The laser Doppler velocimeter measurements of wake vortex characteristics described in this report were carried out by Lockheed Missiles & Space Company, Inc., Huntsville Research & Engineering Center working in conjunction with AeroVironment, Inc., under the "Wake Decay near the Ground" program sponsored by the U.S. Department of Transportation. Lockheed-Huntsville's role in the program consisted of operating the Lockheed Mobile laser Doppler velocimeter system and collecting measurements of vortex characteristics with the system and processing and analyzing the measurements to determine the dominant vortex decay characteristics.

The following Lockheed-Huntsville personnel made significant contributions to this effort: C.E. Craven, B.B. Edwards, J.L. Jetton, A.J. Jordan, M.C. Krause, T.R. Lawrence, and K.R. Shrider. The authors are grateful to the Optics Branch at NASA-Marshall Space Flight Center for making their filter bank and signal processor available for this study and to J.W. Bilbro and H.B. Jeffreys at NASA-MSFC and to Bill Keenum, Earl Lucas, and Rick Bynum at Computer Sciences Corporation for processing the measurements obtained with the NASA-MSFC filter bank and signal processor. The authors are grateful to Dr. J. N. Hallock, TSC Contracting Officer's Technical Monitor, and to Dr. D.C. Burnham, staff scientist at TSC, for their technical contributions and able assistance during the performance of this contract.

#### 1. INTRODUCTION

Wake vortex transport and decay parameters near the ground are important factors in determining safe aircraft separation distances for terminal areas. For an operational Wake Vortex Avoidance System (WVAS), a knowledge of the location and intensity of wake vortices near the terminal area is necessary to determine the minimum-delay safe spacings. Under light crosswind conditions, a wake vortex can remain in the approach corridor, and the minimum aircraft separation distance is dictated primarily by the wake decay process near the ground. Therefore, an important consideration in determining safe aircraft separations is the decay of the wake vortex near the ground. While numerous vortex decay theories have been proposed, there are little full-scale experimental data available for comparison. Experimental vortex decay data near the ground are also lacking for aerodynamic wake minimization concepts where variations in aircraft geometry are used to tailor the wake vortex flow. Flight tests by NASA have shown that certain flap and spoiler settings can reduce the imposed rolling moments on following aircraft (in the near wake); however, wake vortex measurements near the ground for full-scale aircraft with different wake minimization concepts are needed. Thus, for both wake vortex avoidance and wake vortex minimization techniques, a knowledge of the vortex-rollup, transport, and decay characteristics near the ground is important.

e

ہ

ð

3

To determine the behavior of aircraft wake vortices at low altitudes, a flight test program was conducted by DOT/NASA. The primary goal of the test program was to measure the wake vortex decay process behind a conventional jumbo jet as a function of altitude above ground, flap and spoiler settings, and different flight configurations. To isolate the influence of aircraft and flight parameters on the wake decay process, the flight tests were conducted at the Rosamond Dry Lake test area in California during the

early morning hours when calm atmospheric conditions prevailed. The Rosamond wake decay measurements were sought to quantify the effect of burst, link and viscous decay parameters on the wake vortex dissipation process. The wake decay measurements were also sought to demonstrate the effectiveness of recently developed vortex minimization concepts. In addition to the wake decay measurements, the flight tests were also focused on measuring the wake vortex rollup and transport phenomena in ground plane proximity.

D

.

₹.

The Rosamond flight tests involved airborne and ground-based meteorological sensors, an acoustic Doppler system, a mobile laser Doppler velocimeter, a flow visualization using smoke and balloons. In this report the measurements obtained with the laser Doppler velocimeter system (LDV) are discussed including: (1) the initial downwash field; (2) the lateral and horizontal transport of the coherent wake vortex; and (3) the decay of the vortex flow in terms of the time history of the circulation, peak tangential velocity, and the diffusion of the viscous core radius. While the application of LDV techniques for the study of wake vortex flows is not novel, this is the first time, to our knowledge, that the details of the vortex formation and decay process have been extracted for a full-scale aircraft using an LDV system. In addition to providing detailed wake measurements for comparison with available theoretical and empirical models, the results show the influence of changes in flap, spoiler, and landing gear settings on the wake characteristics.

The report discusses the LDV wake vortex measurements including the instrumentation used, the experimental test sequence, and the results of the wake measurements in terms of the vortex-rollup, transport, and decay trends, and a comparison of the wake vortex decay characteristics for different configurations. A brief discussion of the LDV wind measurements is given followed by the overall conclusions and recommendations.

#### 2. INSTRUMENTATION

The wake vortex and atmospheric wind measurements were carried out by means of a scanning LDV system contained in a mobile van. Preliminary processing of the data was carried out with a SEL computer aboard the van. Reduction and analysis of the vortex and wind signatures were carried out by off-line processing software using a Univac 1108 and a PDP11 computer. A description of the instrumentation and the data processing methods for the Rosamond tests is given in terms of the LDV system configuration and the data processing techniques used.

#### 2.1 Laser Doppler Velocimeter System

The Lockheed-Huntsville LDV was used to obtain wake vortex measurements during the Rosamond flight tests. A photograph of the van-mounted LDV system is given in Fig. 1. The wake measurements were accomplished as follows: (1) the wake generated by the aircraft was scanned by the  $CO_2$  laser; (2) the radiation backscattered from the aerosol in the wake was collected; (3) the radiation was photomixed with a portion of the transmitted beam on a photodetector; and (4) the intensity and Doppler shift frequency of the signal were displayed.

The difference in frequency between the transmitted and backscattered signal generated at the photodetector, the Doppler shift frequency, is a measure of the aerosol's absolute line-of-sight velocity within the laser focal volume

$$\left| \overline{\mathbf{V}} \right| = \frac{\lambda \,\Delta \mathbf{f}}{2 \cos \gamma} \,, \tag{1}$$

where  $|\overline{\mathbf{v}}|$  is the magnitude of the velocity component in the region being sensed,  $\lambda$  is the laser radiation wavelength (10.6µm),  $\Delta \mathbf{f}$  is the Doppler shift,

U

G,

The Lockheed-Huntsville LDV was used to obtain wake vortex measurements during the Rosamond flight tests. A photograph of the van-mounted LDV system is given in Fig. 1. The wake measurements were accomplished as follows: (1) the wake generated by the aircraft was scanned by the  $CO_2$  laser; (2) the radiation backscattered from the aerosol in the wake was collected; (3) the radiation was photomixed with a portion of the transmitted beam on a photodetector; and (4) the intensity and Doppler shift frequency of the signal were displayed.

