple model to explain the phenomenon of vortex bursting. The model considers the steady state axial pressure and momentum forces on an element of a vortex core in the presence of an external static pressure gradient, and the changes in core radius that must take place for this steady state to be maintained. A particular idealized vortex model is proposed, and it is shown that the vortex will grow infinitely rapidly when subjected to an external static pressure rise greater than a certain critical amount that depends on the initial core helix angle and axial dynamic pressure. Some experimental data are presented that show that the predictions are in fairly good agreement with the observed results.

Spahr, J. R.

"THEORETICAL PREDICTION OF THE EFFECTS OF VORTEX FLOWS ON THE LOADING, FORCES, AND MOMENTS OF SLENDER AIRCRAFT"

NASA TR R-101, 1961, NASA Ames Research Center, Moffett Field, C.

A general calculative method based on slender-body theory is developed for predicting the paths of vortices in the presence of wing-body combinations at subsonic, transonic, and supersonic speeds, and the influence of the vortices on the loading forces and moments acting on the combinations. The method is applied to wing-body combinations to study the effects of vortex strength and initial position, combined angles of pitch and roll and wing aspect ratio on the vortex paths and induced loads. The results indicate that these effects were significant because of the dependence of the vortex paths and induced loads on the vortex strengths and on the proximity of the vortices to the surface of a wing-body combination. Comparison of theoretical and experimental results indicated that the vortex paths and vortex-induced force and moments for slender-wing-body combinations were closely predicted by the slender-body method but for non-slender combinations these characteristics were only approximated. The application of an alternate method based on reverse flow theory improved the predictions of the vortex-induced forces and moments for the latter combinations but impaired those for slender combinations. The induced forces and moments on the non-slender combinations were sufficiently small that the total forces and moments could be predicted adequately through the use of either method.

Spahr, J. R. and Dickey, R. R.

"WIND-TUNNEL INVESTIGATION OF THE VORTEX WAKE AND DOWNWASH FIELD BEHIND TRIANGULAR WINGS AND WING-BODY COMBINATIONS AT SUPERSONIC SPEED"

NACA RM-A53D10, June 1953, Langley Aeronautical Lab., Langley Field, VA

The flow field behind triangular wings (aspect ratios of 0.67 to 4) alone and in combination with a pointed cylindrical body has been investigated at Mach numbers of 1.5 and 2.0 through an angle-of-attack range of 0 degrees to 24 degrees. The character of the vortex wake was observed by means of the vapor-screen flow-visualization technique, and certain regions of the downwash field associated with the observed vortex systems were surveyed. Estimates of the downwash distributions were also made using a method based on existing theories, and the results have been compared with experiment. The initial character and subsequent behavior of the wing trailing vortex wake with or without the body present were observed to vary significantly with the wing aspect ratio and with the angle of attack. For low-aspect-ratio wings at small angles of attack and for large-aspect-ratio wings throughout the test angle-of-attack range, the nature and behavior of the wake is in accord with theoretical predictions; that is, the vortex wake leaves the wing trailing edge as a sheet and proceeds to roll up into one or two (depending on the type of spanwise load distribution) regions of vorticity behind each wing panel as it progresses downstream.

Spaid, F. W. and Keener, E. R.

"BOUNDARY-LAYER AND WAKE MEASUREMENTS ON A SWEEPED, CIRCULATION-CONTROL WING"

J. Aircraft, Vol. 28, No. 11, November 1991, pp. 706-71.

Wind-tunnel measurements of boundary-layer and wake velocity profiles are presented for a swept, circulation-control wing. The model is a semispan, rectangular wing with a constant cross section mounted on the tunnel sidewall at a sweep angle of 45 deg. A circulation-control slot is located ahead of the trailing edge on the upper surface. Flow surveys were obtained at midsemispan at freestream Mach numbers of 0.425 and 0.70. Boundary-layer profiles measured on the forward portions of the wing are approximately streamwise and two dimensional. The flow in the vicinity of the jet exit and in the near wake is highly three dimensional. The jet flow near the slot on the Coanda surface is directed normal to the slot. Near-wake surveys show large outboard flows at the center of the wake. The variation in the lower-surface separation location with blowing rate was determined from boundary-layer measurements at Mach 0.425. In addition to providing an experimental description of a complex, three-dimensional flowfield, these data should serve as test cases for computational fluid dynamics methods.

Spalart, P. R.

"ON THE MOTION OF LAMINAR WING WAKES IN A STRATIFIED FLUID"

J. Fluid Mech., Vol. 327, November 1996, pp. 139-160

We present numerical solutions for 2D laminar symmetric vortex systems descending in a stably stratified fluid within the Boussinesq approximation. Three types of flow are considered: (I) tight vortices; (II) those deriving from an elliptical wing lift distribution; and (III) those deriving from a 'high-lift' distribution, with a part-span flap on the wing. The non-dimensional stratification ranges from zero to moderate, as it does for airliners. For types I and II, with high Reynolds numbers and weak stratification, the solutions confirm the theory of Scorer and Davenport (1970). Contrary to common conceptions and observations in small-scale experiments, the descent velocity increases exponentially with time, as the distance between vortices decreases and the circulation of the vortices proper is conserved. With moderate stratification, wakes with sufficient energy also attain the accelerating regime, until the vortices make contact. However, they first experience a rebound, which is both of practical importance and out of reach of simple formulas. We argue that airliner wakes have very little inherent diffusion, and that a rapid end to the wake's descent must reveal effects other than simple buoyancy. In particular, stratification promotes the Crow instability.

Spalart, P. R.

"WAKE-VORTEX PHYSICS: THE GREAT CONTROVERSIES"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 33-44

Several controversies are articulated, which are unresolved and seen to be serious obstacles to a consensus and to the use of scientific knowledge in wake-turbulence precautions and regulations. The questions are as follows. Do vortices decay? Why does ATC work today? Do wakes ever rise? What is the effect of stable atmospheric stratification? Are the vortices bathing in turbulence sustained by it (not atmospheric turbulence)? How much can happen to ONE vortex (destruction, cuts)? Better to use passive or active control strategy?

Spalart, P. R.

"AIRPLANE TRAILING VORTICES"

Annual Review of Fluid Mechanics, Vol. 30, Annual Reviews Inc., Palo Alto, CA, 1998, pp. 107-138

The formation, motion, and persistence of trailing vortices is surveyed, as relevant to the safety and productivity of air travel. Findings or shifts made since Widnall's 1975 Annual Review article are highlighted. Examined are the predictability of the vortices, particularly in terms of lifespan; the durability of multiple vortex pairs; the controversy between expectations of vortex decay and of vortex collapse; the many types of turbulence that may influence the flow; the rich interplay between the rotational and the axial velocity fields in the vortex; the various atmospheric and ground-related factors that dominate the late behavior; a few instances of wakes rising back; and the still unexplained bursting of the vortices. Prospects for detection and control are briefly covered.

Spalart, P. R.

"ON THE FAR WAKE AND INDUCED DRAG OF AIRCRAFT"

J. Fluid Mech., Vol. 603, 2008, pp. 413-430

A set of matched asymptotic expansions is proposed for the flow far behind an aircraft, with the primary purpose of identifying lift, thrust and drag, particularly induced drag, in a unified manner in integral statements of the momentum equation. The fluid in the far wake is inviscid and incompressible, and variations of total pressure are allowed, as are vortex sheets. A notable feature is that the Trefftz-plane approximation is not invoked; instead, the wake is taken as fully rolled-up, and the analysis proceeds without the assumption of light loading. Attention is paid to the absolute convergence of integrals over infinite domains and handling of discontinuities. The expansion includes a sink term, which appears new, so that the mass flux through a transverse plane is non-zero, as is the flux of mechanical energy. The lift can be formally attributed to the velocity induced by the bound vortex of the wing, which is at odds with some treatments, although consistent with Prandtl's analysis over a ground plane.

Spalart, P. R.

"HOW CAN WE TRULY REDUCE THE WAKE-VORTEX HAZARD BY MODIFYING THE WING?"

Conference on Capacity and Wake Vortices, Imperial College of Science, Technology and Medicine, London, England, September 2001

The airframers wish to contribute to the combination of safety and airport capacity, in the context of wake turbulence. When viewing the airplane as the leader, the airframers are ready for limited compromises to make the wakes less troublesome. Characteristics that may be traded for this include: drag, lift, weight, complexity, control authority, pilot workload, or noise. The Airbus A380 is the first model for which such steps are, to our knowledge, being taken. Here we attempt to concretely identify what could make a less troublesome wake. A classic trade between wake properties involves the circulation and the effective span of a single vortex pair. Given the weight and speed, circulation times effective span is fixed. Lowering circulation makes a weaker wake, and encounters are less severe. However the wake descends more slowly, and its Crow instability grows more slowly; the wake lingers. Both effects increase the probability of an encounter. Thus, the preference between circulation and effective span depends on the policy (avoidance or tolerance of encounters) and on factors such as the leader and follower sizes, actual in-trail separation, phase of flight, and weather. The trade is not simple. Flow-control designs can be classified as active, when the configuration is varied cyclically to initiate an instability, or passive. Boeing's active system is discussed in this volume. The aim is wake collapse. Approaches such as tip turbines appear intermediate but are closer to passive systems, in that they divide and displace the vortices, and/or increase mixing. Most passive designs use a static geometry, winglets for example. The trade between circulation and effective span leaves little room. The known passive designs are presumed to produce 'weaker' wakes, for the same circulation and effective span, making encounters less violent. The aim is wake alleviation. Common measures of a

wake's threat include the peak vorticity, peak velocity, and kinetic energy. Useful changes to these will be very difficult to demonstrate.