The difference in frequency between the transmitted and backscattered signal generated at the photodetector, the Doppler shift frequency, is a measure of the aerosol's absolute line-of-sight velocity within the laser focal volume

$$\left| \overline{\mathbf{V}} \right| = \frac{\lambda \,\Delta \mathbf{f}}{2 \cos \gamma} \,, \tag{1}$$

where  $|\overline{V}|$  is the magnitude of the velocity component in the region being sensed,  $\lambda$  is the laser radiation wavelength (10.6µm),  $\Delta f$  is the Doppler shift,

Fig. 1 - Lockheed LDV System Monitoring Wake Vortex Generated by a B-747 Aircraft at the Rosamond, California, Test Site

4

P

and  $\gamma$  is the angle subtended by the velocity vector and the optic system line of sight. From Eq.(1), it is noted that the Doppler shift is a direct and absolute measure of aerosol velocity component and a frequency shift of 188 kHz corresponds to a 1 m/sec magnitude line-of-sight velocity.

A sketch of the optical and electronic equipment for measuring the intensity and frequency spectrum of the coherent backscatter from the focal volume is shown in Fig. 2, and described in more detail in Refs. 1, 2, and 3. Photographs of the optical and electronic equipment for measuring the aerosol backscatter are shown in Figs. 3, 4, and 5.

The Lockheed LDV system used in the Rosamond wake vortex tests monitors the magnitude of the velocity component of ambient atmospheric particulate matter within its instantaneous sensing volume. The pertinent operating characteristics of the LDV are summarized as follows:

#### Performance

\$

4

ø

۵

Ð

-

- 1. Threshold of Magnitude of Velocity Component: 0.5 m/sec
- 2. Range of Magnitude of Velocity Component: 0.5 to 28 m/sec

#### Sample Rate

- 1. Low Data Rate: 70 Hz
- 2. High Data Rate: 500 Hz (using the NASA filter bank processor).

#### Spatial Resolution

- 1. Range Accuracy: +0.4 m at 30 m, +44 m at 300 m
- 2. Elevation Angle Accuracy: ±0.25 deg.

- 8. Line-of-Sight Velocity Component

The characteristic output signal from the LDV system is an intensity versus frequency spectrum illustrated in Fig.6. The output parameters  $V_{pk}$  and  $V_{ms}$  are indicative of the magnitude of the velocity component in the LDV focal volume corresponding to the fastest particle (or particles) above the amplitude threshold and the particle (or particles) having the highest back-scatter, respectively. The bandwidth, N, is a measure of the range of particle velocities in the focal volume. Intensity and frequency thresholds are applied to the signal, as shown, to eliminate noise and to improve the resolution of the system. For example, in the vortex tracking mode the frequency signal associated with the ambient wind.

The velocity resolution of the LDV is determined by the signal-to-noiseratio characteristics of the system as well as the atmospheric aerosol particlesize distribution. During the Rosamond tests, no difficulty was encountered detecting the high velocity regions, as high as 28 m/sec, associated with the wake vortex phenomena. The very low ambient winds, on the order of 1 to 2 m/sec, were also detected by the LDV at Rosamond which were above the system's threshold of 0.5 m/sec.

The spatial resolution of the LDV is determined by the size of the laser beam sensing volume where the beam is focused. The extent of the laser Doppler system sensing volume is a function of range which is shown in the following table ( $\Delta r = 9.84 \times 10^{-4} \text{ (m}^{-1}) \text{ R}^2$ ) obtained from calibration measurements (Ref. 4).

For example, if the LDV system is tracking wake vortices at a range of 60 m, a needle-shaped volume of the vortex 3.54 m long and 4 mm in diameter is sampled. During the Rosamond tests, the typical vortex range was 60 m so that the spatial resolution due to the spreading of the focal volume was 3.54 m.

In addition to the finite focal volume, the sampling rate of the LDV plays an important role in determining the overall resolution of the system. During the Rosamond tests, measurements were obtained at two data rates, at 70 and 500 Hz. The lower data rate was achieved with a scanning spectrum analyzer and the higher data rate with a filter bank provided by NASA-MSFC. Since the spatial resolution of the flow is a function of the selected data rate and scan mode, the resolution must be considered separately for each type of operation; the arc scan, finger scan, and LDV modes.

## 2.1.1 Arc-Scan Mode of Operation

In the arc-scan mode, the LDV interrogates the vortex wake at a fixed range along an arc normal to the aircraft flight path. As shown in Fig. 7, the sensing volume is moved between two elevation limits (the typical cone angle is  $2\alpha = 30$  deg) at a fixed rate (the typical scan rate is 0.5 Hz) while the vortex drifts past the scanned arc. Thus, the arc scan measurements indicate the spanwise downwash distribution in the wake of the aircraft, provided that vortex range is sufficiently close to the selected scan range.

Fig. 7 - Geometry for Arc Scanning for Rosamond Wake Vortex Tests

ά,

During one arc scan of the vortex wake, the vortex flow field is sampled at discrete evenly spaced intervals along the arc as shown in Fig. 7. The separation between successive sample points,  $\Delta S$ , based on the sampling rate f, range R, and cone angle  $2\alpha$  is given by

$$\frac{\Delta S}{R} = \frac{2\pi}{360^{\circ}} \frac{2\alpha/\text{sec}}{f}, \qquad (2)$$

-07

9

Ņ

5

where  $2\alpha/\sec$  is the elevation angle scan rate at a frequency of 0.5 Hz. For a typical arc scan wake vortex measurement at Rosamond, f = 500 and 70 Hz, R = 60 m and  $2\alpha$  = 30 deg, so that the wake vortex flow field is sampled every 0.06 and 0.4 m at the high- and low-data rates, respectively. Since the range of vortex core diameters measured for a B-747 aircraft is 0.3 to 2 m based of tower flybys (Ref. 5), the sampling rate of the LDV system is sufficient to obtain several cuts through the vortex core along the arc (or essentially in the spanwise direction), particularly at the high data rate.

The drift of the wake vortex affects the resolution of the vortex measurements in the vertical direction. During a single scan frame, the vortex is translated by an amount depending on the cross-wind velocity and on the mutual induction of the complete vortex field. Since the tests were conducted during the early morning hours, cross winds were generally negligible and the primary motion of the wake vortex was in the downward direction. Assuming a typical vortex descent rate of 2 m/sec, and a typical scan rate of 0.5 Hz, this implies that a spanwise traverse of the wake vortex is taken every 2 m in the vertical plane in the arc-scan mode. Based on these values, it is noted that the LDV arc-scan technique can observe the detailed characteristics of the wake vortex phenomena which are larger in extent than 0.06 and 2 m in the horizontal and vertical directions, respectively.

## 2.1.2 Finger-Scan Mode of Operation

During the Rosamond flight tests, 56% of the LDV wake vortex measurements were conducted using the finger-scan mode. In the finger-scan mode, both the range and elevation of the laser beam were varied simultaneously and linearly with time, producing a multiple lobe scan pattern with the laser beam as shown in Fig.8. The settings and sampling rates for the finger-scan mode are given in Appendix A.