"INITIATION OF THE CROW INSTABILITY BY ATMOSPHERIC TURBULENCE"

Proceedings of 78th Fluid Dynamics Panel Symposium, Characterization and Modification of Wakes from Lift: Vehicles in Fluids, AGARD, CP-584, Trondheim, Norway, May 1996, pp. 18-1 to 18-8

The interaction between vortex pairs and well-developed isotropic turbulence is studied by Direct Numerical Simulation. It is a model of the effect of natural environmental disturbances on airplane wakes. The nondimensional turbulence intensity is in the range (0.02, 0.5), typical of airplanes. The most-amplified wavelength of the Crow instability is placed within the inertial range of the turbulence, which is typical in the atmosphere and fits the theoretical setting of Tombach and Crow & Bate. The vorticity peaks in cross-flow planes are tracked to reveal the deformation of the vortices. In agreement with visual observations, the Crow instability dominates in weak turbulence, whereas chaotic deformations are seen in stronger turbulence. The average wavelength is about 27% shorter than the most amplified one. The beginning of destruction is identified with the first changes in the connectivity of the lines; identifying the end of destruction is more elusive. The wake lifespans overlap those from flight tests, laboratory tests, and the theory of Crow & Bate. However, in strong turbulence, theory and simulation both predict shorter average lifespans than the tests do. The scatter in lifespans is almost as large in simulations as in flight tests; thus, the intermittence of turbulence appears to explain the scatter even without any other differences in conditions. We conclude that the predictability of wake destruction by this mechanism is very poor.

"MODELING THE INTERACTION OF A VORTEX PAIR WITH THE GROUND"

Fluid Dynamics, Vol. 36, No. 6, 2001, pp. 899-908

The results of a numerical investigation of the interaction between an aircraft vortex wake (vortex pair) and the ground during the takeoff and landing phases are presented. The calculations were performed within the framework of the time-dependent two-dimensional Reynolds-averaged Navier-Stokes equations using the Spalart-Shur turbulence model generalizing the turbulent viscosity transport model of Spalart and Allmaras to the case of the flows with curved streamlines and rotation. Similar calculations were carried out based on the original Spalart-Allmaras model and the k- ω model of Menter. Some new qualitative and quantitative data on the distinctive features of the phenomenon under consideration are obtained.

Spalart, P. R., Strelets, M.-Kh., Travin, A. K. and Shur, M. L.

"MODELING THE TURBULENT VORTEX WAKE BEHIND A HIGH-LIFT WING"

Fluid Dynamics, Vol. 36, No. 5, 2001, pp. 726-733

A mathematical model and the results of a numerical simulation of the multiple vortex structure behind the high-lift wing (with deflected flaps) of a civil aircraft model are presented. The calculations are performed within the framework of the simplified (with allowance for the specific features of the flow under consideration) three-dimensional Reynolds equations using three turbulence models. The results obtained are compared with the experimental data; a considerable influence of the streamline curvature, typical of vortex flows, not only on the turbulence parameters but also on the parameters of the average flow is demonstrated. As a result, only one of the turbulence models considered, namely, that taking the streamline curvature and rotation effects on the turbulence into account, ensures acceptable accuracy of the main wake characteristics.

Spall, R. E.

"TRANSITION FROM SPIRAL- TO BUBBLE-TYPE VORTEX BREAKDOWN"

Phys. Fluids, Vol. 8, No. 5, May 1996, pp. 1330-1332

Numerical calculations employing the fully three-dimensional, time-dependent Navier-Stokes equations have been utilized to compute a transition from spiral- to bubble-type vortex breakdown for an unconfined longitudinal vortex. The transition was initiated through a small increase in the magnitude of the free-stream axial velocity deceleration. The resulting bubble structure, which consisted of a single toroidal recirculation cell, ultimately grew unstable. Transition back to a stronger spiral breakdown followed. Results are in qualitative agreement with experimental observations.

Spall, R. E.

"NUMERICAL STUDY OF A WING-TIP VORTEX USING THE EULER EQUATIONS"

Journal of Aircraft, Vol. 38, No. 1, January-February 2001, pp. 22-27

The issue of excessive diffusion of wing-tip vortex calculations is addressed. In particular, a second-order accurate pressure-based finite volume algorithm was employed to solve the Euler equations for the flow over a NACA 0012 rectangular wing at an angle of attack of 5 deg. A computational mesh was constructed that allowed for very localized grid clustering about the wing tip and about the vortex centerline over arbitrary downstream distances. Comparisons with existing experimental data show that the vortex strength and core radius are well preserved at 10 chords downstream from the wing leading edge. It is concluded that by employing well-designed computational grids, second-order accurate numerical algorithms may present a viable alternative to higher-order schemes in the solution of the tip vortex problem.

Spall, R. E. and Gatski, T. B.

"TURBULENT VORTEX BREAKDOWN: A NUMERICAL STUDY"

IUTAM Symposium on Dynamics of Slender Vortices, Aachen, Germany, August 31-September 3, 1997

Three-dimensional and axisymmetric solutions to the Reynolds-averaged Navier-Stokes equations have been obtained for turbulent vortex breakdown within a slightly diverging tube. Inlet boundary conditions were derived from experimental data for the mean flow and turbulence kinetic energy provided by Sarpkaya (Private Communications). The performance of both two-equation and full differential Reynolds stress models is evaluated. The experimentally determined location of breakdown was well predicted by the differential Reynolds stress model. However, the two-equation models failed to predict the occurrence of breakdown. Failure of the two-equation models is attributed to their inability to accurately account for Reynolds stress anisotropies. Further comparisons between the experimental data of Sarpkaya and the Reynolds stress model results are presented and discussed.

Spall, R. E., Gatski, T. B. and Grosch, C. E.

"A CRITERION FOR VORTEX BREAKDOWN"

Phys. Fluids, Vol. 30, No. 11, November 1987, pp. 3434-3440

A criterion for the onset of vortex breakdown over a wide range of the Reynolds number is proposed. Based upon previous experimental, theoretical, and numerical studies, as well as a new numerical study, an appropriately defined local Rossby number is used to delineate the region where breakdown occurs. Comparisons are made with previously suggested criticality parameters and the unique features of the proposed Rossby number parameter are shown. Several previous theoretical studies concentrating on inviscid standing-wave analyses for trailing wing-tip vortices are reviewed and reinterpreted, along with the previous numerical and experimental studies, in terms of the Rossby number parameter. For the case of trailing wing-tip-type vortices, it is shown that previous numerical studies were performed at lower Reynolds numbers than the corresponding laboratory experiments. Utilizing a consistently defined Reynolds number, Rossby number-Reynolds number plots of these previous vortex breakdown studies, for both trailing wing-tip and leading-edge vortices, are obtained. A criticality condition is identified for both types of vortices.

"ASSESSMENT OF A WAKE VORTEX FLIGHT TEST"

NEAR-TR-48, July 1974, Nielsen Engineering and Research Inc., Mountain View, CA

A proposed flight test program to measure the characteristics of wake vortices behind a T-33 aircraft was investigated. Several facets of the flight tests were examined to define the parameters to be measured, the anticipated vortex characteristics, the mutual interference between the probe aircraft and the wake, the response of certain instruments to be used in obtaining measurements, the effect of condensation on the wake vortices, and methods of data reduction. Recommendations made as a result of the investigation are presented.

Sparaco, P.

"TEST FACILITIES INAUGURATED"

Aviation Week & Space Technology, Vol. 158, No. 3, January 2003, p. 53

A European technology program dubbed Aircraft Wing with Advanced Technology Operations (Awiator) is expected to significantly advance studies on airflow control, wake vortices and aeroelasticity. In an initiative set to support the European Commission's (EC) four-year program, Onera French aerospace research agency has completed an innovative free-flight laboratory. It will enable scientists to scrutinize flight characteristics of catapult-launched scale models of aircraft, visualized with the help of a smoke screen. Measurements will be recorded on 20 video cameras while turbulence, vertical and lateral wind gusts will be generated by sophisticated simulation systems. Such tests are scheduled to complement earlier studies on the Airbus A380 mega-transport's wake vortices and, if needed, could help aviation authorities determine revised horizontal separations between heavy transports during final approach.

Spearman, M. L.

"INNOVATIVE CONCEPT FOR A HEAVY-LOAD AIRCRAFT UTILIZING A TWO-DIMENSIONAL WING"

AIAA Paper No. 2007-4439, Miami, FL, June 2007.

Heavy-load aircraft of conventional wing-body-tail design have become very large. Excessive size of such aircraft may present problems in the manufacturing process. In addition, large wing spans may cause some difficulties in ground handling. Increasing lift loads on large span cantilever wings will also increase the strength of the wing tip vortex. The concept presented herein proposes a means for substantially increasing the lift load capability of an aircraft without increasing the overall length and span of the configuration. The concept has a rectangular wing with a relatively low span and a large chord to provide the area required for high lift. Large fuselages are attached at each wing tip to provide the volume required for high lift. The fuselages serve as endplates for the wing and should preclude tip flow so that two-dimensional flow might be established on the wing. Elimination of the wing tip flow should prevent the formation of a tip vortex and eliminate the tip vortex hazard to trailing aircraft. Exploratory wind tunnel tests of such an aircraft concept have been conducted. Lessons learned from these tests are discussed herein to determine the validity of the concept.

Speijker, L.

"DEVELOPMENT AND APPLICATION OF THE WAVIR SAFETY ASSESSMENT METHOD FOR CURRENT PRACTICE SINGLE RUNWAY APPROACHES"

First Workshop WakeNet2-Europe, 'Wake Data and Safety Assessment Methods', London, November 2003.

The current separation minima stem from the early 70's. Although they have 'proven to be sufficiently safe', the current safety level is unclear and there is a deficiency of tools to support new

developments in operational usage at busy airports. The S-Wake project has proposed a probabilistic model to assess safety, and to evaluate the relation between wake vortex induced risk and aircraft separation distances. This probabilistic approach supports two commonly accepted rationales for acceptance of a newly proposed ATM concept (or procedure) by involved interest groups by showing that the number of wake vortex induced risk events: does not exceed some pre-defined, and agreed upon, safety requirement; and does not increase with the introduction of a new ATM procedure. The WAVIR methodology and tool-set has been extended and applied, following modeling improvements of all its major three sub-models: flight path evolution model, wake vortex evolution model, and wake encounter model. A safety assessment of single runway approaches under different weather, wind and operational conditions was carried out. The results show that the impact of the investigated procedural aspects - as compared to the impact of weather and wind conditions - is relatively small. Reduction of separation distances requires a reduction of the risk near the runway threshold, by measures that reduce the probability and/or consequences of such encounters. The risk assessment results also show that - for single runway approaches - the largest runway capacity improvement might be achieved through exploiting weather conditions favorable for a rapid decay or destruction of the vortices, in particular when located close to the runway threshold. This conclusion is supported by wake encounter data analysis from different sources (including ETWIRL data and NTSB data).

Speijker, L. J. P.

"S-WAKE FINAL REPORT FOR WORK PACKAGE 4, PROBABILISTIC SAFETY ASSESSMENT"

NLR TP-2003-248, March 2003, National Aerospace Lab., Amsterdam, The Netherlands.

This document describes work undertaken in WP4 'Probabilistic Safety Assessment' of the project S-WAKE for the European Commission. The study comprises a quantitative safety assessment of wake vortex induced risk related to single runway approaches under current practice flight regulations. In view of the uncertainties and the difficulties in understanding the wake vortex phenomena, a probabilistic approach has been followed to evaluate the safety related to different separation distances between landing aircraft on a single runway. This probabilistic model is based on a stochastic framework that incorporates sub models for wake vortex evolution, wake encounter, and flight path evolution, and relates the severity of encounters to possible risk events (i.e. incidents/accidents).

Speijker, L. J. P., Blom, H. A. P. and Kos, J.

"ASSESSMENT OF WAKE-VORTEX SAFETY TO EVALUATE SEPARATION DISTANCES"

CEAS/AAAF Conf. On Research for Safety in Civil Aviation, Paris, October 1999 (also TP-99454, October 1999, National Aerospace Laboratory, Amsterdam, The Netherlands)

The steady increase in air traffic imposes a need for enhanced airport capacity, and the desire to safely reduce existing separation standards. An important limiting factor in establishing required separation standards is the risk imposed by wake vortices. A probabilistic model is developed for the determination of wake vortex induced accident risk. The modeling approach is integrated within a

stochastic framework. Four probabilistic sub models are being used: wake vortex evolution model, wake vortex interaction model, aircraft control capability model, and flight path evolution model. This probabilistic model can be used for an assessment of wake vortex safety related to different ATM concepts or procedures. A safety management framework, which describes how to judge the acceptability of the obtained safety assessment results, is developed.

Speijker, L. J. P., Kos, J., Blom, H. A. P. and van Baren, G. B.

"PROBABILISTIC WAKE VORTEX SAFETY ASSESSMENT TO EVALUATE SEPARATION DISTANCES FOR ATM OPERATIONS"

NLR-TP-2000-326, June 2000, National Aerospace Laboratory, and ICAS 2000, Harrogate, UK

The steady increase in air traffic imposes a need for enhanced airport capacity, and the desire to safely reduce existing separation minima. An important limiting factor in establishing required separation minima is wake vortex induced risk. A novel probabilistic methodology is under development for the assessment of wake vortex induced accident risk. The methodology is integrated within a stochastic framework. Three probabilistic sub models are being used: wake vortex evolution model, wake encounter model and flight path evolution model. This probabilistic methodology can be used for an assessment of wake vortex safety of different Air Traffic Management (ATM) concepts or procedures. It provides a tool to evaluate separation distances for the current practice, and for promising new ATM concepts which may enable a safe reduction of current separation minima. Numerical results can be fed back to ATM designers, who can use these results to redesign or improve their proposed ATM concept. The safety management approach to regulate and control wake vortex induced risk can, and should, be based on an assessment of accident risk probabilities, followed by a comparison with risk criteria. Some guidelines for the development of a risk criteria framework, to be agreed upon by involved interest groups, are given. This paper outlines the probabilistic methodology, and illustrates its initial application for the single runway approach under current flight regulations.

"ATC-WAKE: INTEGRATED WAKE VORTEX SAFETY AND CAPACITY SYSTEM"

IST-2001-34729, National Aerospace Lab., Amsterdam, The Netherlands, December 2005

The project ATC-Wake aims to develop an integrated system for ATC (Air Traffic Control) that would allow variable aircraft separation distances, as opposed to the fixed distances presently applied at airports. A variety of existing subsystems has been integrated within the ATC-Wake Integrated Platform, which was used in a test bed environment role: to evaluate the interoperability of the ATC-Wake system with existing ATC systems currently used at various European airports; to assess the safety and capacity improvements that can be obtained by local installation of the ATC-Wake system at various European airports; to evaluate operational usability and acceptability of the ATC-Wake system; and to make a plan and to assess the costs for further implementation and exploitation of the ATC-Wake IP platform into the system that can be installed at European airports. The Final Report provides

an overview of all the activities performed, including conclusions and recommendations to continue the exploitation towards installation of the ATC-Wake system at European airports.

Speijker, L., van Baren, G., Sherry, L., Shortle, J. and Rico-Cust, F.

"ASSESSMENT OF WAKE VORTEX SEPARATION DISTANCES USING THE WAVIR TOOLSET"

AIAA-IEEE 23rd Digital Avionics Systems Conference, Vol. 1, October 2004, pp. 2.E.2-1-2.E.2-11

Increases to the capacity of the National Airspace System (NAS), and reduction of delayed and cancelled flights, can be achieved by increasing the landing and takeoff capacity of the runways at the nation's busiest hub airports. NASA and the FAA are evaluating the feasibility of increasing runway capacity through reduced wake vortex separation distances between aircraft in the arrival and departure flows. Traditionally three methods have been used to determine safe wake vortex separation distances: (i) flight test experiments, (ii) historic operational data, and (iii) analytical models. This paper describes the WAVIR toolset, developed by the National Aerospace Laboratory NLR (the Netherlands), for evaluation of wake vortex separation distances. WAVIR is an analytic tool that uses stochastic models for wake vortex generation, wake vortex encounter, aircraft separation, and pilot/aircraft response to an encounter of varying magnitudes. The WAVIR tool provides the ability to evaluate the feasibility of different separation distances between fleets of heterogeneous aircraft under different operational, weather and wind conditions. The approach is applied to evaluate the safety related to current practice single runway arrivals.

Spence, G. T., Allerton, D. J., Le Moigne, A. and Qin, N.

"REAL-TIME MODEL OF WAKE VORTICES BASED ON LARGE EDDY SIMULATION DATASETS"

AIAA Paper No. 2005-6205, San Francisco, CA, August 2005.

An alternative model is presented to represent a counter rotating vortex pair for wake vortex interaction in a real-time flight simulation. Rather than describing the characteristics of the wake vortex system as an analytical model, this model is based upon directly accessing a three-dimensional time-varying dataset that is pre-computed by Large Eddy Simulations (LES). The model is designed to run on a low-cost PC and is integrated with a six-degree-of freedom real-time flight simulator. The success of using LES data as the basis of a wake vortex encounter model, depends on the ability to access the dataset in real-time. This paper focuses on implementation issues of the real-time data management aspects, and describes the data compression scheme implemented to reduce the size of the time-varying dataset. Preliminary comparisons of the model with traditional analytical wake vortex models are discussed together with discussion of flight-test data from several example interactions with wake vortices in a flight simulation.