2

2

ŝ

Э

ø

The distance between sample points for the finger-scan mode is higher than for the previous arc-scan mode. From Appendix A, it is noted that the typical range scan excursion for the finger scan mode is 105 m, and the normal range rate is 3.5 Hz. It follows that the beam-scan velocity is 735 m/sec. Because the LDV measurements were sampled every 2 and 14.3 msec at the low and high data rates, the wake vortex flow field is measured at every 1.5 and 10.5 m increment in range, respectively. Thus, the finger scan mode can interrogate a large cross-sectional area rapidly, and this is ideal for vortex tracking. In addition, the LDV finger scan measurements contain essential information regarding the wake vortex phenomena.

The characteristic line-of-sight component as a function of range and elevation angle during one finger-scan sweep is shown in Fig.8. A pair of double-peak patterns is noted in the line-of-sight velocity profile as a function of elevation angle. The maximum values occur at the elevation angles where the line of sight is tangent to the viscous core radius of the vortex. Thus, the mean elevation angle of the local maxima in the V vs  $\theta$  curve yields the elevation angle of the wake vortex,  $\theta_{vortex} = (\theta_1 + \theta_2)/2$ . Simi-larly, the difference between the two elevation angles is a measure of the vortex viscous core radius,  $r_{vortex 1} = R_1 \left| \tan \frac{\theta_1 - \theta_2}{2} \right|$ . The peak tangential velocity and core cirdulation of the vortex is given by  $V_{pk}$  vortex 1, =  $(V_{pk \theta_1} + V_{pk \theta_2})/2$  and  $\Gamma_{vortex 1} = 2\pi R_{vortex 1} V_{pk vortex 1}$ , assuming circular symmetry. The peak line-of-sight component at the two edges of the vortex,  $V_{pk} \theta_1$  and  $V_{pk} \theta_2$  are not necessarily equal due to a contribution by the other vortex and the ambient winds. The range of the vortex,  $R_1$ , is given by the local maximum in the line-of-sight component at the two edges of the in the bottom of Fig.8, and is not affected by the ambient winds. Based on the characteristic LDV signature observed for one scan, it is noted

.+

~

<u>بع</u>

Þ

Fig. 8 - Magnitude of Characteristic LDV Velocity Component Observed During One Finger-Scan Sweep

that several successive finger scans contain the essential decay history of the wake vortices, provided that at least two sample points are obtained for each vortex, one upwash and one downwash measurement, where the line of sight is tangent to the viscous core and the mean vortex range is within the LDV focal volume.

### 2.2 DATA PROCESSING

ę

2

₽.

Þ

ð

6

The output from the LDV system consisting of the coherent backscatter intensity versus frequency from the focal volume as well as the location of the focal volume in space was processed to yield the aircraft downwash field and the wake vortex characteristics. Reduction and analysis of the LDV measurements were carried out as follows: (1) the low-speed signal was digitized and stored on magnetic tape by the onboard SEL computer and subsequently processed off-line on a Univac 1108 computer, and (2) the high-speed data were both digitized and processed off-line on a Univac 1108 computer and the vortex tracks computed on a PDP 11 computer. A flow chart of the data processing sequence used for the Rosamond wake decay study is shown in Fig. 9. The software system for processing the low-speed and high-speed LDV data is described in more detail in Refs. 4 and 6, respectively.

The high-speed processor utilized the raw range and elevation signal, while the low-speed processor used the raw range and commanded elevation signal to determine the location of the LDV focal volume. As a result, the magnitude of the velocity component versus elevation angle measured with the high-speed processor showed scatter due to the  $\pm 0.25$  deg elevation angle resolution. In addition, noise was present in the elevation angle versus time distribution from the high-speed data characterized by a square wave with a 14 Hz and an amplitude of 0.7 deg. This was believed to be a frequency of sympton of a processing or decode problem. The normal scatter in the elevation angle was not noticeable at the low data rate, but the low-speed data did show a finite lag in the scan pattern. A time lag of approximately 0.3 sec, and a corresponding lag in the position of the LDV focal volume depending on the selected scan rate was observed. The lag in the system resulted from the difference between commanded versus actual angular position of the scanning mirror.

3

ų,

5

Þ

Fig. 9 - Data Processing Sequence Carried Out for the Rosamond Wake Decay Measurements

The manner in which the wake vortex measurements were processed from both the high-speed and low-speed data is summarized as follows. The frequencies and amplitudes associated with the laser Doppler signal were sampled at fixed intervals. The spectrum was recorded if it was above the frequency and amplitude threshold settings (Fig. 6). The amplitude and frequency threshold settings for the Rosamond tests are given in the log sheets in Appendix A. From the array of recorded frequency and intensity points, the magnitude of the line-of-sight velocity component was computed, and the vortex parameters including location and velocity distribution were determined.

æ

ä

Ş

۵

3

6

To compute the wake vortex transport and decay characteristics from the low-speed line-of-sight velocity component magnitude, the Rosamond measurements were analyzed using the "Velocity Azimuth Display and Vortex Track Program" (Ref. 5). Based on previous experience with the program, the following parameters were selected for the analysis of the Rosamond data:

INTVEL = 2	Flag INTVEL = 1, Velocity oriented vortex determination INTVEL = 2, Intensity oriented vortex determination
NPSUF = 4	Sufficient number of points to determine vortex position
APERCT = 0.1	Fraction of points below the maximum velocity or intensity points
BPERCT = 0.1	Fraction of points within the correlation circle where Q is at least APERCT fraction of the maximum Q (Q is velocity or intensity as determined by INTVEL)
RPERCT = 0.3	Fraction of number of points in correlation circle used for determining vortex 1 (required for determ- ination of vortex 2)
RPERCT = 0.3	Fraction of aircraft wing span used for correlation radius
EPERCT = 2.0	Fraction of correlation radius from vortex 1 for excluding initial point of vortex 2
NOISEF = $0$	Noise floor
ADJI = 0.0	Intensity adjustment (fraction of noise floor added to total intensity).

A sample output from the VAD and Vortex Track Program is presented in Appendix B. The intermediate sorting parameters used in determining the location of the vortex core region are also given in the printouts along with "scatter plots" indicating the line-of-sight velocity magnitudes. From the typical line-of-sight velocity magnitude illustrated in Appendix B, the time history of the vortex wake was determined for many of the flybys.

In parallel with the low-speed data acquisition and processing, the LDV signal was also fed into the high-speed NASA-MSFC data processing system as illustrated in Fig. 9. The high-speed data processing technique is similar to the low-speed technique described earlier, and is described in detail in Ref. 6. A sample output from the NASA-MSFC LDV data processing routines is shown in Appendix C, including the listing of the magnitude of the raw line-of-sight velocity component, the plot of  $|V_{pk}|$  versus elevation angle, and plots of the vortex trajectory.

.)

## 3. DESCRIPTION OF EXPERIMENTAL TESTS

A two-day test sequence was carried out to determine the wake vortex characteristics of a B-747 aircraft as a function of spoiler, flap, and landing gear settings, altitude above ground, and glideslope. The test consisted of 54 low level passes during the early morning hours over the LDV system deployed at Rosamond Dry Lake near Edwards AFB, California, on 2 and 3 December 1975.