Spence, G. T., Le Moigne, A., Allerton, D. J. and Qin, N.

"WAKE VORTEX MODEL FOR REAL-TIME FLIGHT SIMULATION BASED ON LARGE EDDY SIMULATION"

Journal of Aircraft, Vol. 44, No. 2, March-April 2007, pp. 467-475

An alternative approach is presented to represent a counter-rotating vortex pair for wake vortex interaction in a real-time flight simulation. Rather than using an analytical model, the model directly accesses a precomputed three-dimensional time-varying dataset. This dataset is generated using implicit large eddy simulations on unstructured grids. The methodology enables a realistic vortex decay to be reproduced with the apparition of short- and long-wave instabilities. The vortex model based on these simulations is designed to run on a personal computer and is integrated with a six-degree-of-freedom real-time flight simulator. The paper combines the use of large eddy simulation data as the basis of a wake vortex encounter model with methods to access the dataset in real time. The second half of this paper describes the data compression scheme implemented to reduce the size of the time-varying dataset. Additionally, rapid data access and issues regarding the real-time data management aspects are discussed. Analysis of the performance of the model is made and preliminary comparisons with a traditional analytical wake vortex model are discussed.

Spencer, T. L. and Trani, A. A.

"PREDICTIVE MODELS OF DEPARTURE AND ARRIVAL OCCUPANCY TIME AND TAKE-OFF DISTANCE"

AIAA Paper 2018-4141, June 2018, Atlanta, GA.

Values of departure and arrival runway occupancy time and take-off distance are commonly used parameters for many airport and air transportation simulation models. However, these data are typically found either aggregated by weight or wake class or are otherwise unavailable. Furthermore, field collection of these data can be prohibitively time-consuming and expensive. To fill this data gap, we present predictive models of departure runway occupancy time, take-off distance, and arrival runway occupancy time. Through comparison of multiple frameworks, we find that the Bayesian modeling framework offers the strongest predictive performance. Using hierarchical Bayesian regression, the models developed cover 85 individual aircraft types and address the considerable variability present in the arrival and departure performance of different aircraft. The additional benefit of the Bayesian model is its output of probability distributions, which many simulation models readily accept.

Spentzos, A., Barakos, G. N., Badcock, K. J., Richards, B. E., Coton, F. N., Galbraith, R. A. McD., Berton, E. and Favier, D.

"COMPUTATIONAL FLUID DYNAMICS STUDY OF THREE-DIMENSIONAL DYNAMIC STALL OF VARIOUS PLANFORM SHAPES"

Journal of Aircraft, Vol. 44, No. 4, July-August 2007, pp. 1118-1128.

Numerical simulation of 3-D dynamic stall has been undertaken using computational fluid dynamics. As a first step, validation calculations have been performed for cases in which experimental data were available. Although the amount and quality of the experimental data available for 3-D dynamic stall does not match what is available for 2-D cases, the computational fluid dynamics was found capable of

predicting this complex 3-D flow with good accuracy. Once confidence on the computational fluid dynamics method was established, further calculations were conducted for several wing planforms. The calculations revealed the detailed structure of the 3-D dynamic stall vortex and its interaction with the tip vortex. Remarkably, strong similarities in the flow topology were identified for wings of very different planforms.

Spillman, J. J.

"THE USE OF WING TIP SAILS TO REDUCE VORTEX DRAG"

Aeronautical Journal, Vol. 82, September 1978, pp. 387-395.

Small cambered and twisted surfaces, called sails, fitted to the wing tips of an aircraft can reduce its lift-dependent drag by up to 30 percent. Flight tests on a Paris aircraft show a 25 percent increase in maximum lift-drag ratio. Three or four sails per wing tip, each having a span of about a quarter of the wing tip chord and a root chord of about 16 percent of that of the wing tip seem to give the greatest vortex drag reductions when fitted, almost horizontally, outboard of the rear half of the wing tip. The sails need to be set in a spiral array round the tip, each sail being further away from the top surface of the wing, by 15 degree or more, than the sail in front of it. The sails need to turn the air smoothly from the spiral flow from lower to upper surface round the tip to a near streamwise direction. This requires the root sections of the sails to have circular arc camber lines bringing the tangent to the camber line at the nose of the sail more nearly into line with the local flow direction at positive wing incidences.

Spillman, J. J. and Allen, J. E.

"THE USE OF WING TIP SAILS TO REDUCE VORTEX DRAG"

Report No. 38, 1977, Cranfield Institute of Technology, Cranfield, Bedford, UK.

Windtunnel measurements of the flow around the tip tanks of a model of a Morane-Saulnier Paris aircraft have been used to design cambered and twisted auxiliary surfaces, each with only 0.4 to 0.6 percent of the wing area, which unwound the tip vortices formed at the incidence and in so doing experienced a thrust, effectively reducing the vortex drag. Flight tests on a Paris aircraft showed that three such sails per tip tank increased the effective aspect ratio of the wing by over 40 percent. The increase in the overall lift-drag ratio at a lift coefficient of 0.35 was 21 percent and the maximum lift-drag ratio increased from 12.5 to 15.8. More recent wind tunnel tests have shown that sails have a similar effect when fitted to plain wing tips. The results suggest that three or four sails spiraled round the rear half of each wing tip will give best results. These encouraging results suggest that far more wind tunnel, flight and design work should be done to realize the potential savings in drag and fuel.

Spilman, D. R. and Stengel, R. F.

"JET TRANSPORT RESPONSE TO A HORIZONTAL WIND VORTEX"

J. Aircraft, Vol. 32, No. 3, May-June 1995, pp. 480-485

The dynamic response of a twin-jet transport aircraft encountering a single-axis wind vortex on final approach to landing is investigated. Dynamic simulations are used to determine the effects of vortex strength, vortex length, lateral entry position, vertical entry position, and encounter incidence angle on the aircraft roll response parameters. Maximum roll rate and roll angle increase proportionally with vortex strength and vortex length, until a 'saturation length' is reached. Roll response is highly dependent on entry location: changes in lateral entry position affect maximum roll angle while changes in vertical entry position affect maximum roll rate. Peak roll rate and roll angle obtain their largest values at near-zero incidence angles. The response is highly dependent on the precise initial conditions of the encounter - even small variations from this initial condition cause significant changes in aircraft roll response.

Spitzer, E. A.

"OPERATIONAL SYSTEM GUIDELINES FOR VORTEX ADVISORY SYSTEM"

FAA-RD-79-20, April 1979, DOT Transportation Systems Center, Cambridge, MA

The phenomenon of wake vortices has introduced a major operational constraint on airport operations, resulting in a reduction of runway capacities. Increased knowledge about the behavior of wake vortices has resulted in the development of a model of vortex behavior as a function of meteorological conditions. Based on this vortex behavior model, a Vortex Advisory System (VAS) has been designed and built. The VAS measures the primary meteorological parameter (wind) which affects vortex behavior and indicates to controllers via displays when conditions are such that more efficient runway use is possible. A detailed description of the VAS and guidelines for an operational system are given.

Spitzer, E. A.

"PROJECT SOCRATES"

Proceedings of the International Wake Vortex Meeting, TP 13166, edited by H. Posluns, Transport Canada, Montreal, Ottawa, Canada, December 1997, pp. 129-132.

Various environmental and man-made atmospheric disturbances (such as windshear, microbursts, clear air turbulence and wake vortices) have proven hazardous to aviation safety. Those atmospheric phenomena also represent mechanisms known to generate low frequency and infrasonic sound. These sonic emissions arise in the form of passive broadband sound sources having signatures that can be detected, classified, located, and tracked over extreme stand-off distances from a passive receiver through acoustic array and signal processing. Short optical path forms of acoustic-optic sensing devices can detect, classify, locate, and track the acoustic signatures. These infrared laser-based forms of acoustic-optic remote sensors are called a Sensor for Optically Characterizing Ring-eddy Atmospheric Turbulence Emitting Sound (SOCRATES) system. The SOCRATES system provides a remote-sensing set or line array of virtual microphones. Phase I of the program is to focus on the detection of wake

vortices and the goal is to prove the viability of the technology. A testbed configuration is to be installed at the Volpe Center JFK vortex test site, so that concurrent data from the Volpe wind line sensors can be used to validate the SOCRATES sensor for wake detection. Phase II of the program is a detailed theory and modeling effort. Preliminary measurements at JFK have identified a passive broadband spectral hump centered around 50 Hz which is thought to be representative of wake vortex noise.

Spitzer, E. A., Hallock, J. N. and Wood, W. D.

"STATUS OF THE VORTEX ADVISORY SYSTEM"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 326-334

A Vortex Advisory System is currently undergoing tests at the Chicago O'Hare International Airport. By measuring the wind magnitude and direction with respect to a runway heading, the VAS indicates via a display when aircraft separations could be safely reduced to three nautical miles for all landing aircraft. The paper presents the rationale for the system, the concept, the system design, how data are being acquired to check the operation of the system, and the test results to date.

Spitzer, E. A., Hallock, J. N., Burnham, D. C. and Rudis, R. P.

"PAST WAKE VORTEX INVESTIGATIONS AND DYNAMIC SPACING SYSTEMS"

Proceedings of the NASA First Wake Vortex Dynamic Spacing Workshop, NASA/CP-97-206235, edited by L. Credeur and R. Perry, NASA Langley Research Center, Hampton, VA, November 1997, pp. 45-60

A review of past wake vortex investigations is divided into the early years (late 1960's to early 1970's), the active years (mid-1970's to early 1980's), the lean years (mid-1980's to early 1990's), and the current years (early 1990's to the present). Vortex motion and decay information is highlighted to summarize the current state of knowledge as gleaned from the many past data collection programs. Dynamic spacing systems defined in the 1970's and 1980's are described (Vortex Advisory System (based on wind alone), Vortex Warning System (based on wind and vortex tracking), Wake Vortex Avoidance system (based on wind and wind forecasting, vortex tracking, vortex strength, and Air Traffic Control interfaces), and a Parallel Runway Vortex Advisory System (based on wind, wind forecasting, and vortex tracking)).

"AN OVERVIEW OF PROJECT SOCRATES"

XXIII General Assembly, European Geophysical Society, Nice, France, April 1998

Project SOCRATES is a research and development project aimed at addressing air safety and airport productivity through application of advanced technologies previously investigated for the U.S.

Department of Defense. The basic premise is remote detection and localization of acoustic signatures from man-made and natural atmospheric turbulence. An acoustic-optic technology is used to sense low frequency sound that has propagated from the atmospheric hazard to an optical sensing beam. This presentation will describe the basic sensing concept as well as the current effort to demonstrate concept feasibility for detection of sound generated by aircraft wake vortices. Results from measurements taken at JFK airport will be presented. Subsequent efforts to develop an array of sensors and the processing to achieve interference reduction and sound source localization will also be described. The long-term view is to integrate this novel sensing technology with appropriate air safety systems to enhance overall capability and effectiveness.

Spitzer, E. A., Rudis, R. P., Hallock, J. N. and Greene, G. C.

"WINDLINE FOR PARALLEL RUNWAY OPERATIONS AT SFO"

XXV General Assembly, European Geophysical Society, Nice, France, April 2000

Wake turbulence poses a potential problem for side-by-side approaches to close-spaced parallel runways (229 m apart at SFO), particularly when the ceiling is too low to permit visual operations. The wake encounter risk depends upon the crosswind and the longitudinal displacement of the aircraft pair. The SFO windline tracks landing wakes generated over the first 650 m of the runway, a region where few prior wake measurements have been made.

"A THEORETICAL STUDY OF THE AERODYNAMICS OF SLENDER CRUCIFORM-WING ARRANGEMENTS AND THEIR WAKES"

NACA TR-1296, January 1957, Langley Aeronautical Lab., Langley Field, VA

A theoretical study is made of some cruciform-wing arrangements and their wakes by means of slender-body theory. The basic ideas of this theory are reviewed and equations are developed for the pressures, loadings, and forces on slender cruciform wings and wing-body combinations. The rolling-up of the vortex sheet behind a slender cruciform wing is considered at length and a numerical analysis is carried out using 40 vortices to calculate the wake shape at various distances behind an equal-span cruciform wing at a 45-degree bank. Analytical expressions are developed for the corresponding positions of the rolled-up vortex sheets using a 4-vortex approximation to the wake, and these positions are compared with the positions of the centroids of vorticity resulting from the numerical analysis. The agreement is found to be remarkably good at all distances behind the wing. Photographs of the wake as observed in a water tank are presented for various distances behind a cruciform wing at a 0 degree and a 45-degree bank. For a 45-degree bank, the distance behind the wing at which the upper two vortices pass between the lower two is measured experimentally and is found to agree well with the 4-vortex analysis. The calculation of loads on cruciform tails is considered in some detail by the method of reverse flow, and equations are developed for the tail loads in terms of the vortex positions calculated in the earlier analyses.

"THE ROLLING UP OF THE TRAILING VORTEX SHEET AND ITS EFFECT ON THE DOWNWASH BEHIND WINGS"

J. Aeronautical Sciences, Vol. 18, No. 1, January 1951, pp. 21-32

The motion of the trailing vortices associated with a lifting wing is investigated by theoretical and visual-flow methods for the purpose of determining the proper vortex distribution to be used for downwash calculations. This involves the study of the rolling up and displacement of the trailing vortex sheet and the development of the cores of the rolled-up vortices. Both subsonic and supersonic speeds are considered in the analysis.

Squire, H. B.

"THE GROWTH OF A VORTEX IN TURBULENT FLOW"

ARC-16666, March 1954, Imperial College, London, England

The growth of a line vortex with time and the spread of a trailing vortex behind a wing due to turbulence are considered. It is shown that the eddy viscosity for this type of motion may be taken to be proportional to the circulation round the vortex and the solution is then similar to the solution for the growth of a vortex in laminar flow. The method is applied to calculate the distance behind a wing for which the trailing vortices will touch one another.

Squire, H. B.

"THE GROWTH OF A VORTEX IN TURBULENT FLOW"

Aero. Quarterly, Vol. 16, August 1965, pp. 302-306

The growth of a line vortex with time and the spread of a trailing vortex behind a wing due to turbulence are considered. It is shown that the eddy viscosity for this type of motion may be taken to be proportional to the circulation around the vortex and the solution is then similar to the solution for the growth of a vortex in laminar flow. The method is applied to calculate the distance behind a wing for which the trailing vortices will touch one another.

"LARGE EDDY SIMULATION OF A LONGITUDINAL VORTEX"

AIAA Paper No. 1994-0529, Reno, NV, January 1994.

Temporal large-eddy simulation is used to study the transitional and turbulent structure of stationary longitudinal vortices. Simulations are obtained for a high Reynolds number and at a low subsonic Mach number. The dynamic eddy-viscosity model is utilized to model the subgrid-scale stress tensor. Emphasis is given to the evolution of large-scale structures due to centrifugal instability and their subsequent breakdown into turbulence. When the vortex is unstable, ring-shaped structures appear around the vortex core. These structures interact with the core exchanging angular momentum between the core and the surroundings, which causes the decay of the mean tangential velocity. The turbulent kinetic energy of the initial disturbance increased rapidly and then a period of slow decay prevailed. The mean circulation profile showed good agreement with the universal inner profile of Hoffman and Joubert at the time of maximum turbulent kinetic energy.

Srigrarom, S.

"VORTEX BREAKDOWN SUPPRESSION BASED ON SELF-INDUCTION MECHANISM THEORY"

AIAA Paper No. 2000-0017, Reno, NV, January 2000

This study provides evidence to support an explanation of the phenomena of vortex breakdown proposed recently. The vortex breakdown is a phenomenon observable over a delta wing, where the vortex filament emanating from the apex suddenly enlarges and takes either spiral or bubble forms. The 'self-induction' mechanism due to the confined shear layer within the vortex filament is confirmed as the prime cause of the 'pile-up' effect of the vortices, and this leads to the vortex breakdown phenomena. Although, the 'self-induction' mechanism is unavoidable, the 'pile-up' effect can be avoided by changing the straightness of the vortex filament to a curved path. This reduces induction, which prevents the 'pile-up' of vortices (the threshold process of the vortex breakdown phenomena). In this study, we have modified the straight path of the vortex filament by two methods: 1) by changing the straight leading edge to a sinusoidal contour, and 2) by placing excrescence on the upper surface of the wing. Both methods lead to the absence of vortex breakdown, up to angle of attack of 35 degrees. Laser-induced fluorescence flow visualization images are presented together with the ordinary dye-injection flow visualization images. Digital particle image velocimetry results are also included to emphasize, upon the suppression of vortex breakdowns, the absence of backflow and the absence of a vorticity sign change, which are well-known criteria for the indication of vortex breakdown. A model analysis based on the proposed 'self-induction' model is also included.

"NUMERICAL SIMULATION OF TIP VORTICES OF WINGS IN SUBSONIC AND TRANSONIC FLOWS"

AIAA Paper No. 1986-1095, May 1986, Atlanta, GA.

A multi block zonal algorithm which solver the thin-layer Navier-Stokes and the Euler equation is used to numerically simulate the formation and roll-up of the tip vortex in both subsonic and transonic flows. Four test cases which used small and large aspect ratio wings gave been considered to examine the influence of the tip-cap shape, the tip-platform and the free-stream Mach number. It appears that

both the tip-platform and the tip-cap shape have some influence on the formation of the tip vortex, but its subsequent roll-up seems to be more influenced by the tip-platform shape. In general, a good definition of the formation and the roll-up of the tip vortex has been observed for all the cases considered here. Comparisons of the numerical results with the limited, available experimental data show good agreement with both the surface pressures and the tip-vortex strength.