#### 3.1 FLIGHT TEST PROGRAM

2

ė

ŝ

۵

2

۵

The aircraft used for the tests was a Boeing 747-123 aircraft. A plan view of the aircraft showing the details of the flap and spoiler configurations is presented in Fig. 10.

Aircraft configuration varied from run to run, with dominant emphasis on as close to a normal landing configuration as operating conditions would allow. The clean configuration was also studied, and special flap and spoiler configurations were investigated for vortex alleviation effectiveness. The Boeing 747 flew at 30 to 250 m above the ground level of 700 m MSL. Runs were made in level flight as well as in descending and climbing flight. Descents were at about 250 m/min. A lift coefficient of approximately 1.4 was used for all flaps-down runs.

Of the 54 runs, 35 (or about 65%) were made with the inboard flaps lowered 30 deg and the outboard flaps lowered 30 deg (denoted 30/30); eight (approximately 15%) with 10/10 flaps; and five (approximately 9%) with flaps retracted. The remaining six runs had the inboard flaps lowered 30 deg and the outboard flaps lowered 1 deg, to test the effects of this configuration

ુ⊎

ę

<u>e</u>

æ

Fig. 10 - Spoiler and Flap Arrangement on B-747 Aircraft

on vortex alleviation. For each flap setting, runs were conducted with the gear down or retracted, and some had spoilers deployed (the extension angle was always 41 deg) in addition to the flap. A summary of the aircraft altitude, speed, weight, and flap, landing gear, and spoiler settings for each of the flybys is given in Table 1.

# 3.2 OPERATION OF LASER DOPPLER VELOCIMETER REMOTE SENSOR

The LDV system was set up and calibrated at the Rosamond test site prior to conducting the actual wake surveys. A discussion of the calibration procedure and the conduct of the wake vortex surveys is summarized below.

### 3.2.1 Calibration

2

4

4

24

۵

During the set-up process, the optical bench was leveled with the external van jacks using a bubble level for reference (estimated accuracy of  $\pm 0.5$  deg). For the second day of the tests, the scanner was offset 45 deg using a tri-square for reference (estimated accuracy of  $\pm 0.5$  deg). Prior to the actual wake surveys, the elevation and azimuth angle readouts from the LDV were calibrated. The calibration involved pointing the optical system at the sun and comparing the observed elevation and azimuth angle readouts with those given in the ephemeris. The results indicated that a -3 deg and  $\pm 139$ deg correction should be applied to the raw elevation and azimuth readouts from the LDV, respectively.

During the Rosamond tests, the range resolution and signal-to-noise ratio characteristics of the LDV were not recalibrated. The range and signalto-noise ratio calibrations taken a few months earlier and documented in Ref. 4 were assumed to be representative of the systems overall performance.

#### 3.2.2 Wake Surveys

During the Rosamond wake decay tests, 53 aircraft flybys were recorded with the LDV system (flyby 36 was lost due to a loss in electrical power). The test conditions and the LDV scan, range, and elevation settings for the

Rosamond tests are summarized in the log sheets given in Appendix A, while a list of the flight parameters is given in Table 1. Primarily, those flybys have been processed from the wake measurements where flow visualization and photographic data (photographs were taken of vortices at 1 sec increments) were available for comparison with the LDV measurements.

4

3

5

D

34

6

To maximize the amount of data collected regarding wake vortex trajectories, velocity profiles, and decay rates, the LDV was operated in different scan modes including: arc-scan and, finger-scan configurations. The wake vortex surveys were conducted in the following manner.

On the first test day, the LDV was located directly under the flight path (Fig. 11) and scanned arcs in a plane perpendicular to the flight path (Fig. 12) with a complete scan every 2 sec. Scans were at a fixed range until the vortex passed through the scan arc, at which time the sensor range was lowered and remained fixed again until the vortex descended through the new range. The objective of the overhead arc scan measurements was the measurement of the initial downwash field and the wake vortex roll-up process.

On the second test day, the LDV was moved 60 m north of the flight path (Fig. 11) and scanned simultaneously in elevation and range (finger-scan mode) at a frequency of 0.2 Hz, and 2 to 2.5 Hz, respectively. The objective of the finger scan measurements was to track the location of the vortex pair and to observe the vortex decay rates. The coordinated variations in range and elevation settings for the finger scan mode were selected on the basis of the aircraft wake vortex parameters. In addition, during the last sorties, the azimuth angle was changed during the run to 90- and 180-deg angles to scan both down the vortex (axially) and to follow the vortex drift away from the LDV.

Fig. 12 - Overhead Arc Scan Configuration Illustrated for Rosamond Flyby 11

## 4. RESULTS OF WAKE VORTEX MEASUREMENTS

The LDV measurements obtained during the Rosamond tests have been analyzed to determine the dominant characteristics of the B-747 wake. In the following discussion, the observed wake vortex characteristics are described including the vortex roll-up, vortex transport, and vortex decay parameters.

## 4.1 VORTEX ROLL-UP

To determine the vortex roll-up parameters, the downwash field behind the B-747 aircraft was measured with the LDV operated in a constant-range arc-scan mode. In the typical arc-scan configuration, illustrated earlier in Fig. 13, the magnitude of the line-of-sight velocity component observed by the LDV was essentially a measure of the spanwise downwash distribution in the aircraft nearwake. Thus, from the magnitude of the LDV line-of-sight velocity distribution in the near wake the downwash and vortex formation and roll-up characteristics were determined.

2

## 4.1.1 Initial Spanwise Downwash Distribution

The magnitude of the peak line-of-sight velocity component,  $|V_{pk}|$  (m/sec), from the high-speed data is shown as a function of lateral distance, y(m), in Figs. 13 through 16 for flybys 8, 11, 12, and 13, respectively, over the time interval t = 0 to 8 sec. Each scan is defined as the period between two successive elevation angle reversals and is approximately 1 sec in duration. Occasionally, some overlapping occurs between successive scans due to limitations in the processing software. Therefore, successive scans shown in Figs. 13 through 16 do not always have the same starting and ending limits, and, as a result, the lateral scales can be different. The direction and midtime of each scan is indicated in the figures. The lateral distance, y, was computed directly from the raw range, R, and raw elevation angle

measurements,  $\theta$ , where  $y = -R \cos \theta$ . This resulted in a nonlinear lateral scale at extended distances from the flight path centerline.

To illustrate the maximum downwash or upwash velocities in the aircraft near wake, the highest values of  $|V_{pk}|$  occurring over 1 deg increments were faired by a smooth curve. The solid lines in the plots represent a faired curve through the highest LDV measurements given by the circles. Since the arc-scan measurements were made at an initial range equal or somewhat less than the airplane height, and since the maximum descent rate of the trailing vortices was on the order of 2 m/sec, the wake vortex remained essentially in the focal volume of the LDV system over the time period of 0 to 8 sec. Thus, the solid lines shown in Figs. 13 through 16 are indicative of the peak velocities observed with the LDV system in the aircraft near wake.