Srinivasan, G. R., McCroskey, W. J., Baeder, J. D. and Edwards, T. A.

"NUMERICAL SIMULATION OF TIP VORTICES OF WINGS IN SUBSONIC AND TRANSONIC FLOWS"

AIAA Journal, Vol. 26, No. 10, October 1988, pp. 1153-1162

A multiblock zonal algorithm is used to solve numerically the thin-layer Navier-Stokes and the Euler equations for simulating the flowfields of isolated wings, with particular emphasis on understanding the formation and roll-up of tip vortices in subsonic and transonic flows. Four test cases consisting of wings of different planforms have been considered to examine the influence of the tip-cap shape, tip planform, and freestream Mach number. Comparison of the numerical results with the available experimental data shows good agreement for the surface pressures in the regions where the flow is attached or mildly separated. However, discrepancies exist in regions of massive shock-induced separation in transonic flow and in the immediate vicinity of the wing tip in subsonic flow. In general, a good definition of the formation and roll-up of the tip vortex is demonstrated for all the cases considered here, subject to the coarseness of the grid in the far field. Finally, the calculated lift, drag, and pitching-moment coefficients agree well with the experimentally determined values, where available.

"LIDAR MEASUREMENTS OF WIND VELOCITY PROFILES IN THE BOUNDARY LAYER"

Journal of Applied Meteorology, Vol. 19, May 1980, pp. 598-605.

A lidar technique for measuring wind in the atmospheric boundary is presented. Inhomogeneities in ambient aerosol content are used as tracers of the wind. This technique yields both horizontal components of the wind and the wind velocity variance. These results are achieved using a model which assumes an isotropic Gaussian distribution of turbulent velocities. Experimental results comparing lidar wind measurements with winds derived from radar-tracked pilot balloons and tower-measured anemometers show good agreement. Wind measurements have been obtained at slant range distances up to 6.5 km.

"COLLECTION OF OPERATIONAL DATA ON WAKE VORTEX INCIDENTS IN THE UK"

Proceedings of the Aircraft Wake Vortices Conf., DOT Transportation Systems Center, FAA-RD-77-68, June 1977, pp. 6-10

Data relating to pilots' reports of a total of over 300 incidents have been collated and analyzed covering a 5-year period.

Stack, J.

"EXPERIMENTAL INVESTIGATION OF ROTOR VORTEX WAKES IN DESCENT"

ICAS 2004, Paper 2004-2.9.3, Aug.-Sept. 2004, Yokohama, Japan.

An experimental study is performed on a three-bladed rotor model in a water tow tank. The rotor's rotational velocity, the rotor plane angle of attack, and the carriage speed are all varied in order to simulate a wide range of rotorcraft operating states. The focus is on descent speeds and angles where the rotor is operating in or near vortex ring state. Circulation Reynolds numbers are of order 100,000 and chord Reynolds numbers are of order 10,000. Flow visualization is done using air bubbles and fluorescent dye injected tangentially from the blade tips to mark the vortex core, showing the development of both short-wave and long-wave instabilities on the helical vortices in the wake. Strain gages are used to record transient loads, allowing a correlation between the rotor thrust performance and the development of the vortex wake. The data indicate that as the instability develops, the adjacent vortices merge and form thick vortex rings, especially during descent. Periodic shedding of vorticity from the wake associated with vortex ring state is observed, resulting in peak-to-peak thrust fluctuations of up to 95% of the mean and occurring at regular intervals of 20 - 50 rotor revolutions, depending on flow parameters.

Stack, J.

"EXPERIMENTAL INVESTIGATION OF ROTOR VORTEX WAKES IN DESCENT"

AIAA Paper No. 2004-0297, Reno, NV, January 2004

An experimental study is performed on a three-bladed rotor model in a water tow tank. The blade pitch and rotational velocity, the rotor plane angle of attack, and the carriage speed are all varied to simulate a wide range of rotorcraft operating states. The focus is on descent speeds and angles where the rotor is operating in or near vortex ring state. Circulation Reynolds numbers are of order 100,000 and chord Reynolds numbers are of order 10,000. Flow visualization is done using air bubbles and fluorescent dye injected tangentially from the blade tips to mark the vortex core, showing the development of both short-wave and long-wave instabilities on the helical vortices in the wake. Strain gages are used to record transient loads, allowing a correlation between the rotor thrust performance and the development of the vortex wake. The data indicate that as the instability develops, the adjacent vortices merge and form thick vortex rings, especially during descent. Periodic shedding of vorticity from the wake associated with vortex ring state is observed, resulting in peak-to-peak thrust fluctuations of up to 95% of the mean and occurring at regular intervals of 20 - 50 rotor revolutions, depending on flow parameters.

Stack, J. A.

"AN EXPERIMENTAL INVESTIGATION OF THE VORTEX WAKES OF HOVERING AND DESCENDING ROTORS"

PhD Thesis, 2006, University of California, Berkeley, CA.

Two sets of experiments are performed on a three-bladed rotor model, one in a towing tank to simulate descent, and the other in a stationary tank to simulate hover. The rotor's rotational speed, collective pitch angle, descent angle, and descent speed are all varied, simulating a wide range of rotorcraft operating states. For this work, circulation-based Reynolds numbers are of order 100000 and chord-based Reynolds numbers are of order 10000. The focus of the first set of experiments is on descent speeds and angles where the rotor is operating in or near vortex ring state. Simultaneous flow visualization and thrust measurement allow the rotor's performance to be correlated to the development of the vortex wake. Periodic shedding of vorticity from the wake associated with vortex ring state is observed, resulting in peak-to-peak thrust fluctuations of up to 95 percent of the mean and occurring at regular intervals of 20-50 rotor rotations with the oscillation period exhibiting a power law dependence on the advance speed and varying inversely with the collective angle. The hover experiments use particle image velocimetry and flow visualization to analyze the development of the wakes from either rectangular planform rotor blades or blades with triangular flaps attached near the blade tips. The dynamics of the two wakes differ substantially, with short-wave instabilities observed developing on the tip vortices of both wakes, while a long-wave instability develops only in the wake of the rectangular blades. The rectangular blade wake also decays somewhat more rapidly than the triangular-flap blade wake. While the wake can be altered significantly through modifications to the blade planform geometries, the trajectories of the tip vortices are not significantly affected by varying the rotor speed or collective angle. The effects of the experimental techniques employed here on the flow are also explored, with the injection of fluid from the blade tips in flow visualization experiments having a particularly strong effect on the strengths of the tip vortices.

Stack, J., Caradonna, F. and Savas, O.

"FLOW VISUALIZATION AND PARTICLE IMAGE VELOCIMETRY ANALYSIS OF ROTOR VORTEX WAKES"

American Physical Society, 57th Annual Meeting Division of Fluid Mechanics, Nov. 2004, Seattle, WA.

An experimental study is performed on a three-bladed rotor model in a stationary water tank, simulating a helicopter rotor operating in hover at Reynolds numbers of order 10,000. Flow visualization is done by injecting air bubbles and fluorescent dye tangentially from the blade tips to mark the vortices, showing the development of both short-wave (sinuous) and long-wave (leapfrogging) instabilities on the helical vortex filaments in the wake. The flow images show that as the instabilities develop, adjacent vortices merge and form thick vortex rings as quickly as half a rotor diameter downstream of the rotor disk. Particle image velocimetry data demonstrate the existence of the short-wave instability, evidenced by oscillations in the adjacent vortex core separation distance. At the same time, the long-wave instability is also apparent, as the vortices can be seen orbiting each other prior to merger. The circular axis and the moments of vorticity distribution are used to analyze

the kinematics of vortex filament triads during formation, instability, and merger phases. Comparison of flow visualization and vorticity movies, however, shows interesting differences in the vortex merger process, possibly as a result of axial flow in the vortex cores.

Stack, J., Caradonna, F. and Savas, O.

"EXPERIMENTAL STUDY OF ROTOR WAKES IN DESCENT"

American Physical Society, 55th Annual Meeting Division of Fluid Mechanics, Nov. 2002, Austin, TX.

An experimental study is performed on a three-bladed rotor model in a water tow tank. The blade pitch and rotational velocity, the rotor plane angle of attack, and the carriage speed are all varied in order to simulate a wide range of rotorcraft operating states. Circulation Reynolds numbers are of order 100,000 and blade Reynolds numbers are of order 10,000. Flow visualization is done using air bubbles or dye injected from the blade tips to mark the vortex core, showing the development of an instability on the helical vortices in the wake. PIV data provide quantitative measures of the flow field as the wake develops. Strain gages are also used to record transient load measurements, allowing a correlation to be made between the rotor performance and the development of the vortex wake. The data so far indicate that as the instability develops, the adjacent vortices merge and form thick vortex rings, especially during descent. The vorticity spreads and is periodically shed from the wake, resulting in significant fluctuations in the rotor loading.

Stack, J., Caradonna, F. and Savas, O.