Available measurements of vortex lateral position obtained from a triangulation of simultaneous photographs or estimated from overhead photographs are also shown in Figs. 13, 14, and 15.

21

The spanwise downwash distribution for flyby 8, the 0-spoiler configuration, shows a well defined double-peak signature in most of the plots shown in Fig. 13 which is suggestive of a coherent vortex. For example, in Fig. 13 at t = 2.2 sec, two broad peaks are observed separated by a spacing of 0.76 wingspan. The lack of signature in the inboard regions may be attributed to the lack of high velocities or aerosols near the flight path centerline. The two broad peaks become more well defined at later times (t = 3.3to 8.2 sec), showing a double-peak signature characteristic of the rotational velocity profile of a viscous vortex. The lateral separation and the maximum speed for the two double-peak signatures do not change significantly over this time range.

In contrast to the coherent wake structure observed earlier for the 0-spoiler configuration (Fig. 13), the downwash field for flybys 11, 12 and 13, where the two outer spoilers were deployed, shows a broad high amplitude region composed of narrower closely spaced peaks. This is suggestive of multiple

vortices and an incomplete vortex roll-up phase. These measurements indicate that the deployment of spoilers has a marked effect on the near-wake strucuture, tending to retard the early formation of a coherent trailing vortex pair. Analysis of the downwash field shown in Figs. 13 through 16 has been carried out to determine the basic characteristics of single and multiple vortices such as location, circulation strength, and the magnitude of the velocity component.

77

e

. 2

Ļ

## 4.1.2 Vortex Pair Characteristics

For the 0-spoiler configuration, the spanwise downwash distribution in the wake shows a well defined double-peak signature (Fig. 13). A double-peak signature is predicted theoretically when a vortex pair is interrogated in the arc-scan mode. For example, the magnitude of the line-of-sight velocity component for Rosamond flyby 11 at  $t \sim 2$  sec assuming a fully rolled-up vortex pair is shown in Fig. 17. The magnitude of the line-of-sight velocity generated by a distribution of N line vortices with the LDV located at the origin is given by

$$\left| \mathbf{v}_{\text{fos}} \right| = \frac{1}{2\pi} \sum_{n=1}^{N} \Gamma_n \frac{\left[ (\mathbf{Y}_n - \mathbf{Y}_0) \, \mathbf{X}_0 + (\mathbf{X}_0 - \mathbf{X}_n) \, \mathbf{Y}_0 \right]}{\left[ (\mathbf{X}_0 - \mathbf{X}_n)^2 + (\mathbf{Y}_0 - \mathbf{Y}_n)^2 \right] \left[ \mathbf{X}_n^2 + \mathbf{Y}_n^2 \right]^{1/2}} \tag{3}$$

where  $(X_0, Y_0)$  is the location of the centroid of the focal volume, and  $(X_n, Y_n)$ and  $\Gamma_n$  are the coordinate and circulation strength of the  $n^{th}$  vortex, respectively.

In Fig. 17, the magnitude of the computed line-of-sight velocity is shown for a pair of line vortices with spacing b' = Kb = 41.8 m and circulation strength  $\Gamma = U_{\infty} \ \overline{c} \ C_L/2K = 606 \ m^2/sec$  where the spanwise loading coefficient, wingspan, flight velocity, mean chord, and lift coefficient are taken to be K = 0.7,  $b = 59.7 \ m$ ,  $U = 72.5 \ m/sec$ ,  $\overline{c} = 8.3 \ m$ ,  $C_L = 1.41$ . The vortex pair was assumed to be located at an altitude of 180 m and the selected arc scan range was 183 m. The magnitude of the computed line-of-sight velocity for the vortex pair shows the characteristic double peak signatures noted earlier in the LDV measurements. The magnitude of the peak velocity is determined by the separation distance between

3

Ŷ

Fig. 17 - Magnitude of Line-of-Sight Velocity Component for Rosamond B-747 Flyby 11 at t~2 sec, Computed Assuming a Fully Rolled-Up Vortex Pair
the vortex pair and the scan arc. The slight asymmetry in the double peaks results from the velocity contribution of the adjoining vortex, the scan geometry, and the decrease in the contribution of the vortex rotational velocity along the line of sight at extended lateral distances from the centerline.

Note the two double-peak patterns in the  $V_{los}$  distribution in Fig. 17 at  $y = \pm 23$  m which correspond to the approximate location of the two vortices. As the vortex pair is traversed by the arc-scan pattern, the peak tangential velocity, resolved about the line of sight, is observed giving rise to the closely spaced double peaks. When the vortex center is intersected exactly by the arc scan, the location of the peaks is a measure of the vortex position, the magnitude of the peaks is indicative of the magnitude of the peak tangential velocity in the core, and the lateral separation between the peaks is a measure of the vortex core diameter. If the vortex is below (or above) the arc-scan, as shown in the sample simulation in Fig. 17, the vortex position is bounded by the lateral location of the two peaks, the magnitude of the two peaks is less than the peak tangential velocity, and the lateral separation between the two peaks is a function of the separation distance between the vortex and the scan arc.

2

\*

..

The magnitude of the predicted line-of-sight velocity shown in Fig. 17 agrees with the trends shown by the 0-spoiler flyby (Fig. 13), while the 1, 2, 11, and 12-spoiler flybys (Figs. 14 to 16) are noticeably different. Since the LDV signature for flyby 8 is suggestive of a coherent vortex pair, it is useful to make a more detailed analysis of this case. From the seven scans shown in Fig. 13 the earliest scan showing the two double peak signatures was selected (t=3.3 sec); the minimum points were used to determine the lateral position of the port vortex (vortex altitude was assumed to be the scan range R = 240 m), and the peak velocity magnitudes observed by the LDV for the port vortex were plotted as a function of radius about the vortex center in Fig. 18. For comparison, the magnitude of the velocity for a potential line vortex and a turbulent viscous vortex are also shown in Fig. 18 matched to the experimentally measured core circulation and core velocity. - O Starboard Scan
- Port Scan

Theory

4

Fig. 18 - Magnitude of Wake Vortex Velocity Distribution with 0 Spoilers

The results in Fig. 18 indicate that the velocity distribution observed with the LDV is in general agreement with the theoretical model of Hoffman and Joubert near the core region of the vortex. In the outer flow region, the experimental velocity distribution decreases more rapidly than the theoretical logarithmic circulation model and approaches the 1/r profile. However, sufficient scatter exists in the LDV data points to make a detailed comparison difficult, and agreement with other theoretical models is possible. 3

లే

7

\_8

The circulation distribution derived from the vortex velocity distribution is shown in Fig. 19. Note that essentially all of the circulation is contained within the viscous core region of radius  $r_c = 4.5$  m and of circulation  $\Gamma_c = 565 \text{ m}^2/\text{sec.}$  This suggests that the vortex roll-up process is complete for the 0-spoiler configuration at t = 3.3 sec. In comparison, the predicted vortex circulation strength for this flyby is  $\Gamma = \frac{1}{2} U_{\infty} \overline{c} C_L/K = 565 \text{ m}^2/\text{sec.}$ where the flight velocity, mean wing chord, lift coefficient and spanwise loading coefficient, are given by  $U_{\infty} = 73.6 \text{ m/sec}, \overline{c} = 8.3 \text{ m}, C_L = 1.41, K = 0.762.$ The value of K was selected on the basis of the observed separation between the vortex pair. The circulation distribution predicted from the turbulent viscous vortex model using the observed core parameters is also shown in Fig. 19 where

 $\Gamma = \Gamma_{c} 1.83 (r/r_{c})^{2},$  $\Gamma = \Gamma_{c} [1 + 2.14 \log_{10} (r/r_{c})],$ 

in the inner and outer core regions, respectively.