"FLOW VISUALIZATION AND EXTENDED THRUST TIME HISTORIES OF ROTOR VORTEX WAKES IN DESCENT"

American Physical Society, 56th Annual Meeting Division of Fluid Mechanics, Nov. 2003, Easrt Rutherford, NJ.

An experimental study is performed on a three-bladed rotor model in a water tow tank. The blade pitch and rotational velocity, the rotor plane angle of attack (descent angle), and the carriage speed are all varied in order to simulate a wide range of rotorcraft operating states, with the focus being on descent speeds and angles where the rotor is operating in or near vortex ring state an area in which there is currently very little available data. Circulation and blade Reynolds numbers are of order 100000. Flow visualization is done by injecting air bubbles and fluorescent dye tangentially from the blade tips to mark the vortex core, showing the development of both short-wave (sinuous) and long-wave (leapfrogging) instabilities on the helical vortices in the wake. Strain gages are used to record transient loads, allowing a correlation between the rotor thrust performance and the development of the vortex wake. Test runs are performed for extended periods up to 500 rotor revolutions demonstrating the repeatability of the patterns of thrust variation. The data indicate that as the instabilities develop, adjacent vortices merge and form thick vortex rings, particularly during descent. Periodic shedding of these rings from the wake associated with vortex ring state is observed, resulting in peak-to-peak thrust fluctuations of up to 95 percent of the mean and occurring at regular intervals of

2050 rotor revolutions, depending on flow parameters. Preliminary particle image velocimetry data provide a quantitative measure of the entire rotor flow field for the case of a hovering rotor. The data yield additional information on the vortex filament instability, in particular the axial flow in the vortex cores.

Stack, J., Caradonna, F. X. and Savas, O.

"FLOW VISUALIZATIONS AND EXTENDED THRUST TIME HISTORIES OF ROTOR VORTEX WAKES IN DESCENT"

Proc. American Helicopter Society 4th Decennial Specialists' Conf. on Aeromechanics, Jan. 2004, San Francisco, CA.

An experimental study is performed on a three-bladed rotor model in two water tanks. The blade pitch, rotational velocity, descent angle, and descent speed are all varied to simulate a wide range of rotorcraft operating states, focusing on descent cases where the rotor is operating in or near vortex ring state -- an area in which there is currently very little available data. Flow visualization is done by injecting air bubbles and fluorescent dye tangentially from the blade tips to mark the vortex core, showing the development of both short-wave (sinuous) and long-wave (leapfrogging) instabilities on the helical vortices in the wake. Strain gauges are used to record transient loads, allowing a correlation between the rotor thrust performance and the development of the vortex wake. Reynolds numbers are of order 100,000 and test runs are performed for extended periods -- up to 500 rotor revolutions -- demonstrating the repeatability of the patterns of thrust variation. The data indicate that as the instabilities develop, adjacent vortices merge and form thick vortex rings, particularly during descent. Periodic shedding of these rings from the wake associated with vortex ring state is observed, resulting in peak-to-peak thrust fluctuations of up to 95 percent of the mean and occurring at regular intervals of 20-50 rotor revolutions, depending on flow parameters.

Starn, A. D.

"DOPPLER GLOBAL VELOCIMETRY MEASUREMENTS IN A WING FLOW FIELD WITH TIP BLOWING"

MS Thesis, 2004, West Virginia University, Morgantown, WV.

A two-component Doppler global velocimetry (DGV) system has been developed, improved, and tested. DGV is a non-intrusive optical velocity measurement technique. DGV measures the Doppler shift of the frequency of the light scattered by seed particles at a specific location. The velocity of the particles is related to the Doppler shift. DGV measurements were made in the WVU low speed wind tunnel on a turbulent jet and on a NACA 2412 airfoil model with and without tip blowing. The jet data generally agreed with previous measurements. The jet velocity error was generally within ± 2 -4 m/s. The offset error of up to ± 10 m/s was attributed to difficulties in cell calibration. The velocity data obtained from the airfoil measurements was limited to the regions of space where the gray levels were high enough to yield meaningful results. In these regions, the observed error was comparable to that of the jet.

"AIRCRAFT VORTEX DETECTION USING DUAL LASER BEAMS"

J. Aircraft, Vol. 12, No. 2, February 1975, pp. 123-124

The note reports laboratory experiments on a dual laser beam vortex detection system which in practice could be relatively simple, insensitive to heating effects, and would not interfere with visibility or normal airport functions. The laser beams are directed along the length of the runway and are used in pairs to detect the difference in the deflection of the beams. The optical vortex detection system works on the same principal as a schlieren system in which the individual laser beams act as schlieren system beams which are cut off by their own knife edge.

"WINGTIP VORTEX DIAMETERS, TANGENTIAL SPEEDS AND HORIZONTAL TRANSPORT WITHIN THE FIRST 100 FEET ABOVE THE GROUND"

Report, September 1970, Air Resources Laboratories Field Research Office, Idaho Falls, Idaho.

The research supported in this study was part of a joint government and industry accelerated evaluation of the operational impact of wake turbulence produced by large jet aircraft. Data were collected through low altitude aircraft flybys of instrumented towers by Boeing 727 and 707 aircraft, a Douglas DC9, and a Convair 880. Aircraft induced air circulations were measured by hot film anemometry. Smoke visualized vortex circulations were filmed by FAA personnel to supplement the vortex measurements. The fundamental purpose of this data set is the provision of a quantitative estimate of vortex characteristics for FAA follow-on studies. These studies would attempt to relate these characteristics to the characteristics of the test aircraft, its flight configuration, and other relevant aerodynamic parameters. The tower measurements and calculated vortex characteristics are shown in several data tables and graphical depictions. The vortex characteristics presented are vortex size, basic shape, tangential speed versus radial distance, core diameter, age, speed of horizontal transport, separation of vortex pair centers, and supplemental measurements of atmospheric wind speeds and temperatures. A smaller vertical spacing of tower sensors, on the order of one foot, is necessary to better measure and better quantize the vortex core characteristics and the radial distribution of tangential speeds. Sequential tower measurements of the energy of circulation for the same vortex, combined with the appropriate micrometeorological measurements are needed to evaluate and quantize vortex decay in the atmosphere.

"AIRCRAFT VORTEX WAKE - ENVIRONMENTAL AND FLIGHT SAFETY ASPECTS OF THE PROBLEM"

AIAA Paper No. 1998-5590, Anaheim, CA, September 1998

Vortices in fluid and gas are very stable formations featuring a slow mass, momentum, and energy exchange with surrounding atmosphere. The 'closure' of vortices, on the one hand, facilitates their visualization and, on the other hand, results in accumulating and for long retaining hot engine exhaust gases entrained into the vortices in the stage of their formation in the near jet-vortex wake behind an aircraft. The latter problem is closely related to the environmental impact of aviation, especially within airport areas and ozone layer of the Earth's atmosphere. In this paper the problem of light scattering by particulates arising during water vapor condensation, droplet coagulation or breakdown is considered. Numerical results are presented of gas dynamic and optical properties of the aerosol-containing wakes of the Boeing-747-type aircraft and of the prospective Russian second-generation supersonic civil transport.

"PHYSICAL MODELS OF VISUALIZATION OF A CIVIL AIRCRAFT AEROSOL VORTEX WAKE IN THE AIRPORT VICINITY"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

At present, the interest of the scientific community seems to shift more and more to the problem of augmentation of the airport capacity and providing simultaneously the vortex wake safety. The most radical method to diminish the hazard from a heavy airliner vortex is to make it visible. The most convenient way to realize this method is to illumine the aircraft wake with a laser beam (in optical or IR wave-band).

Staufenbiel, R. and Vitting, T.

"FORMATION OF TIP VORTICES AND VORTEX WAKE ALEVIATION BY TIP DEVICES"

Proceedings 17th ICAS Congress, Stockholm, Sweden, September 1990, Vol. 1, pp. 279-291

Formation and structure of wing tip vortices as well as some methods of vortex wake alleviation are subjects of the paper. The formation of vortices is investigated theoretically and experimentally. For calculating the roll-up of vortices, a modified line vortex method is introduced using an amalgamation process which preserves important conservation laws. A comparison of experimental and theoretical data yields good agreement. In the second part of the paper, different ways of tip vortex dissipation have been tested such as destabilization of vortices, stimulation of vortex breakdown and redistribution of the vorticity in tip vortices. Experiments, carried out in the water tunnel, evaluated vortex structure as well as profiles of tangential and axial velocity components using LDV and flow visualization techniques.

Staufenbiel, R. and Vitting, T.

"ON AIRCRAFT WAKE PROPERTIES AND SOME METHODS FOR STIMULATING DECAY AND BREAKDOWN OF TIP VORTICES"

Vortex Flow Aerodynamics, AGARD-CP-494, July 1991, pp. 26-1 - 26-14

Investigations on the formation and structure of wing tip vortices are presented. A computational method for the time-dependent roll-up process is derived, which is based on the Biot-Savart approach with a particular technique of amalgamation which preserves energy, center of vorticity, and the second moment of vorticity distribution. The results are compared with laser Doppler velocimeter (LDV) measurements performed in a water tunnel. The influence of lift distribution on maximum circumferential velocity of trailing vortices is investigated. Moreover, some special devices for vortex wake alleviation were experimentally investigated to reveal the potential of three methods for vortex wake alleviation: (1) artificially destabilizing the vortex; (2) inducing breakdown of the vortex core; and (3) spreading and splitting the vorticity of trailing vortices.

Staufenbiel, R. W.

"STRUCTURE OF LIFT-GENERATED ROLLED-UP VORTICES"

J. Aircraft, Vol. 21, No. 10, October 1984, pp. 737-744

Widely used analytical models describing the structure of lift-generated vortices behind aircraft wings (e.g., models of Betz or Lamb) are generally not in acceptable agreement with experiments. The lack in conservation of vortical dispersion and rotational energy, which relates to the induced drag of the generating wing, is considered as a reason for this discrepancy. The model of Lamb is modified in a simple way to account for the conservation laws. These modifications yield a reduction in the core radius and a remarkable increase in the maximum tangential speed. A comparison with experiments is made and reasonable agreement is found. For the modification of the vorticity distribution in the Lamb model, the Kirchhoff-Routh function is used. This function is proportional to the rotational energy for a continuously spaced array of point vortices having the proper vorticity. The proposed model can be adapted to arbitrary vorticity distributions and, hence, wing loadings.

"INVESTIGATING THE POTENTIAL FUTURE USAGE OF COMBINED AIRBORNE WAKE VORTEX PREDICTION MODELS AND MEASUREMENT SENSORS"

AIAA Paper 2018-3022, June 2018, Atlanta, GA.

As world-wide air traffic is constantly increasing, new possibilities are currently investigated and planned to restructure the airspace including a reduction of also enroute separations for increasing the overall airspace capacity. As soon as enroute separations are reduced to a minimum, enabled by navigational means, the wake vortex phenomenon needs to be considered for separation, because the needed separations due to a generated wake vortex might be larger under certain atmospheric conditions than the separations enabled by navigational accuracy and integrity. As this evolution had been predictable, attempts have been made over the last years to introduce airborne methods to predict the wake vortex behavior of a preceding aircraft. Additionally, some research focus has also been on the usage of airborne sensors to detect the wake vortex for the purpose of wake vortex

encounter avoidance, but also to act as a safety net by feeding information on the wake vortex induced lift distribution to the flight controls in case a wake vortex is in almost vicinity and an encounter is not avoidable. For wake vortex avoidance, both a wake vortex prediction and a detection are applicable independently, but a combination of both would take advantage of their complementarity. Such a combination of wake vortex prediction by means of a wake vortex model and wake vortex detection by means of an airborne sensor would be the optimum during cruise to ensure reduced separations on the one hand side, and safe wake vortex separations on the other hand. For such a combined system, this paper will introduce the needed theoretical background and will show possible future applications for envisaged new operational concepts. A combined airborne wake vortex prediction and detection system is being investigated by means of a simulation environment, and potential improvements in prediction accuracy in the presence of ambient uncertainties are presented.

"COLLABORATION OF WAKE VORTEX MODELS AND SENSORS IN MODERN AVIONICS SYSTEMS"

Digital Avionics Systems Conf., Oct. 2009, Orlando, FL, pp. 1.C.1-1-9.

Today's airport capacity is severely limited by separation of approaching and to a lesser extent departing aircraft to ensure that following aircraft do not encounter the wake vortex generated by the preceding one. The encounter of wake vortices, especially during take-off and landing, can cause critical or even catastrophic flight situations for the succeeding plane. Historically, the wake vortex separation standards are based on a 'worst-case-scenario'.

"IN-FLIGHT TESTING OF AIRBORNE LIDAR FOR WAKE VORTEX DETECTION, CHARACTERIZATION AND TRACKING"

AIAA Paper 2014-2336, June 2014, Atlanta, GA.

Today wake vortex dependent spacing between aircraft is achieved by static distances for arrival but also for enroute. With the upcoming operational novelties foreseen in NextGen and SESAR like in-trail

procedures and aircraft self-separation, aircraft wake vortex encounter mitigation comes into focus especially for the enroute flight phase. For the localization of aircraft wake vortices generated by surrounding aircraft, two possibilities exist in general: determining the position, movement, and strength by means of wake vortex model prediction and the detection by dedicated airborne sensors. While prediction is prone to uncertainties in model input quantities, airborne detection sensors like LIDAR are prone to a large scanning domain, adverse scanning geometry and challenging signal processing. To overcome the drawbacks of both model prediction and sensor detection, the Institute of Flight Guidance of the Technische Universitaet Braunschweig is planning to conduct flight trials with an airborne LIDAR equipment for wake vortex detection and tracking utilizing special prediction-detection fusion approaches. This paper describes the airborne LIDAR installation, the system layout, and the connection to the aircraft avionics for the steering of the LIDAR scanning.

"IMPLICIT FINITE-DIFFERENCE PROCEDURES FOR THE COMPUTATION OF VORTEX WAKES"

AIAA Journal, Vol. 15, No. 4, April 1977, pp. 581-590

Implicit finite-difference procedures for the primitive form of the incompressible Navier-Stokes and the compressible Euler equations are used to compute vortex wake flows. The partial differential equations in strong conservation-law form are transformed to cluster grid points in regions with large changes in vorticity. In addition to clustering, fourth-order accurate, spatial difference operators are used to help resolve the flowfield gradients. The use of implicit time-differencing permits large time steps to be taken since temporal variations are typically small. Computational efficiency is achieved by approximate factorization. Both two-dimensional and preliminary three-dimensional calculations are described.

"THREE-DIMENSIONAL CO-OPERATIVE INSTABILITIES IN WAKE VORTEX PAIRS"

ICAS-2002-2.8.2, Toronto, Canada, September 2002

A numerical study is presented concerning three-dimensional cooperative instabilities in vortex pairs. A counter-rotating vortex pair can develop two fundamentally different types of instabilities: short-wavelength or elliptic instabilities and long-wavelength or Crow instabilities. The role of both types is considered in the decay of an aircraft vortex wake.

"THE DYNAMICS OF THE SHORT-WAVELENGTH INSTABILITY IN AIRCRAFT WAKE VORTEX PAIRS"

EUROMECH Colloquium No. 433, Dynamics of Trailing Vortices, Aachen, Germany, March 2002

This presentation focuses on the short-wavelength instability in a counter-rotating vortex pair. In aircraft wake vortex studies, this type of instability has not been studied as extensively as the long-wavelength instability. The dynamics of the long-wavelength, or Crow, instability forms a major aspect of the decay process of aircraft wake trailing vortices. In most visualization studies of aircraft trailing vortices, short-wavelength instability modes are not observed. Therefore, the contribution of this type of instability to the decay of trailing vortices is generally considered to be less important than that of the Crow instability. However, understanding the dynamics of the short-wavelength instability can be crucial in the design of (active) devices or methods that enhance the decay of trailing vortices. This paper studies the effect of Reynolds number, spacing of the vortex pair and axial wave number of the prescribed instability mode on the temporal evolution.

"HIGH-RESOLUTION SIMULATIONS OF CROW AND WIDNALL INSTABILITIES IN A VORTEX PAIR"

AIAA Paper No. 2001-1033, Reno, NV, January 2001

This paper describes simulations performed for both short-wavelength (Widnall) and long-wavelength (Crow) instabilities in counter-rotating line-vortex pairs. Both types of instabilities result from the mutually induced velocity of the two vortices and form fast-growing sinusoidal perturbations, at very different wavelengths: of the order of the vortex core radius for the Widnall instability and 5 to 10 times the initial vortex spacing for the Crow instability. The paper starts with a discussion of the governing equations and the numerical method used. Then, a study is presented for the long-wavelength instability, including an analysis of the spatial resolution of the simulation. The transfer of kinetic energy towards smaller scales as the development of the instability progresses, is studied, showing that the flow field is indeed well-resolved in the simulations. The short-wavelength instability simulations are initialized with an initial condition computed from a normal mode analysis of the linearized equations in cylinder coordinates. This procedure is discussed in some detail, followed by a presentation of preliminary results from a time-accurate simulation of the instability well into the regime in which non-linear effects become important.

"WAKE VORTEX SIMULATIONS USING A PARALLEL HIGH-ORDER ACCURATE NAVIER-STOKES SOLVER"

ICAS Paper 2000-6.5.3, August 2000, Harrogate, UK.

A well-known problem in the operation of commercial jet transports is the so-called 'wake vortex hazard.' This problem originates from the compact, strong vortices emanating from the wing tips which persist without much decay in their strength. The velocity field induced by these tip vortices forms a threat to following aircraft. Vortex wakes generally develop 3D instabilities of which the long-wavelength, or Crow, instability can often be observed as sinusoidal perturbations in aircraft contrails. The present paper describes a high-resolution algorithm for solving the Navier-Stokes equations

developed to numerically simulate these wake-vortex flows. Results obtained for an evolving long-wavelength instability in a vortex pair are discussed.