### 4.1.3 Multiple Vortex Characteristics

The spanwise downwash distributions for the 1, 2, 11, and 12-spoiler configurations (Figs. 14 to 16) showed multiple closely spaced peaks which did not resemble the velocity distribution predicted for a coherent trailing vortex pair (Fig. 17). Since the multiple high-velocity peaks in the nearwake downwash field are found in multiple vortex wakes; and the 1, 2, 11, and 12-spoiler configurations (flybys 11, 12, and 13) have been analyzed to identify possible multiple vortex characteristics.

Fig. 19 - Circulation as a Function of Radius for 0 Spoiler Flight Configuration

ъ

The magnitude line-of-sight velocity component predicted for a B-747 aircraft assuming the multiple vortices are shed from the inboard and outboard flaps and wing tips is presented in Fig. 20. The strength and lateral spacing of the multiple vortices given on the top of Fig. 20 were calculated from the modified Betz roll-up technique (Ref. 9) and the altitude of the vortices was 180 m, and the arc scan range was 183 m. From the magnitudes of the velocity shown in Fig. 20 it is noted that the multiple vortices generate multiple peaks of varying magnitudes with the zero points occuring near the vortex locations. Assuming the LDV arc scan intersects the centers of the multiple vortices, the spacing and magnitudes of the multiple peaks can be used to deduce the location, strength, and magnitude of the peak velocity component of the wake vortices.

As an example, consider the profile shown in Fig. 14. Note that for the 1.5-sec plot high velocity magnitudes are recorded, but the peaks are scattered and it is difficult to distinguish the location of the multiple vortices suggested in Fig. 20. At 2.6 sec the multiple peaks in Fig. 14 are more ordered and resemble the line-of-sight velocity magnitudes predicted by the multiple vortex model. For example, the starboard vortex occupies a broad region spanning from approximately 3 to 40 m from the centerline, and the zero points occur at  $y \sim 0$ , 10, 15, 22, and 30 m at t=2.6 sec in Fig. 14. The superimposed predicted multiple vortex locations are at y=3, 10.4, 14, 21.3, and 29.6 m (Fig. 20). Thus, the broad multiple peak regions in flyby 11 contain to some extent the multiple vortex peaks predicted from theory. A similar trend can be noted for the other 1, 2, 11, and 12-spoiler cases. In Fig. 15 at t=2.4 sec, the zero points on the starboard side are located at  $y \sim 0$ , 17, 25, and 32 m, and in Fig. 18 at t=2.9 sec, the zero points on the port side occur at  $y \sim 0$ , 5, 10 and 18 m. Comparing all three 1, 2, 11, and 12 spoiler runs, it is observed that minimums occur in the downwash velocity profile repeatedly for lateral spacings of  $y \sim 0$ , 10, 15, and 25 m from the wake centerline.

4

...

2

These results suggest that three or four merged vortices are present in the near wake for each semispan. A more detailed analysis of the LDV measurements may establish the strength and core radii of these vortices.

$$\Gamma_1 = 62.3 \text{ m}^2/\text{sec}, \Gamma_2 = 433.5 \text{ m}^2/\text{sec}, \Gamma_3 = -158.4 \text{ m}^2/\text{sec}, \Gamma_4 = 298 \text{ m}^2/\text{sec}, \Gamma_5 = -16.2 \text{ m}^2/\text{sec}$$
  
 $\Gamma_6 = -62.3 \text{ m}^2/\text{sec}, \Gamma_7 = -433.5 \text{ m}^2/\text{sec}, \Gamma_8 = 158.4 \text{ m}^2/\text{sec}, \Gamma_9 = -298 \text{ m}^2/\text{sec}, \Gamma_{10} = 16.2 \text{ m}^2/\text{sec}$   
 $y_1 = 29.6 \text{ m}, x_1 = 180 \text{ m}, y_2 = 21.3 \text{ m}, x_2 = 180 \text{ m}, y_3 = 14 \text{ m}, x_3 = 180 \text{ m}, y_4 = 10.4 \text{ m}, x_4 = 180 \text{ m}, y_5 = 3 \text{ m}, x_5 = 180 \text{ m}, y_6 = -29.6 \text{ m}, x_6 = 180 \text{ m}, y_7 = -21.3 \text{ m}, x_7 = 180 \text{ m}, y_8 = -14 \text{ m}, x_8 = 180 \text{ m}, y_9 = -10.4 \text{ m}, x_9 = 180 \text{ m}, y_{10} = -3 \text{ m}, x_{10} = 180 \text{ m}$

### 4.2 VORTEX TRANSPORT

The line-of-sight velocity measurements obtained by the LDV in the wake of the B-747 aircraft in the finger-scan mode have been processed to yield the altitude and lateral position of the vortices, and have been compared with photographic and theoretical wake trajectories. The following analysis of the vortex transport characteristics includes the early near-wake flow as well as the subsequent far-wake transport process.

### 4.2.1 Near-Wake Vortex Tracks

From the Rosamond wake measurements, those flybys where photographic measurements of the near-wake trajectory were available for comparison with the LDV tracks have been selected. The near wake was assumed to be the region within 20 spans downstream of the aircraft, x/b < 20.

The lateral versus horizontal wake vortex location 5 to 10 sec after aircraft passage is shown in Figs. 21 and 22. The LDV and photographic measurements indicate that the center of the wake vortex pair is located at approximately 80% semispan and descends at  $\sim 1.5$  m/sec over the 4 to 10 sec interval. However, as much as a 15% scatter in the vortex lateral location and 50% scatter in the descent rate can be noted in the initial vortex trajectories which may be associated with uncertainties in the airplane location or may be due to the different flight configurations. The photographic measurements shown in Figs. 21 and 22 are in general agreement with the LDV trends.

### 4.2.2 Far Wake Vortex Tracks

The line-of-sight velocity measurements obtained with the LDV system in the finger-scan mode have been processed with the VAD and Vortex Track Program and the  $I_{nk}$  program to determine the far-wake vortex trajectories.

ð

The regions of the maximum backscatter intensity were used to locate the vortex core region. The wake vortex tracks from the Rosamond tests include the results from the low-speed data and high-speed data.

### 4.2.2.1 Low-Speed Data

24

\$

7

The wake vortex trajectories from the low-speed LDV measurements are presented in Appendix D. From the wake vortex trajectories presented in Appendix D, the following wake transport characteristics can be noted: (1) the wake vortex descends nearly vertically with very little horizontal motion; (2) the initial descent rate over the period 0 through 20 sec after aircraft passage is in general agreement with the prediction; and (3) the wake descent diminishes after 20 sec and the vortex tends to remain at a constant altitude in ground effect. In addition to the above trends, some scatter is noted in the location of the vortices. Since both the photographic and LDV tracks show the vortex wandering in lateral position and altitude, particularly at late times, this is believed to be the effect of random atmospheric winds and gusts. However, in some cases, a large scatter is noted in the LDV vortex tracks which is not seen in the corresponding photographic measurements. This has been investigated using the high-speed data since accurate determination of the vortex position is a prerequisite in determining other relevant parameters such as the decay of the vortex rotational velocity and circulation strength.

4.2.2.2 High-Speed Data

The wake vortex tracks computed from the high-speed LDV data using the I algorithm are given in Appendix E for flybys 27, 28, 44, 47, 48, and 49. The vertical and lateral vortex trajectories computed from the high-speed data show the same trends as the low-speed tracks discussed earlier.

Comparison of the high-speed wake vortex measurements with the observed photographic vortex position is shown in the  $V_{pk}$  versus elevation angle curves in Figs.23 and 24. With the exception of any dominant low

magnitude spikes, the solid line in the plots connects the maximum values of  $\left| \begin{array}{c} V \\ pk \end{array} \right|$  observed by the LDV in the finger scan mode for one scan between the two elevation angle limits (i.e., it represents the maximum value of  $V_{pk}$  for many finger-scan lobes). Since the LDV is scanned rapidly in range (3.5 Hz) and slowly in elevation angle (0.2 Hz), the peaks in the  $|V_{pk}|$  versus elevationangle curves indicate the elevation angle at which the maximum line-of-sight velocity is observed by the LDV system. Thus, when a vortex is interrogated by the LDV system, two maxima occur in the  $|V_{pk}|$  versus elevation angle at those angles where the line of sight is tangent to the vortex core and a minimum occurs at the mid-elevation angle, or in other words, a double-peak signature results. The low magnitude spike bounded by the high amplitude peaks marks the vortex core, and here, the minimum  $|V_{pk}|$  points are connected. For a number of LDV measurements, this double-peak signature can be clearly recognized; for example, at t = 6.6, 9.0 and 14.1 sec for flyby 23 (Fig. 27) and at t = 4.2 and 14.2 sec for flyby 28 (Fig. 24). In addition, the elevation angle at which these double-peak patterns occur is often within a few degrees of the vortex elevation angle measured photographically.

•

\$

2

a

...

While the photographic and LDV measurements agree well for some scans in terms of the location of the vortex signature, for other scans, the scatter in elevation angle is as high a 6 deg (Fig. 24, t = 5 and 9 sec). It is possible that the core diameter of the vortex is small, and the scan pattern misses the peak-tangential velocity regions. It is also possible that the photographic measurements may be subjected to some errors, or that the smoke does not mark the exact vortex location accurately. Lastly, the error may be a result of anomalies in the determination and processing of the LDV elevation angle.

### 4.3 VORTEX DECAY

Information regarding the decay of wake vortices such as the time history of the peak tangential velocity, circulation and viscous core radius is contained in the line-of-sight velocity magnitudes measured by the LDV system.

# 4.3.1 Decay of Vortex Rotational Velocity

9

đ

ø

.....

To determine the decay of the wake vortex rotational velocity from the LDV line-of-sight velocity magnitudes, two basic methods were used to pick out the maximum tangential velocity of the vortex:

- a. Selection of the maximum value of  $|V_{pk}|$  (or  $|V_{ms}|$ ) occurring during each scan between minimum and maximum elevation settings.
- b. Selection of the maximum value of  $|V_{pk}|$  occurring within  $\pm 3$  deg of the known elevation angle of the vortex.

For both techniques, the maximum value of  $|V_{pk}|$  is a good measure of the magnitude of the peak tangential velocity of the vortex if the LDV line of sight is tangent at some point with the circular core region of the vortex, and the vortex range falls within the focal volume. However, in the first approach, the  $|V_{pk}|$  time history becomes meaningless if the vortex drifts out of the scan area. To eliminate this uncertainty, in the second approach, other information, i.e., photographic vortex position, is used to establish the approximate location of the vortices. These regions are then searched for the maximum  $|V_{pk}|$  values which are associated with the vortex phenomena.

The  $|V_{pk}|$  and  $|V_{ms}|$  time histories determined using the first technique are shown in Appendix F. A bandwidth criterion of  $N \ge 2$  was used in the analysis to filter out random high-frequency noise (i.e., at least two of the 100 frequency bins had to be activated for the data to be used). A sample of the results, presented in Fig. 25, indicates that the wake vortex rotational velocity is nearly constant approximately 50 spans downstream of the aircraft followed by 1/time decay. Some scatter which may be associated with the uncertainty in vortex location may be noted in the velocity decay curve.

Using the photographic vortex tracks to determine the approximate vortex location (the second technique above), the  $|V_{pk}|$  time history has been

Fig. 25 - Decay of Magnitude of Wake Vortex Rotational Velocity Component for Flyby 44

(þ

10

14

82

.

-34

recomputed for flybys 27 and 28 and is presented in Figs. 26 and 27. The results shown in Figs. 26 and 27 also indicate a nearly constant magnitude of the vortex velocity component within 50 spans downstream of the aircraft. Less scatter occurs in  $|V_{pk}|$  versus time plots when the photographic tracks are used to establish the vortex center. Unfortunately, photographic measurements were not available at late times to establish the final vortex decay process.

## 4.3.2 Core Radius Time History

Ð

٩

S

÷

:5

The vortex core radius was determined from the observed variations in  $|V_{pk}|$  with range and elevation angle according to the technique discussed earlier in Section 2.1.2. The computed vortex core radius time history for flybys 27, 28, and 44 is given in Figs. 28, 29, and 30, respectively. Photographic vortex tracks were compared with LDV  $|V_{pk}|$  distributions to compute the core radius time history in Figs. 28 and 29, while the predicted vortex tracks were used to compute the core radius time history in Fig. 30. The LDV wake vortex measurements show that the vortex core radius is approximately constant in the aircraft near wake. The observed core radius ranges from 1 to 4 m, and the mean core radius is approximately 2 m.

## 4.3.3 Circulation Decay

The circulation time history was computed from the observed LDV lineof-sight velocity distribution using: (1) the vortex tracks from the low-speed data, and (2) the photographic tracks to determine the vortex location. In the first technique, the circulation was determined from the average moment of the line-of-sight velocity components within a correlation radius of the computer vortex center. In the second technique, the circulation was computed from the moment of the two maximum  $|V_{pk}|$  values adjacent to the center of the vortex as outlined earlier in Section 2.1.2, and the photographic vortex tracks were used to determine the vortex location. It was found that this technique was very sensitive to errors in core radius.

2

đ

Þ

a.

Ø

ې

÷

**.** 

e

The circulation time history computed from the low-speed data vortex tracks is shown in Appendix G. The computed circulation is shown from 20 sec to the time of the last measurement. At periods earlier than a few sec, circulations are not shown since the vortex may not be fully rolled up. The general circulation decay trend is similar to the velocity decay trends noted earlier - relatively small decay initially followed by rapid decay in the far wake. More scatter is evident in the circulation distributions than the velocity or core radius distributions presented earlier because the circulation involves the product of the scatter of the previous two measurements. To reduce this scatter, the circulation has been recomputed using the photographic vortex tracks to define the vortex center more closely.

a

a

Ø

4.3.4 Comparison of Vortex Decay Trends for Different Flight Configurations

To determine the vortex decay trends for different flight configurations, the time history of the vortex rotational velocity, circulation, and core radius presented earlier can be cross correlated. The decay of the wake vortex rotational velocity for different spoiler and flap and landing gear settings and flight paths is compared in Figs. 31 through 34, respectively. These results indicate that the deployment of spoilers decreases the vortex rotational velocity in the near wake while flap and landing gear settings and aircraft flight path angle do not appear to have a significant effect. However, care must be used in interpreting the above results since for some of the runs the wake vortices drifted out of the field of view (see Appendix D).

### 5. CONCLUSIONS

ē

3

۲

2

4

Laser Doppler velocimeter measurements of the wake vortex characteristics of a B-747 aircraft in various configurations have shown the following trends.

# 5.1 FOR VORTEX FORMATION:

- a. The rollup of the vortex sheet occurred rapidly within a few spans downstream of the aircraft.
- b. The observed location, spacing, and strength of the multiple vortices were in general agreement with theoretical rollup calculations.
- c. The peak tangential velocity and circulation of the merged vortices remained nearly constant in the near wake.
- d. The B-747 spoilers affected the vortices, producing vortices with large cores.
- 5.2 FOR VORTEX TRANSPORT;
  - a. The wake vortices descended vertically with little horizontal motion.

## 5.3 FOR VORTEX DECAY:

- a. A decrease in the peak tangential velocity and circulation and an increase in the core radius was observed in the far wake.
- b. Deployment of spoilers and flaps enhanced the vortex peak tangential velocity decay process in the near wake.

# Appendix B

# SAMPLE OUTPUT FROM VELOCITY AZIMUTH DISPLAY AND VORTEX TRACKER PROGRAM FOR ROSAMOND FLYBY 25

Page B-2 indicates the relative intensity (INTENSITY) and  $V_{ms}$  (SPEED (ft/sec)) of the LDV signal as a function of time and space for one sweep between the minimum and maximum elevation-angle setting in the finger-scan mode. A list of the data sorted according to INTENSITY is given on page B-3 followed by the list of the values selected for determining the vortex location on page B-4. A "scatter plot" showing the location of the intensity points in units of ft and their relative magnitude (on a scale of A to 0) is given on page B-5 along with the selected center of the two correlation circles (labeled Z) and the centroid of the correlation circles (the vortex locations labeled P and S for port and starboard, respectively). On page B-6, the points used in determining the vortex location are listed. The data are printed out on pages B-7 through B-12 and B-13 through B-17 for two other sample scans during flyby 25. A summary of the port and starboard locations from each of the scans is given on pages B-18 through B-20. The vortex trajectories are displayed on the last two pages of Appendix B, including time versus lateral displacement of the vortices (page B-21) and time versus vertical location as a function of time (page B-22).

# SAMPLE OUTPUT FROM NASA-MSFC LASER DOPPLER VELOCIMETER DATA PROCESSING ROUTINES FOR ROSAMOND FLYBY 47

Results from the Rosamond high-speed data are given on page C-2 including a printout of the relative intensity of the LDV signal (IPEAK) and the frequency (or velocity) of the flow field including  $V_{ms}$  and  $V_{pk}$  in units of meters per second (VMAX and VPEAK, respectively). The sweep count from the start of the flyby is shown by the column labeled SCAN while the lateral and vertical location and range and elevation angle of the focal volume are given by X (m), Y (m), R (m), and T (deg), respectively. The time at which the LDV signal was sampled is contained in the frame count (1 FRAME = 1/500 sec).

From the array of LDV sample points illustrated on page C-2, plots of VPEAK versus the scan elevation angle in degrees, THETA, are generated as illustrated on pages C-3 through C-6. Note that the characteristic double peak signature of the wake vortex is evident in the sample plots.

Applying the "I<sub>pk</sub>" algorithm (p. 4-7 of Ref. 7) to the threshold LDV spectrum illustrated above, the vortex location is determined. The vortex trajectory for flyby 47 as computed from the high speed data is shown on pages C-7 through C-9. On page C-7 the vertical and lateral motion of the vortices is given as a function of time, while page C-8 shows the altitude versus lateral position of the wake vortex. Page C-9 lists the vortex locations. For additional information regarding the vortex location, criteria, and coefficients used in the "I<sub>pk</sub>" algorithm and shown in the plots, refer to Ref. 7.

Note that the coordinate system used in the NASA-MSFC data processing routines is not the same as the coordinate system used in the text earlier. The runway centerline is located at y = -200 ft in the NASA plots.

# WAKE VORTEX TRACKS COMPUTED FROM LOW-SPEED MEASUREMENTS

The circles, triangles and diamond symbols represent the port, starboard and undefined vortex, respectively. For each flyby, the predicted wake vortex trajectory assuming zero crosswind is shown by the solid lines. The vortex tracks were computed from the predicted model described in Ref. 10 for a circulation strength of  $\Gamma = 662 \text{ m}^2/\text{sec}$  and an initial vortex spacing of b' = 41.8 m. Available photographic and acoustic measurements also appear on the plots, the solid circles and triangles representing the former and the x's the latter measurements. The dashed line is a smooth curve drawn through the photographic vortex tracks.

### WAKE VORTEX TRACKS COMPUTED FROM HIGH-SPEED MEASUREMENTS

The measurements obtained with the NASA high-speed filter bank and processor and software system are summarized in this appendix. The output consists of three plots: (1) vortex altitude versus time; (2) lateral distance versus time; and (3) altitude versus lateral distance. A listing of the vortex locations is given in a table following the three plots. The port and starboard vortices are indicated by (0\*) and (\*) on the altitude and lateral distance versus time plots. The vortices are labeled by letters A to Z on the lateral distance plots (each pair of letters corresponds to a successive elevation scan frame).

## Appendix H REPORT OF INVENTIONS

In accordance with the objectives of the contract, wake vortex and wind measurements were carried out at the Rosamond, California, test site with a scanning laser Doppler velocimeter system, and the LDV measurements were processed, reduced, and analyzed. The contract objectives were met, and no invention, discovery, or innovation was found.
